Neutron stars harbour extremely powerful magnetic fields, leading to their shape being deformed. Their magnetic deformation depends both on the geometry - and strength - of their internal magnetic field and on their composition, encoded by the equation of state. However, both the details of the internal magnetic structure and the equation of state of the innermost part of neutron stars are mostly unkown. We performed a study of numerical models of magnetised, static, axisymmetric neutron stars in general relativity and in one of its most promising extensions, scalar-tensor theories. We did so by using several realistic equations of state currently allowed by observational and nuclear physics constraints, considering also those for strange quark stars. We show that it is possible to find simple relations among the magnetic deformation of a neutron star, its Komar mass, and its circumferential radius in the case of purely poloidal and purely toroidal magnetic configurations satisfying the equilibrium criterion in the Bernoulli formalism. These relations are quasi-universal, in the sense that they mostly do not depend on the equation of state. Our results, being formulated in terms of potentially observable quantities, could help to understand the magnetic properties of neutron stars interiors and the detectability of continuous gravitational waves by isolated neutron stars, independently of their equation of state. In the case of scalar-tensor theories, these relations depend also on the scalar charge of the neutron stars, thus potentially providing a new way to set constraints on the theory of gravitation.

Keywords: Neutron stars; magnetic deformation; scalar-tensor theories.

1. Introduction

The most compact material objects in the known Universe are neutron stars (NSs), which are also known to harbour extremely powerful magnetic fields, especially in the sub-class known as magnetars[1–4]: the surface magnetic field of NSs has been found to be in the range 10^{8-12}G for radio and γ-ray pulsars,[5–7] while estimates in magnetars reach 10^{15}G.[8,9] While the surface and magnetospheric magnetic fields of NSs can be probed through many different methods,[10,11] their internal magnetic field remains mostly unknown, both in its strength and geometry. Predictions expect that values up to 10^{16}G and 10^{17-18}G could be reached inside magnetars and newly-born proto-NSs, respectively.[12–14] On the other hand, while it is known that neither purely poloidal nor purely toroidal magnetic configurations are stable[15,16]

and mixed configurations are more favoured,[17–19] the extact magnetic field geometry in the interior of NSs is less clear. Fortunately, these magnetic fields present potentially observable effects to the structure of NSs: they can modify the torsional oscillations of NSs,[20,21] their cooling properties[22,23] and their deformation.[24,25]

In this scenario, another unknown regarding the internal structure of NSs enters the game: the equation of state (EoS) of NSs remains mostly unconstrained. Recent observational results rejected the validity of many EoS: the observation of very massive NSs [e.g. the most massive NS known to date, with a mass potentially reaching $\sim 2.28 M_\odot$[26]]; the limits on the stiffness of NSs[27,28] obtained by the first observation of gravitational waves (GWs) emitted by a binary NS merger[29]; the results of the NICER telescope[30,31] on the possible NSs radii. However, this uncertainity is further enhanced by the effect that the strong magnetic field buried inside NSs exherts on their composition, for example determining the presence of exotic particles or the existence of a superconducting phase.[32–36] For these reasons, undertanding and constraining the interplay between the magnetic field of NSs and their EoS is fundamental in order to improve our knowledge of these objects.

Other than observations in the electromagnetic domain, GWs can help to probe the inner structure of NSs. Of particular importance are continuous GWs (CGWs), which are emitted, for example, by a time-varying deformation. Such scenario can happen e.g. in the case of magnetically-deformed NSs whose magnetic axis is not aligned with their rotation axis.[25,37,38] Since magnetic fields found in regular pulsars are too low to cause a significant deviation from spherical symmetry,[24] newly-born proto-NSs and millisecond magnetars are the most promising sources of CGWs,[39] along with millisecond pulsars which possess a superconducting core.[38]

While the problem of the inner composition and magnetic field of NSs is an interesting problem on its own, it is deeply intertwined with the long-standing quest for the definitive theory of gravity. Even if general relativity (GR) remains the best theory to model the gravitational interaction, it has long been known that our understanding of gravity through GR presents some issues on the galactic and cosmological scales.[40] While one possibility is to introduce a dark sector,[41,42] another path is to introduce modification to GR, leading to alternative theories of gravity.[43] Among the possible alternatives to GR, scalar-tensor theories (STTs) - in which gravity is mediated also by a scalar field non-minimally coupled to the spacetime metric - have gathered a strong interest because of their simplicity, because they derive from some suggested theories of quantum gravity,[44] in general they satisfy the weak equivalence principle, and they are free of the issues affecting other alternatives to GR.[45–47] Of great importance in the development of STTs was the discovery of a non-perturbative strong field effect, exhibited in some of these theories, named 'spontaneous scalarisation',[48] which leads to strong deviations from GR in the vicinity of compact material objects (i.e. NSs), while it remains unconstrained in the weak-field limit. The presence of a scalar field leads to an enrichment of the physics of NSs, for example by causing the emission of additional modes of

GWs[49,50] or by modifing the mass-radius relation of NSs, the binary NS merger dynamics,[51] the frequency of NS normal modes,[52] their tidal and rotational deformation,[53,54] their magnetic deformation[55–57] and the light propagation properties in their vicinity.[58] While massless STTs have been mostly ruled out by observations,[59–61] STTs with a massive scalar field are still viable.[62–64] As anticipated, part of the phenomenology of STTs is degenerate with the EoS of NSs, for example concerning the mass-radius relation or their deformabilities. For such reason, disentangling their roles is important in order to have a more informative interpretation of observations.

In the following we assume a signature $\{-,+,+,+\}$ for the spacetime metric and use Greek letters μ, ν, λ, ... (running from 0 to 3) for 4D spacetime tensor components, while Latin letters i, j, k, ... (running from 1 to 3) are employed for 3D spatial tensor components. Moreover, we use the dimensionless units where $c = G = \mathrm{M}_\odot = 1$, and we absorb the $\sqrt{4\pi}$ factors in the definition of the electromagnetic quantities. All quantities calculated in the Einstein frame (E-frame) are denoted with a bar $(\bar{\cdot})$ while all quantities calculated in the Jordan frame (J-frame) are denoted with a tilde $(\tilde{\cdot})$.

2. Neutron stars in general relativity

The spacetime metric in the case of static, axisymmetric configurations can be well approximated[65,66] using the conformally flat condition (CFC).[67,68] Then, for spherical-like coordinates $x^\mu = [t, r, \theta, \phi]$, the line element is

$$g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu = -\alpha^2\mathrm{d}t^2 + \psi^4\left[\mathrm{d}r^2 + r^2\mathrm{d}\theta^2 + r^2\sin^2\theta\mathrm{d}\phi^2\right] , \tag{1}$$

where $g_{\mu\nu}$ is the spacetime metric, with determinant g, $\alpha(r,\theta)$ is the lapse function and $\psi(r,\theta)$ is the conformal factor. The energy-momentum tensor for a magnetised ideal fluid is[69,70]

$$T^{\mu\nu} = (\rho + \varepsilon + p)\, u^\mu u^\nu + p g^{\mu\nu} + F^\mu_\lambda F^{\nu\lambda} - \frac{1}{4}F^{\lambda\kappa}F_{\lambda\kappa}g^{\mu\nu} , \tag{2}$$

where ρ is the rest mass density, ε is the internal energy density, p is the pressure, u^μ is the four-velocity and $F^{\mu\nu}$ is the Faraday tensor. The 3+1 formalism[71,72] can be used to recast the equations in a more computationally-friendly way; under these assumptions, the Einstein equations for the metric become two Poisson-like equations, one for ψ and one for $\alpha\psi$.[19]

As for the magnetohydrodynamics (MHD) quantities, using the pseudo-enthalpy h, related to the pressure and density by $\mathrm{d}\ln h = \mathrm{d}p/(\rho + \varepsilon + p)$, Euler's equation becomes the 'generalised Bernoulli integral',[19]

$$\ln\left(\frac{h}{h_\mathrm{c}}\right) + \ln\left(\frac{\alpha}{\alpha_\mathrm{c}}\right) - \mathcal{M} = 0 , \tag{3}$$

where $\mathcal{M}$ is the magnetisation function and h_c and α_c are the values of h and α at the centre of the star, respectively (having assumed $\mathcal{M}_\mathrm{c} = 0$). The magnetisation

function in the case of a purely poloidal magnetic field is assumed to be $\mathcal{M} = k_{\rm pol} A_\phi$, where $k_{\rm pol}$ is the poloidal magnetisation constant and A_ϕ is the ϕ-component of the vector potential, computed by solving the relativistic Grad-Shafranov equation. For a purely toroidal magnetic field, we instead use $\mathcal{M} = -k_{\rm tor}^2(\rho+\varepsilon+p)\mathcal{R}^2$, where $k_{\rm tor}$ is the toroidal magnetisation constant and $\mathcal{R}^2 = \alpha^2\psi^4 r^2 \sin^2\theta$. In the first case, the poloidal components of the magnetic field are found through the Grad-Shafranov equation[66,73] for A_ϕ; in the second case, the toroidal component is proportional to $(\rho+\varepsilon+p)\mathcal{R}^2/\alpha$. Finally, the EoS closes the system of equations. We describe the EoS we used in Sect. 5. For a more detailed description of the equilibrium formalism the reader is referred to Refs. 55–57.

3. Scalar-tensor theories in a nutshell

The action of massless STTs in the J-frame, according to the 'Bergmann-Wagoner formulation',[74–76] is

$$\tilde{S} = \frac{1}{16\pi}\int \mathrm{d}^4x\sqrt{-\tilde{g}}\left[\varphi\tilde{R} - \frac{\omega(\varphi)}{\varphi}\tilde{\nabla}_\mu\varphi\tilde{\nabla}^\mu\varphi\right] + \tilde{S}_{\rm p}\left[\tilde{\Psi},\tilde{g}_{\mu\nu}\right] , \tag{4}$$

where $\tilde{g}$ is the determinant of the spacetime metric $\tilde{g}_{\mu\nu}$, $\tilde{\nabla}_\mu$ its associated covariant derivative, $\tilde{R}$ its Ricci scalar, $\omega(\varphi)$ is the coupling function of the scalar field φ, and $\tilde{S}_{\rm p}$ is the action of the physical fields $\tilde{\Psi}$. In the E-frame, the action is obtained by making the conformal transformation $\bar{g}_{\mu\nu} = \mathcal{A}^{-2}(\chi)\tilde{g}_{\mu\nu}$, where $\mathcal{A}^{-2}(\chi) = \varphi(\chi)$ and χ is a redefinition of the scalar field in the E-frame, related to φ by $\mathrm{d}\chi/\mathrm{d}\ln\varphi = \{[\omega(\varphi)+3]/4\}^{1/2}$. In the E-frame, the scalar field is minimally coupled to the metric: Einstein's field equations retain their usual form in the E-frame, but the energy-momentum tensor is now the sum of the one describing the fluid and electromagnetic fields and of the scalar field one. On the other hand, the scalar field is minimally coupled to the physical fields in the J-frame: the MHD equations in the J-frame have the same expression as in GR. In addition to the metric and MHD equations, in STTs we have an additional equation to solve for the scalar field. In the E-frame it is

$$\Delta\chi = -4\pi\bar{\psi}^4\alpha_{\rm s}(\chi)\mathcal{A}^4\tilde{T} - \partial\ln\left(\bar{\alpha}\bar{\psi}^2\right)\partial\chi , \tag{5}$$

where $\Delta = f^{ij}\hat{\nabla}_i\hat{\nabla}_j$ and $\hat{\nabla}_i$ are, respectively, the 3D Laplacian and nabla operator of the flat space metric f_{ij}, $\partial f\partial g = \partial_r f\partial_r g + (\partial_\theta f\partial_\theta g)/r^2$, $\alpha_{\rm s}(\chi) = \mathrm{d}\ln\mathcal{A}/\mathrm{d}\chi$ and $\tilde{T} = 3\tilde{p} - \tilde{\varepsilon} - \tilde{\rho}$ is the trace of the J-frame energy momentum tensor of the fluid and electromagnetic fields. We used an exponential coupling function $\mathcal{A}(\chi) = \exp\{\alpha_0\chi + \beta_0\chi^2/2\}$.[48] The α_0 parameter regulates the effects of the scalar field in the weak-field limit, while the β_0 parameter controls spontaneous scalarisation. We chose $\alpha_0 = -2\times10^{-4}$ and $\beta_0 \in [-6,-4.5]$. The most recent observational constraints to date require that, for massless scalar fields, $|\alpha_0| \lesssim 1.3\times10^{-3}$ and $|\beta_0| \gtrsim 4.3$[61]; in the case of massive scalar fields, lower values of β_0 are allowed,[77] as long as the screening radius is smaller than the separation of the binary NSs whose

observation confirmed the absence of dipolar GWs.[78,79] We emphasise that results found in a massless STT regarding the internal structure of a NS are also valid for STTs containing a screening effect as long as the screening radius is larger than the NS radius; as such, our results regarding the magnetic deformation of NSs are valid also in the case of a massive scalar field, with a mass such that its screening radius is larger than the NS radius but lower than the binary separation. For a more detailed description of the formulation of STTs within the 3+1 formalism the reader is referred to Refs. 55–57.

4. The magnetic deformation of polytropic neutron stars

We now focus on the case of static NSs in the weak magnetic field regime, where the magnetic deformation of the star is well approximated by a perturbative approach; this was shown to happen for $B_{\rm max} \lesssim 10^{17}$G,[80,81] where $B_{\rm max} = \max[\sqrt{B_i B^i}]$ and B_i are the components of the magnetic field. We focus only on the range of masses corresponding to stable configurations. All the results shown are computed using the `XNS` code,[19,55–57,66,80,82] which solves the coupled equations for the metric, scalar field, and MHD structure of a NS under the assumptions of stationarity and axisymmetry, adopting conformal flatness and maximal slicing.

In Newtonian gravity[83,84] and in GR,[16,66] in the limit of weak magnetic fields, the quadrupole deformation e of a magnetised NS can be expressed as a linear function of $B^2_{\rm max}$.[66] Equivalently, instead of using $B^2_{\rm max}$ one can parametrise e also in terms of $\mathcal{H}/W$, where $\mathcal{H}$ is the magnetic energy of the NS, defined in the J-frame as

$$\tilde{\mathcal{H}} = \pi \int \mathcal{A}^3 \tilde{B}_i \tilde{B}^i \sqrt{\bar{\gamma}} {\rm d}r {\rm d}\theta \, , \tag{6}$$

W being its binding energy.

In STTs, we found that $\bar{e}$ still has a linear trend with $\tilde{B}^2_{\rm max}$ (or $\tilde{\mathcal{H}}/\bar{W}$), but with coefficients that depend more strongly on the baryonic mass M_0 (which is the same in the J-frame and in the E-frame) than in GR; the strength of this dependence is related to the value of β_0. In the limit $\tilde{B}_{\rm max} \to 0$, keeping fixed M_0 and β_0:

$$|\bar{e}| = c_{\rm B} \tilde{B}^2_{\rm max} + \mathcal{O}\left(\tilde{B}^4_{\rm max}\right), \quad |\bar{e}| = c_{\rm H} \frac{\tilde{\mathcal{H}}}{\bar{W}} + \mathcal{O}\left(\frac{\tilde{\mathcal{H}}^2}{\bar{W}^2}\right), \tag{7}$$

where $c_{\rm B} = c_{\rm B}(M_0, \beta_0)$ and $c_{\rm H} = c_{\rm H}(M_0, \beta_0)$ are the 'distortion coefficients', and $\tilde{B}_{\rm max}$ is normalised to 10^{18}G.

The coefficients $c_{\rm B}$ and $c_{\rm H}$ as functions of M_0, for various β_0, are shown in Fig. 1, in the case of NSs endowed with a purely toroidal or a purely poloidal magnetic field and described by the POL2 EoS $\tilde{p} = K_{\rm a} \tilde{\rho}^{\gamma_{\rm a}}$, with $\gamma_{\rm a} = 2$ and $K_{\rm a} = 110$ in dimensionless units. The black line represents GR, which corresponds to $\alpha_0 = \beta_0 = 0$. The other lines stand for $\beta_0 = \{-4.5, -4.75, -5.0, -5.25, -5.5, -5.75, -6.0\}$ and $\alpha_0 = -2 \times 10^{-4}$. The effect of scalarisation is visible in the distinctive change in the slope as the scalarised sequences depart from the GR one. The more negative

β_0 is, the more enhanced are the modifications with respect to GR. At a fixed M_0, scalarised NSs have lower distortion coefficient and quadrupole deformation than the GR models with the same mass for most of the scalarisation range. We found that, in the the ranges $1.2 \leq M_0/\mathrm{M}_\odot \lesssim 2.4$ and $-6 \leq \beta_0 \leq -4.5$, the distortion coefficients are well approximated by a combination of power laws of the baryonic mass M_0, the J-frame circumferential radius $\tilde{R}_\mathrm{c}$ and the E-frame scalar charge $\bar{Q}_\mathrm{s}$.[55] In particular

$$c_\mathrm{B} \approx c_1 M_{0;1.6}^{\alpha} R_{10}^{\beta} \left[1 - c_2 Q_1^{\gamma} M_{1.6}^{\delta} R_{10}^{\rho}\right] \ , \tag{8}$$

where $M_{0;1.6}$ is M_0 in units of $1.6\mathrm{M}_\odot$, R_{10} is $\tilde{R}_\mathrm{c}$ in units of 10km, Q_1 is $\bar{Q}_\mathrm{s}$ in units of $1\mathrm{M}_\odot$, $[c_1, \alpha, \beta, c_2, \gamma, \delta, \rho] = [0.16, -2.22, 4.86, 0.87, 1.32, -1.27, -2.21]$ in the toroidal case and $[c_1, \alpha, \beta, c_2, \gamma, \delta, \rho] = [0.077, -1.99, 5.80, 1.38, 1.22, -0.86, -3.49]$ in the poloidal case. The coefficient c_H in the toroidal cases is similar to that in the poloidal case; in fact, it is possible to find a functional form over the entire mass range that holds for both magnetic configuartions with an accuracy of few percents:

$$c_\mathrm{H} \approx 0.5 + \mathcal{F}(M_0)\mathcal{T}(M_0, \bar{Q}_\mathrm{s}, \tilde{R}_\mathrm{c}) \times \begin{cases} 0.65 \text{ for toroidal} \ , \\ 1.02 \text{ for poloidal} \ , \end{cases} \tag{9}$$

where $\mathcal{F}(M_0)$ does not depend explicitly on the scalar field and described the role of the equation of state, $\mathcal{T}(M_0, \bar{Q}_\mathrm{s}, \tilde{R}_\mathrm{c})$ represents the correction due to the presence of scalarisation, and the last numerical factor differentiates the oblate from the prolate geometry, which depends on the magnetic field configuration. We found that:

$$\mathcal{F}(M_0) \quad = 4.98 - 1.95 M_{0;1.6} \ , \tag{10}$$

$$\mathcal{T}(M_0, \bar{Q}_\mathrm{s}, \tilde{R}_\mathrm{c}) = 1 - \frac{1.90}{R_{10}^{2.45}} \left(\frac{Q_1}{M_{0;1.6}}\right)^{1.3} \ . \tag{11}$$

5. Selection of equations of state

The results shown in Sect. 4 are found using a simple polytropic law which, while allowing us to compare our results to previous studies,[16,19] is not allowed by observations. For this reason, we further computed the distortion coefficients for a selection of EoS allowed by observational and nuclear physics constraints.[57] In particular, we selected 13 different EoS that span a diverse range of calculation methods and particle contents. All EoS we used, except the polytropic one, are chosen to satisfy the lates constraints: they reach a maximum mass of at least $\sim 2.05\mathrm{M}_\odot$,[85] satisfy various nuclear physics constraints,[86] are not too stiff,[87] and give the NS a radius between $\sim$10km and $\sim$14km for $1.4\mathrm{M}_\odot$ mass models[88,89]. We chose 6 EoS which contain only $npe\mu$ particles (APR,SLY9,BL2,DDME2,NL3$\omega\rho$,SFH), 2 EoS containing also hyperons (DDME2-Y,NL3$\omega\rho$-Y), 2 EoS containing an *uds* quark matter domain treated with the Nambu-Jona-Lasinio model (BH8, BF9), 2 EoS containing an *uds* quark matter domain treated with the MIT bag model or perturbative QCD (SQM1, SQM2), as well as the POL2 EoS.

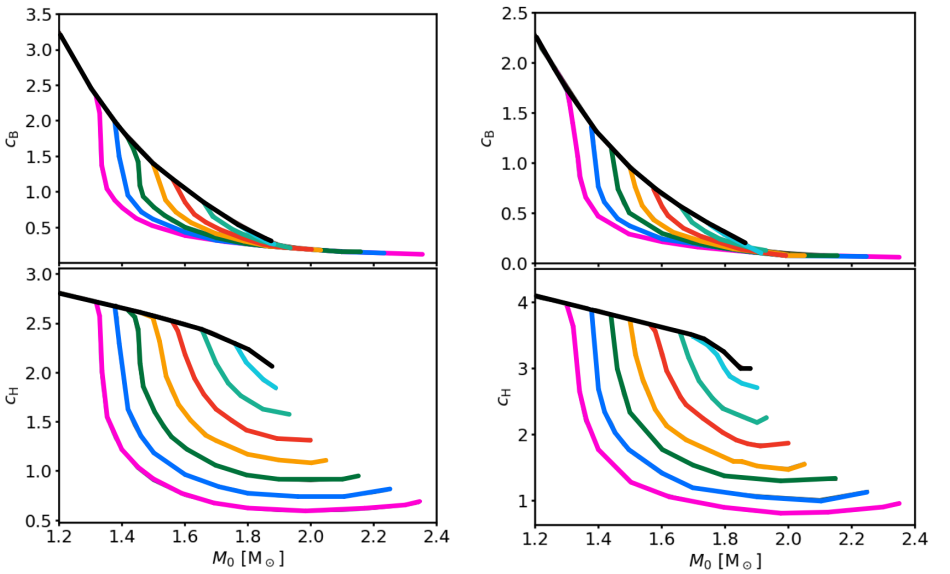

Fig. 1. Distortion coefficients c_B (top panels) and c_H (bottom panels) as functions of the baryonic mass M_0 of models with a purely toroidal magnetic field (left panels) and with a purely poloidal magnetic field (right panels), for various value of β_0: from $\beta_0 = -6$ (magenta curve) to $\beta_0 = -4.5$ (light blue curve) increasing by 0.25 with every line. The black curve corresponds to GR. Adapted from Soldateschi et al., A&A, 645, A39 (2021).

In Fig. 2 we plot the Komar mass $\bar{M}_k$ against the circumferential radius $\tilde{R}_c$ for models of un-magnetised, static NSs computed with the described EoS. The left panel refers to GR, while the right panel to STT with $\beta_0 = -6$. From the left panel of Fig. 2 we see that the NS radii have values ranging from ∼10km to ∼14km for most EoS, excluding the less compact SQM2 and especially the POL2 EoS. The maximum masses are around ∼2-2.2M$_\odot$ for most EoS, except for the NL3$\omega\rho$ and the POL2 EoS.

6. Quasi-universal relations for the magnetic deformation of neutron stars

We computed the distortion coefficients in Eq. 7 for the EoS described in Sect. 5, as well as another distortion coefficient:

$$|\bar{e}| = c_s \tilde{B}_s^2 + \mathcal{O}\left(\tilde{B}_s^4\right) , \tag{12}$$

where $\tilde{B}_s$ is the magnetic field calculated at the pole of the NS, at the surface, normalised to 10^{18}G. The coefficients c_B and c_H contain quantities that are not directly accessible by observations, because they require to know the details of the internal structure and magnetic field geometry of NSs. On the other hand, c_s may prove to be more useful to compare our results to observations. This last coefficient is

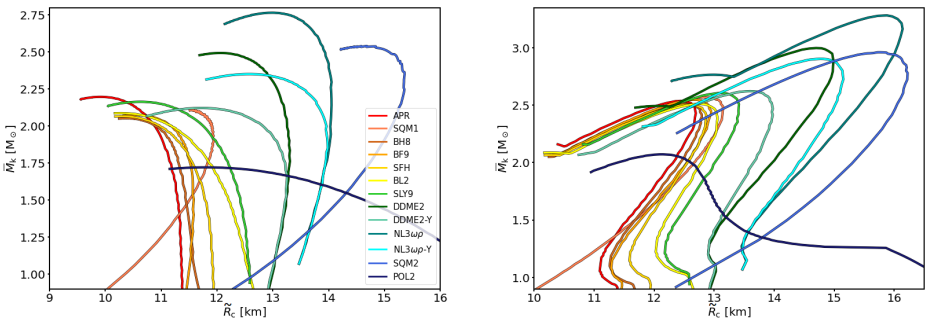

Fig. 2. Komar mass $\bar{M}_{\rm k}$ against circumferential radius $\tilde{R}_{\rm c}$ for un-magnetised, static models of NSs computed with the EoS described in Sect. 5 in GR (left plot) and in STT with $\beta_0 = -6$ (right plot). The EoS are color-coded, and ordered in the legend, according to the compactness $C = M_{\rm k}/R_{\rm c}$ calculated at $M_{\rm k} = 1.4{\rm M}_\odot$ in GR: red for the highest compactness and blue for the lowest compactness. Adapted from Soldateschi et al., ArXiv e-prints (2021), arXiv:2106.00603v2 [astro-ph.HE].

defined only for configurations endowed with a poloidal magnetic field (the toroidal one being hidden under the surface).

We found that $c_{\rm B}, c_{\rm H}$ and $c_{\rm s}$ are similar for all standard EoS (i.e. all EoS except SQM1, SQM2 and POL2) as functions of the Komar mass.[57] For this reason, we chose to consider the dependence also on another potentially observable quantity, namely the circumferential radius $\tilde{R}_{\rm c}$, to understand whether the spread among the various EoS could be further reduced. We used the 'principal component analysis' (PCA) technique to find the best-fit relation between $c_{\rm B,H,s}$, $\bar{M}_{\rm k}$ and $\tilde{R}_{\rm c}$. We found the following formulas approximating $c_{\rm B,H}$ in GR to a satisfying level of accuracy for all standard EoS (thus the name 'quasi-universal relations'):

$$c_{\rm B}^{\rm PCA} = \begin{cases} 0.13^{+0.03}_{-0.02} R_{10}^{5.45} M_{1.6}^{-2.41} \text{ for poloidal,} \\ \\ 0.25^{+0.03}_{-0.03} R_{10}^{5.03} M_{1.6}^{-2.07} \text{ for toroidal,} \end{cases} \tag{13}$$

$$c_{\rm H}^{\rm PCA} = \begin{cases} 5.77^{+0.04}_{-0.06} - 0.77 R_{10} - 4.14 M_{1.6} - 0.27 M_{1.6}^2 + \\ \quad +0.07 R_{10}^2 + 2.28 M_{1.6} R_{10} \text{ for poloidal,} \\ \\ 7.02^{+0.05}_{-0.07} - 5.22 R_{10} - 2.76 M_{1.6} - 0.12 M_{1.6}^2 + \\ \quad +1.92 R_{10}^2 + 1.51 M_{1.6} R_{10} \text{ for toroidal,} \end{cases} \tag{14}$$

where $M_{1.6} = \bar{M}_{\rm k}/1.6{\rm M}_\odot$. Moreover, we found that, in GR, $c_{\rm s}$ is well-approximated by the following relation:

$$c_{\rm s}^{\rm PCA} = 2.97^{+0.12}_{-0.23} R_{10}^{4.61} M_{1.6}^{-2.80} \, . \tag{15}$$

The coefficient $c_{\rm s}$ computed using Eq. 15 is plotted against the value computed with formula Eq. 12 in Fig. 3 (top left plot), together with the error of the approximation (bottom left plot). The dashed black line is a reference $c_{\rm s} = c_{\rm s}^{\rm PCA}$ bisecting line, which represents a perfect approximation. The superscript and subscript in the first coefficient of Eq. 15 are the values defining the purple and magenta lines bounding the magenta shaded area in Fig. 3, top left plot. The dark blue line, bounding the shaded blue area, marks the 90th percentile of the errors (the bounds containing 90% of the results). The corresponding values of these errors are showed with lines of the same colour in the bottom left plot. The approximation $c_{\rm s}^{\rm PCA}$ holds with a very small error, under a few percents. Moreover, we found that the quasi-universal relations for $c_{\rm B}$ hold with a slightly larger error, around $\sim 10\%$. The approximation for $c_{\rm H}$ is even more accurate, with an error that is mostly under $\sim 1\%$. Moreover, we found that performing $c_{\rm H}^{\rm PCA} \to 5/3 c_{\rm H}^{\rm PCA} - 0.9$ allows one to use the coefficients found in the toroidal case also in the poloidal configurations with a $\sim 2\%$ error.

Applying the quasi-universal relations derived in the case of standard EoS, Eqs. 13-14-15, to the polytropic models computed with the POL2 EoS, leads to larger errors, especially in the case of $c_{\rm B}$. We refer the reader to Ref. 57 for more details.

In the case of STTs, we find quasi-universal relations for $\Delta c_{\rm B} = |c_{\rm B} - c_{\rm B}^{\rm GR}|$, $\Delta c_{\rm H} = |c_{\rm H} - c_{\rm H}^{\rm GR}|$ and $\Delta c_{\rm s} = |c_{\rm s} - c_{\rm s}^{\rm GR}|$, where $c_{\rm B}^{\rm GR}, c_{\rm H}^{\rm GR}$ and $c_{\rm s}^{\rm GR}$ are the relations found in the GR case: Eqs. 13-14-15 respectively. In this case, we also allowed the dependence of the distortion coefficients on the scalar charge $\bar{Q}_{\rm s}$. We found the following quasi-universal relations:

$$\Delta c_{\rm B}^{\rm PCA} = \begin{cases} 0.03^{+0.05}_{-0.03} R_{10}^{8.23} M_{1.6}^{-5.08} Q_1^{2.60} \text{ for poloidal,} \\ \\ 0.06^{+0.09}_{-0.05} R_{10}^{5.96} M_{1.6}^{-3.52} Q_1^{1.95} \text{ for toroidal,} \end{cases} \tag{16}$$

$$\Delta c_{\rm H}^{\rm PCA} = \begin{cases} 1.96^{+0.17}_{-0.18} R_{10}^{0.72} M_{1.6}^{-1.96} Q_1^{1.54} \text{ for poloidal,} \\ \\ 1.49^{+0.26}_{-0.17} R_{10}^{0.75} M_{1.6}^{-1.81} Q_1^{1.55} \text{ for toroidal,} \end{cases} \tag{17}$$

$$\Delta c_{\rm s}^{\rm PCA} = 0.92^{+0.20}_{-0.27} R_{10}^{4.77} M_{1.6}^{-4.50} Q_1^{1.71} \ . \tag{18}$$

The quasi-universal relation in Eq. 18 is plotted against the corresponding value $\Delta c_{\rm s}$, computed through formula Eq. 12, in Fig. 3 (top right plot). The bottom right plot displays the relative error of the quasi-universal relation. The dashed line is a reference $\Delta c_{\rm s} = \Delta c_{\rm s}^{\rm PCA}$ bisecting line, which would be a perfect approximation. We can see that the approximation for $c_{\rm s}$ holds with an error that is around 10%. Moreover, we found that the quasi-universal relations for $\Delta c_{\rm B}$ hold with an error of

$\sim 50\%$. The approximation for $\Delta c_{\rm H}$ is more accurate, with a relative error of just a few percents. Similarly to what we found in the GR case, performing $c_{\rm H}^{\rm PCA} \to 3/2 c_{\rm H}^{\rm PCA} - 0.2$ allows us to use the coefficients found in the toroidal case in the poloidal geometry with a $\sim 10\%$ error.

Using Eq. 16 for models computed using the POL2 EoS, errors in approximating $\Delta c_{\rm B}$ remain of the same magnitude in the poloidal case, while they increase by $\sim 20\%$ in the toroidal case. Instead, Eq. 17 holds also for the POL2 EoS, at the expense of an error reaching a few tens of percents for the approximation of $\Delta c_{\rm H}$, as in the case of approximating $\Delta c_{\rm s}$ using Eq. 18 for polytropic models computed using the POL2 EoS.

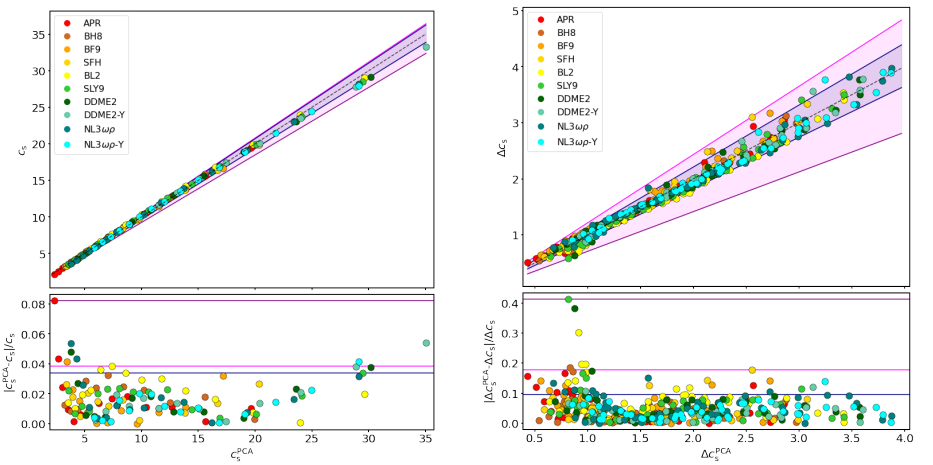

Fig. 3. Top left plot: distortion coefficient $c_{\rm s}$, calculated according to Eq. 12 in GR, versus its approximation $c_{\rm s}^{\rm PCA}$ calculated with the quasi-universal relation in Eq. 15. Top right plot: Difference $\Delta c_{\rm s}$ between the distortion coefficient $c_{\rm s}$, calculated according to Eq. 12 in STT with $\beta_0 \in \{-6, -5.75, -5.5, -5\}$, and the GR quasi-universal relation in Eq. 15. This is plotted versus its approximation $\Delta c_{\rm s}^{\rm PCA}$, calculated with the quasi-universal relation in Eq. 18. The corresponding relative deviations from the PCA are given in the bottom plots. The dashed lines are $c_{\rm B,H} = c_{\rm B,H}^{\rm PCA}$ and $\Delta c_{\rm s} = \Delta c_{\rm s}^{\rm PCA}$, respectively. The magenta shaded areas comprise all data points and the purple and magenta lines represent the upper and lower bounds of Eq. 15 and Eq. 18, respectively; the dark blue lines bounding the shaded blue area mark the 90th percentile error region. The EoS are color-coded, and ordered in the legend, according to the compactness $C = M_{\rm k}/R_{\rm c}$ calculated at $M_{\rm k} = 1.4 {\rm M}_\odot$ in GR: red for the highest compactness and blue for the lowest compactness. Adapted from Soldateschi et al., ArXiv e-prints (2021), arXiv:2106.00603v2 [astro-ph.HE].

As in the case of the POL2 EoS, we incur in larger errors if we apply the quasi-universal relations we found to the case of the SQM1 and SQM2 EoS. In GR, $c_{\rm B}^{\rm PCA}$ is a factor $\sim 0.4 - 0.8$ lower than $c_{\rm B}$. The maximum error for approximating $c_{\rm H}$ with Eq. 14 increases to $\sim 8 - 12\%$ in the case of SQM1, and $\sim 5\% (\sim 40\%)$ for purely poloidal (toroidal) magnetic fields in the case of SQM2. Moreover, $c_{\rm s}^{\rm PCA}$ is at

most a factor ~ 1.4 higher than $c_{\rm s}$. In STT, $\Delta c_{\rm B}^{\rm PCA}$ in the poloidal case is around a factor ~ 2 lower (higher) than $\Delta c_{\rm B}$ for the SQM1 (SQM2) EoS; in the toroidal case, it is a factor ~ 2 lower for both SQM1 and SQM2. The maximum error for approximating $\Delta c_{\rm H}$ using Eq. 17 increases to $\sim 30\%(\sim 50\%)$ for purely poloidal (toroidal) magnetic fields. Finally, $\Delta c_{\rm s}^{\rm PCA}$ is around a factor ~ 1.7 lower than $\Delta c_{\rm s}$.

A time-varying quadrupolar deformation leads to the emission of GWs. While in GR these are only of tensor nature, in the case of STTs a scalar channel is also present, which can contain any multipolar component. We only focus here on quadrupolar modes of GWs, both of tensor and scalar nature. As we have shown, NSs in GR and in STTs posses quite different quadrupolar deformations; for this reason, we compare the amount of GWs emitted by NSs in these two modes. To this end, we introduce the following quantity:

$$\mathcal{S} = \left| \frac{q_{\rm s}}{q_{\rm g}} \right|, \tag{19}$$

where

$$q_{\rm s} = 2\pi \int \alpha_{\rm s} \mathcal{A}^4 \tilde{T} \left(3\sin^2\theta - 2\right) r^4 \sin\theta {\rm d}r{\rm d}\theta, \tag{20}$$

$$q_{\rm g} = \int \left[\pi \mathcal{A}^4 (\tilde{\varepsilon} + \tilde{\rho}) - \frac{1}{8} \partial\chi \partial\chi \right] r^4 \sin\theta \left(3\sin^2\theta - 2\right) {\rm d}r{\rm d}\theta. \tag{21}$$

The quantity $q_{\rm s}$ is related to the source of scalar waves. The mass quadrupole $q_{\rm g}$ is $\bar{I}_{\rm zz} - \bar{I}_{\rm xx} = \bar{e}\bar{I}_{\rm zz}$ and is the source of tensor waves. Thus, the ratio $\mathcal{S}$ computed for a given NS model measures the relative amount of quadrupolar GWs emitted in the scalar and tensor channels. If $\mathcal{S} < 1$, the majority of GWs will be emitted in the tensor channel; if $\mathcal{S} > 1$, in the scalar channel. We found that the following quasi-universal relations hold for $\mathcal{S}$:

$$\mathcal{S}^{\rm PCA} = \begin{cases} 1.98^{+0.18}_{-0.05} R_{10}^{-0.71} M_{1.6}^{-0.54} Q_1^{1.22} \text{ for poloidal,} \\ \\ 1.99^{+0.18}_{-0.07} R_{10}^{-0.74} M_{1.6}^{-0.60} Q_1^{1.23} \text{ for toroidal.} \end{cases} \tag{22}$$

In Fig. 4 we plot the values of $\mathcal{S}$, computed through Eq. 19 for $\beta_0 \in \{-6, -5.75, -5.5, -5\}$, against their PCA approximation, computed through Eq. 22. The approximation is very accurate in both magnetic geometries, with an error that is mostly concentrated under $\sim 4\%$. Moreover, we see that the coefficients in Eq. 22 are almost identical in the poloidal and the toroidal cases, thus the two approximations are practically equivalent. It is possible that this similarity means that there exist a relation between the sources of scalar and tensor waves, $q_{\rm s}$ and $q_{\rm g}$, that does not depend on either the magnetic field geometry or the EoS.

The quasi-universal relations we found are independent on the EoS of standard NSs. For this reason they may be useful in disentangling the effects of the EoS and

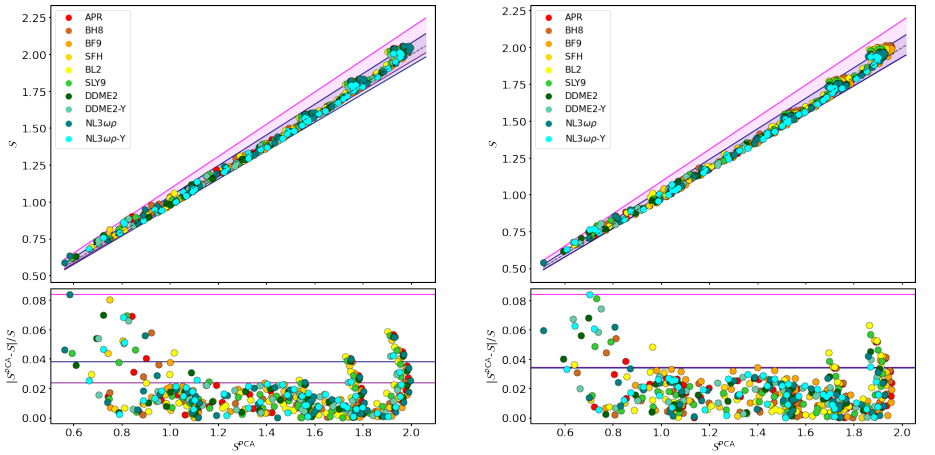

Fig. 4. Ratio $\mathcal{S}$ between scalar and tensor quadrupolar GW losses, calculated according to Eq. 19 in STT with $\beta_0 \in \{-6, -5.75, -5.5, -5\}$. This is plotted versus its approximation $\mathcal{S}^{\rm PCA}$, calculated with the quasi-universal relations in Eq. 22 (top plot in each panel). The corresponding relative devitations from the PCA are given in the bottom plot in each panel. The left panel refers to a purely poloidal magnetic field; the right panel refers to a purely toroidal magnetic field. The dashed line is $\mathcal{S} = \mathcal{S}^{\rm PCA}$. The magenta shaded area comprises all data points and the purple and magenta lines represent the upper and lower bounds of Eq. 22; the dark blue lines bounding the shaded blue area mark the 90th percentile error region. The EoS are color-coded, and ordered in the legend, according to the compactness $C = M_{\rm k}/R_{\rm c}$ calculated at $M_{\rm k} = 1.4{\rm M}_\odot$ in GR: red for the highest compactness and blue for the lowest compactness. Adapted from Soldateschi et al., ArXiv e-prints (2021), arXiv:2106.00603v2 [astro-ph.HE].

the magnetic field structure of NSs, leaving their internal magnetic structure as the only major unknown in GR. In this sense, the most promising relation is that of $c_{\rm s}$. On the one hand, $c_{\rm s}$ can be computed from its definition Eq. 12. In this case, one needs to measure both the magnetic field strength at the surface of the NS, $B_{\rm s}$, and its quadrupolar deformation e, which, in turn, can be estimated from the strain of CGWs emitted by the NS: $h_0 \propto eI$, where I is the moment of inertia of the NS along its rotation axis, which can be computed through an EoS-independent relation by knowing the NS mass and its radius.[90] On the other hand, our quasi-universal relation Eq. 15 allows one to estimate $c_{\rm s}^{\rm PCA}$ by knowing just the NS mass and radius. Comparing these values of $c_{\rm s}$ and $c_{\rm s}^{\rm PCA}$ can give an insight into the internal magnetic geometry of the emitting NS: the quasi-universal relation Eq. 15 was found in the case of a purely poloidal field, that is an extreme configuration which exherts the maximum possible magnetic deformation on the NS. For example, a lower value of $c_{\rm s}$ inferred by observations may imply the existence of a toroidal component of the NS internal magnetic field, which counteracts the effect of the poloidal component and results in a lower magnetic deformation. In the opposite case, another source of deformation may be present other than the magnetic field.

The quasi-universal relations Eqs. 13-14 may be more useful to constrain $B_{\rm max}$ or $\mathcal{H}/W$ themselves, being these quantities generally not observable. In particular,

$B_{\rm max} \approx (e/c_{\rm B})^{1/2}$ and $\mathcal{H}/W \approx e/c_{\rm H}$. As in the case of $c_{\rm s}$, we expect $c_{\rm B,H} < c_{\rm B,H}^{\rm PCA}$. If the NS mass and radius are known, one can esitimate a lower bound for both $B_{\rm max}$ and $\mathcal{H}/W$ by using the quasi-universal relations found in the purely poloidal and purely toroidal case. Moreover, the quasi-universal relations for $c_{\rm B}$, $c_{\rm H}$ and $c_{\rm s}$ can be useful to easily compute the distortion coefficients from the mass and radius of a model, without having to fully simulate the NS model.

In the case of STTs, some of the effects of the EoS are degenerate with the presence of a scalar charge inside the NS. For this reason, quasi-universal relations Eqs. 16-17-18 may help to understand whether a distortion coefficient inferred through relations Eqs. 8-12, is compatible with the observed NS possessing a scalar charge, independently from its EoS. Relation Eq. 22 does not involve knowing the strength of the magnetic field, thus it is probably more promising. In particular, following our previous argument, it may be that $\mathcal{S} \approx \mathcal{S}^{\rm PCA}$ independently of the magnetic configuration. Then, the observation of CGWs coming from a given NS of known mass, radius, distance d and spin period P translates into a lower bound for a function of the scalar charge. On the other hand, the non-observation of CGWs from a given NS can be translated into an upper bound.

Finally, we can use the quasi-universal relations we found to assess the detectability of known NSs, in GR. Since the strain of CGWs emitted by a deformed NS, rotating with frequency $f_{\rm rot}$ and at a distance d, is $h_0 \propto eIf_{\rm rot}^2/d$, by using the quasi-universal relation for $c_{\rm s}$ Eq. 15 we can compute h_0 for the pulsars of the ATNF[91] catalogue. In this case, $f_{\rm rot}$ and d are taken from the data in ATNF catalogue, while $M_{\rm k}, B_{\rm s}$ are generated from the expected distributions.[92,93] The radius $R_{\rm c}$ is computed by assuming the two most diverse standard EoS among the ones we considered, APR and NL3$\omega\rho$, and using the corresponding mass-radius diagram. Our results are shown in Fig. 5, where they are compared to the sensitivity of the advanced LIGO (aLIGO) detector in the design configuration[a] and of the Einstein Telescope (ET) detector in the D configuration[b]: the blue (red) solid line represents the sensitivity of aLIGO (ET), while the blue (red) dot-dashed and dashed lines show the minimum strain detectable by aLIGO (ET) assuming a 1 month or 2 years observing time, respectively. The x-axis represents the frequency f of the emitted CGWs. In the general case, CGWs are emitted at two frequencies, $f = f_{\rm rot}$ and $f = 2f_{\rm rot}$. In this case, we consider only the $f = 2f_{\rm rot}$ wave. As we can see from Fig. 5, many millisecond pulsars contained in the ATNF catalogue have a chance to emit CGWs which could be potentially observed with the future ET detector, especially considering a 1 month or 2 year observing campaign. As for aLIGO, in the case of 1 month or 2 years observing time, a few tens of the ATNF millisecond pulsars could potentially be detected through CGWs. We note that the difference in radii given by the two different EoS does not significantly alter the strain of the

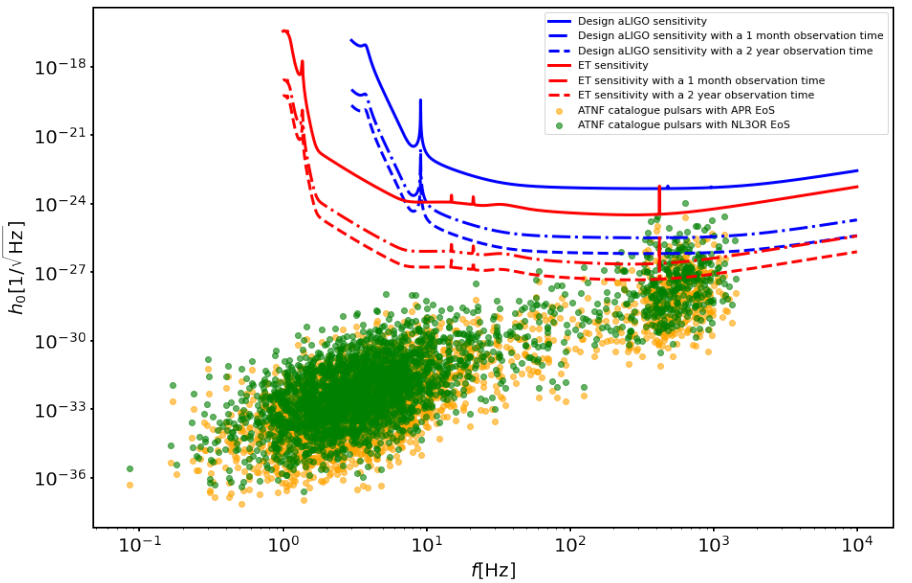

Fig. 5. CGWs strain h_0 computed for pulsars contained in the ATNF catalogue through the use of quasi-universal relation Eq. 15 and by assuming the APR EoS (orange points) or the NL3$\omega\rho$ EoS (green points). The x-axis represents the frequency f of the emitted CGWs. The blue (red) solid line represents the sensitivity of the aLIGO (ET) detector, while the blue (red) dot-dashed and dashed lines show the minimum strain detectable by aLIGO (ET) assuming a 1 month or 2 years observing time, respectively.

emitted CGWs. However, pulsars with smaller rotation period are much less likely to be observed, even with a 3rd generation detector like ET.

We study the stress tensor of the outer crust of Neutron Stars (NSs) under the approximation of the one component plasma (OCP) with screening. In our approach a system of identical ions is placed in an electron degenerate Fermi sea. By using Molecular Dynamics simulations at finite temperature we obtain the stress tensor components and associated pressure including Ewald sums for the electron screened ion potential. Our results show that a careful characterization of the crystallized phase at low temperature is necessary in order to obtain the true ground state. These ion phases are of interest for modelling the effects of large tidal forces and the gravitational wave signal linked to the violent events in binary NS mergers and possible crust crunching in NS continuous emission.

Keywords: Neutron star, dense matter, crust

1. Introduction

The extreme conditions of matter inside Neutron Stars (NSs) are hard to grasp based on our knowledge of regular low density condensed matter on Earth. Nevertheless it is crucial for our understanding of these objects to theoretically model their interior. High density matter present in their core is thought to be a homogeneous system of relativistic particles, mostly neutron rich. Typical NSs are believed to be formed out of nucleons and possibly heavier particles and a lepton sector providing electrical charge neutrality. Located in their outer shells, the crust is far from being a trivial phase.[1] It is composed of non-homogeneous matter, typically a set of irregular shapes, pasta phases,[2] that at lower densities end up forming a regular ion lattice. Besides, in order to maintain electrical charge neutrality there must be a degenerate electron Fermi gas surrounding these structures. Some of the neutrons leaking from these irregular shapes can pair into superfluid phases in the lower density part of the NS crust.[3]

Experimental constraints on the nature of NSs have been difficult to obtain, only in the last decades satellite missions or big water tank detectors have been able to deepen inside the electromagnetic or neutrino probes of dynamics of their interior in different stages of their birth and evolution. The dawn of Multi-Messenger Physics is thus a promising tool to help understand different aspects of NSs and has proven possible to observationally test some of the theoretical assumptions about the physical conditions of not only the crust, but also the core and the

global Equation of State (EoS) of nuclear matter. In particular, another type of messengers, gravitational waves, show that the elastic properties of this material play a significant role in the strength and shape of measured signals involving these objects.

In this contribution we are interested in evaluating the impact of screening on forces, potential energies and stress tensor, as they are key to understand some mechanical properties of the very outer crust, which typically extend within hundreds of meters in the most external layers of the object.[4] Matter in this region is formed by a mixture of ions and electrons are stripped off them forming a degenerate Fermi sea. Typical ion mean densities[5] belong to the range between around 10^{-5} to 10^{-4} fm^{-3}.

As mentioned, in this region one expects to find a state of matter called Coulomb liquid, formed by different nuclear species, embedded in a degenerate electron gas. This gas makes sure that the system is kept charge neutral, and also screens the electromagnetic interactions between the ions so that this interaction is no longer pure Coulomb-wise but accounts for screening due to the electron gas. Thus the potential created by a positive charge Z_i (in units of electron charge e) at position $\vec{r_i}$, that describes this interaction at r is the so-called *Debye potential*, and has the form of a two-body Coulomb interaction with an exponential tail

$$\phi_i\left(\vec{r}\right) = \frac{Z_i}{\left|\vec{r} - \vec{r_i}\right|} e^{-\frac{\left|\vec{r} - \vec{r_i}\right|}{\lambda}}, \tag{1}$$

where λ is the Thomas-Fermi screening length

$$\lambda = \frac{\pi^{\frac{1}{2}}}{\left(4\alpha k_F\right)^{\frac{1}{2}} \left(k_F^2 + m_e^2\right)^{\frac{1}{4}}} \sim \frac{1}{2k_F}\sqrt{\frac{\pi}{\alpha}}. \tag{2}$$

k_F and m_e are the electron Fermi momentum and mass, respectively. α is the fine structure constant.

This potential ϕ_i is such that the interaction described tends to a pure Coulomb interaction when the screening length is much larger than the typical interparticle distance. In terms of the ion species that will be considered to describe the material in the outer NS crust, this will arise after the material in the hot protoNS cools down and its composition finally stabilizes and freezes to a ground state reached at $T \sim 10^5$ K. It is expected that the realistic composition in this layer is that of a multi-component plasma, comprised of different ion species. However, we would like to approach this complex problem by investigating only one, the most frequent nucleus, at a given density and temperature. This is known in the literature as the one-component plasma (OCP).[6]

Our approach is thus to assume that the material under inspection is comprised of a single ion species with fixed electrical charge and atomic mass number (Z, A)

embedded in the degenerate electron gas of number density equal to that of protons $n_e = n_p$, and whose interaction is described by the Debye potential. Note that in our calculation we will be using Molecular Dynamics and solving the equations of motion of ion degrees of freedom described in the quantum perspective as Gaussian charge density distributions. Similarly to the construction for the Coulomb interaction (which has an infinite range) we will consider the efficient Ewald summation technique[7] for the Debye potential.

2. Molecular Dynamics and the Ewald summation technique

Molecular Dynamics (MD) is a many-body technique to simulate the microscopic behaviour of matter in which the equations of motion of the individual degrees of freedom (ions in our case) are integrated while interacting via a prescribed potential. Typically for the integration of the equations of motion an algorithm is used. We use a Velocity Verlet one in our work. The final goal of this is obtaining the time evolution of the positions and velocities of the ions from which derived properties can be calculated once the system is thermalized. We use the NVT ensamble where ions (Fe or more general species with different Z and A) are the degrees of freedom for which we integrate the individual equations of motion, using the aforementioned Debye potential, as we are in the OCP approximation. The number of ions, size of the simulation box $L = V^{1/3}$, and the kinetic energy (or temperature T) remain fixed during the evolution starting from a random distribution. Also, the lepton fraction $Y_e = \frac{N_e}{N_p+N_n}$ obtained from number of protons (N_p), neutrons (N_n) and electrons ($N_e = N_p$) is fixed, as well as the OCP parameters (Z_i, A_i), for which we use fixed $Z_i = Z$, $A_i = A$. The crystallization parameter in the Coulomb case is defined as $\Gamma^{OCP} = \frac{Z^2}{k_B T}\left(\frac{4\pi}{3} n_I\right)^{1/3}$ and for $\Gamma^{OCP} > 175$ an ordered state is thought to arise.

The dynamics of the N_I ions are obtained by solving Newton's law $\vec{F_i} = m_i \vec{a_i}$, $i = 1, N_I$ assuming that the resulting potential is created by adding that of each ion. Note that the charge of each ion, ρ_i is spread into a Gaussian distribution, a more realistic case than the frequently assumed point-like charges, populating the layers in outer NS crusts. More in detail we have

$$\rho_{i,a}(r) = Z_i \left(\frac{a}{\pi}\right)^{\frac{3}{2}} e^{-ar^2}, \tag{3}$$

where a is related to the Gaussian width, σ_a, as $a = \frac{1}{2\sigma_a^2}$ and r is the distance coordinate taken from the center of the Gaussian source.

The Debye interaction potential produced by such a Gaussian source with charge and inverse width Z_i, a at $\vec{r_i}$ is then obtained by solving the Poisson equation

$$-\frac{1}{r}\frac{d^2}{dr^2}(r\phi(r)) + \frac{\phi(r)}{\lambda^2} = 4\pi \left[Z \left(\frac{a}{\pi}\right)^{3/2} e^{-ar^2} \right], \tag{4}$$

so that the solution is

$$\phi_{Zi,a}\left(\vec{r}\right) = \frac{Z_i}{2|\vec{r}-\vec{r_i}|} e^{\frac{1}{4a\lambda^2}} \left[e^{-\frac{|\vec{r}-\vec{r_i}|}{\lambda}} \mathrm{erfc}\left(\frac{1}{2\sqrt{a}\lambda} - \sqrt{a}|\vec{r}-\vec{r_i}| \right) \right.$$
$$\left. - e^{\frac{|\vec{r}-\vec{r_i}|}{\lambda}} \mathrm{erfc}\left(\frac{1}{2\sqrt{a}\lambda} + \sqrt{a}|\vec{r}-\vec{r_i}| \right) \right], \tag{5}$$

with erfc the complementary error function.

Even if the interaction between ions in our simulations is thought to be screened, it can reach longer than the size of the cubic simulation box $L = \left(\frac{N_I}{n_I}\right)^{1/3}$ where N_I and n_I are the number of ions and ion number density used. A proper treatment of the long-range part of the interaction is required. Usually, this is partly dealt with via periodic boundary conditions (PBC), thinking of the system as a infinite lattice of simulation boxes in which the ions interact with the closest neighbors of the different images of a selected box. By using the Ewald summation technique one takes advantage of including all the long-range interactions between ions irrespectively of the values of the screening length and the size of the simulation box. Some previous works have been developed for pure Coulomb potentials,[8] but to our knowledge this has not been done for electron screened versions. In this contribution we have developed the relevant expressions for the MD calculation of the microscopic state of matter.

In order to calculate the energies and accelerations in the Ewald summation scheme, we must first introduce *spurious* Gaussian charges into the system to screen the real ones. These are centered at the same positions as the real charges but have opposite sign, $-Z_i$, and display an inverse squared width α_{Ewald}

$$\rho_{-Z_i,\alpha_{\mathrm{Ewald}}} = -Z_i \left(\frac{\alpha_{\mathrm{Ewald}}}{\pi}\right)^{\frac{3}{2}} e^{-\alpha_{\mathrm{Ewald}} r^2}. \tag{6}$$

These are the so-called *screening charges*. Consequently as a way of maintaing the electrical charge neutrality of the system, we are forced to introduce compensating charges that are identical in shape to the screening ones except for the charge, which in this case is positive $\rho_{Z_i,\alpha_{\mathrm{Ewald}}} = Z_i \left(\frac{\alpha_{\mathrm{Ewald}}}{\pi}\right)^{\frac{3}{2}} e^{-\alpha_{\mathrm{Ewald}} r^2}$.

It is key to note here that the parameter α_{Ewald} is an arbitrary square inverse length that we introduced for convenience to screen the original interaction. The physical observables that one can obtain from the simulation thus must not depend on this parameter.

The total interaction energy U_{tot} is then divided into three parts. Firstly, a short-range part, $U_{\mathrm{short-range}}$, which is the interaction between the real charges and the sum of the real plus the screening charges. The total interaction potential, $\phi_{\mathrm{tot},i}$ concerning this short-range part of the interaction is produced by this sum of real plus screening charges.

$$\phi_{\mathrm{tot,i}}\left(|\vec{r}-\overrightarrow{r_i}|\right)=\frac{Z_i}{2\,|\vec{r}-\overrightarrow{r_i}|}\left\{e^{\frac{-|\vec{r}-r_i|}{\lambda}}\left[e^{\frac{1}{4a\lambda^2}}\,\mathrm{erfc}\left(\frac{1}{2\sqrt{a}\lambda}-\sqrt{a}\,|\vec{r}-\overrightarrow{r_i}|\right)\right.\right.$$
$$\left.-e^{\frac{1}{4\alpha_{\mathrm{Ewald}}\,\lambda^2}}\,\mathrm{erfc}\left(\frac{1}{2\sqrt{\alpha_{\mathrm{Ewald}}}\,\lambda}-\sqrt{\alpha_{\mathrm{Ewald}}}\,|\vec{r}-\overrightarrow{r_i}|\right)\right]$$
$$-e^{\frac{|\vec{r}-r_i|}{\lambda}}\left[e^{\frac{1}{4a\lambda^2}}\,\mathrm{erfc}\left(\frac{1}{2\sqrt{a}\lambda}+\sqrt{a}\,|\vec{r}-\vec{r}_i|\right)\right.$$
$$\left.\left.-e^{\frac{1}{4\alpha_{\mathrm{Ewald}}\lambda^2}}\,\mathrm{erfc}\left(\frac{1}{2\sqrt{\alpha_{\mathrm{Ewald}}}\lambda}+\sqrt{\alpha_{\mathrm{Ewald}}}\,|\vec{r}-\vec{r}_i|\right)\right]\right\}. \tag{7}$$

When using the Coulomb interaction one can verify that expressions have a closed, analytical expression, but for the Debye case, instead, one has to perform numerical integrations each time step of the simulation in order to obtain the forces (as gradient of this potential). The final expression for this short-range part of the interaction energy is given by

$$U_{\mathrm{short-range}}=\frac{1}{2}\sum_{i=1}^{N_I}\sum_{j\neq i=1}^{N_I}2Z_j\left(\frac{a}{\pi}\right)^{\frac{1}{2}}\frac{e^{-ar_{ij}^2}}{r_{ij}}\int_0^\infty r'\phi_{\mathrm{tot},i}\left(r'\right)e^{-ar'^2}\sinh\left(2ar_{ij}r'\right)dr'$$
$$-\frac{2\pi}{V}\sum_{=1i}^{N_I}\sum_{j=1}^{N_I}Z_j\int_0^\infty r'^2\phi_{\mathrm{tot,i}}\left(r'\right)dr', \tag{8}$$

where $r_{ij}=|\vec{r_i}-\vec{r_j}|$ is the distance between the N_I ions labeled i and j.

The usefulness of the separation into short and long range contributions stands clear here as the long-range energy term has a dependence in the interparticle distance that tails off quickly, so that it converges very rapidly in real space. The upper limit of the numerical integration is set, practically, at the finite value $r'=\sqrt{2}L$.

The second energy term, U_{l}, of the scheme is produced by the interaction between real charges and the compensating charges in all the simulation boxes that exist in the infinite lattice that was created using PBCs. This is done by transforming Poisson's equation from the r-coordinate to the Fourier k-space. The derivation's endpoint is a summation over reciprocal lattice vectors, the interaction going to zero when the module of these vectors is high enough so that the sum converges in the Fourier space,

$$U_{\mathrm{l}}=\frac{1}{2}\sum_{i,j=1}^{N_I}\sum_{\vec{k}\neq 0}\frac{4\pi Z_iZ_j}{V\left(k^2+\frac{1}{\lambda^2}\right)}e^{\frac{-k^2}{4}\left(\frac{1}{a}+\frac{1}{\alpha_{\mathrm{Ewald}}}\right)}e^{i\vec{k}(\vec{r_i}-\vec{r_j})}, \tag{9}$$

where $\vec{k}=\frac{2\pi}{L}\left(n_{k,x},n_{k,y},n_{k,z}\right)$ being $n_{k,x},n_{k,y},n_{k,z}\in\mathbb{Z}$ integers in the Cartesian XYZ directions. Finally, it remains to substract the interaction between the real particle and its own compensating charge in the same simulation box, as it is included spuriously in the long-range part. It also includes integrals that are to be

numerically solved. This energy from self-interaction is given by

$$U_{self} = 2\pi \left(\frac{a}{\pi}\right)^{\frac{3}{2}} \sum_{i=1}^{N_I} Z_i \int_0^{\infty} r'^2 \phi_{Z_i,\alpha_{\text{Ewald}}}(r')\, e^{-ar'^2} dr', \tag{10}$$

where $\phi_{Z_i,\alpha_{\text{Ewald}}}$ is the potential produced by the compensating charges alone, from equation 5. The global expression for the interaction energy is $U_{tot} = U_{\text{short-range}} + U_{\text{l}} - U_{self}$.

3. Stress tensor in the OCP approximation

In our study we focus on the OCP stress tensor. We can write the total stress tensor as follows[7]

$$\Pi_{\alpha\beta}^{\text{tot}} = \frac{1}{L^3} \sum_{i=1}^{N_I} m \dot{\vec{r}}_{i\alpha} \dot{\vec{r}}_{j\beta} + \Pi_{\alpha\beta} \tag{11}$$

where m is the mass of ions. This second-order rank tensor can be put into the form $\Pi_{\alpha\beta} = \Pi_{\alpha\beta}^{\text{real}} + \Pi_{\alpha\beta}^{\text{recip}}$, arising from the interparticle forces. As the interactions in real space may be written in a pairwise fashion, the configurational part of the pressure tensor, $\Pi_{\alpha\beta}^{\text{real}}$, can be evaluated directly from the real forces by employing the virial expression

$$\Pi_{\alpha\beta}^{\text{real}} = \frac{1}{2V} \sum_{i,j\neq i=1}^{N_I} \left(F_{ij,\alpha}^{\text{real}}\, r_{ij,\beta} + F_{ij,\beta}^{\text{real}} r_{ij,\alpha}\right), \tag{12}$$

where α, β are tensorial indexes running from 0 to 3 (time and XYZ spatial coordinates). We use Minkowski metric $g_{\alpha,\beta} = diag(1,-1,-1,-1)$.

The real space forces arise from the short-range part of the potential and take the form

$$\begin{aligned} \vec{F}_{\text{ij, short-range}} &= 2\left(\frac{a}{\pi}\right)^{\frac{1}{2}} \frac{Z_j e^{-ar_{ij}^2}}{r_{ij}^2} \left(\frac{\vec{r}_{ij}}{r_{ij}}\right) \\ &\times \left\{ \int_0^{\infty} r' \phi_{\text{tot,i}}(r')\, e^{-ar'^2} \left[\left(1+2ar_{ij}^2\right)\sinh\left(2ar_{ij}r'\right) - 2ar_{ij}r'\cosh\left(2ar_{ij}r'\right)\right] dr' \right\}, \end{aligned} \tag{13}$$

while the reciprocal part is obtained as

$$\begin{aligned} \Pi_{\alpha\beta}^{\text{recip}} &= \frac{1}{2} \sum_{\vec{k}\neq 0}^{\infty} \frac{4\pi}{V^2\left(k^2 + \frac{1}{\lambda^2}\right)} e^{\frac{-k^2}{4}\left(\frac{1}{a}+\frac{1}{\alpha_{Ewald}}\right)} e^{i\vec{k}\cdot(\vec{r}_i - \vec{r}_j)} \\ &\times \left\{ \delta_{\alpha\beta} - 2\left[\frac{1}{4}\left(\frac{1}{a}+\frac{1}{\alpha}\right) + \frac{1}{\left(k^2+\frac{1}{\lambda^2}\right)}\right] k_\alpha k_\beta \right\}. \end{aligned} \tag{14}$$

Note that when solving the equations of motions for the ions the forces involved are not only those of real space but also the reciprocal space contribution from U_l. Their form reads

$$\vec{F}_{\mathrm{i},l} = \frac{1}{2}\sum_{\vec{k}\neq 0} \frac{8\pi Z_i}{V\left(k^2+\frac{1}{\lambda^2}\right)} e^{-\frac{-k^2}{4}\left(\frac{1}{\alpha}+\frac{1}{a_{\mathrm{Ewald}}}\right)} \times \left\{ \sin\left(\vec{k}\cdot\vec{r}_i\right)\left[\sum_j Z_j \cos\left(\vec{k}\cdot\vec{r}_j\right)\right] - \cos\left(\vec{k}\cdot\vec{r}_i\right)\left[\sum_j Z_j \sin\left(\vec{k}\cdot\vec{r}_j\right)\right]\right\}\vec{k}. \tag{15}$$

4. Results of the simulated OCP crystal

In this section we show the results obtained from our OCP MD simulations. In our NVT ensamble we use fixed N_I ions in a box of length $L = \left(\frac{N_I}{n_I}\right)^{1/3}$ for a given outer crust ion number density n_I at temperature T. Typically we set $T = 1$ MeV. In Fig. 1 we show two snapshots (planes XZ, XY) of particle positions for a run with $n_I = 0.017\mathrm{fm}^{-3}$, and $N_I = 50$ particles. We set $a = 2\ fm^{-2}$ and $a_{Ewald} = 10\ fm^2$. Initial random positions are shown in red while those after thermalization ($t = 10^4$ fm/c) are depicted in blue. As shown an ordered crystal forms after this time evolution.

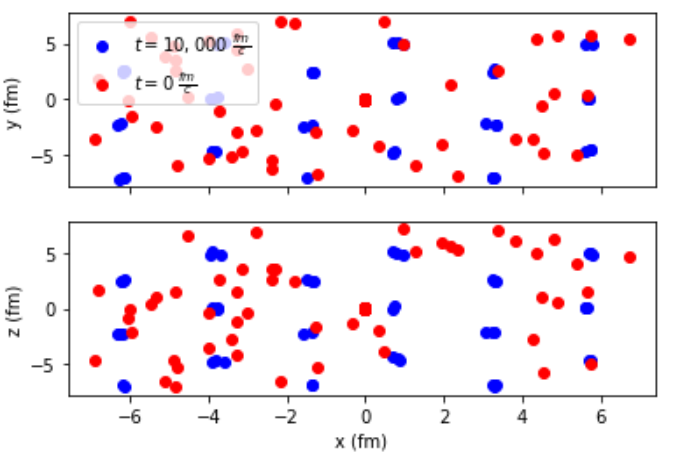

Fig. 1. Two dimensional snapshots of particle positions for a run with $n_I = 0.017\,\mathrm{fm}^{-3}$, and $N_I = 50$ particles with $A = 56$, $Z = 26$. Initial positions are shown in red while those after thermalization ($t = 10^4$ fm/c) are depicted in blue. As shown an ordered crystal forms after this time evolution.

In Fig. 2 we show the pair correlation function $g(r)$ versus distance in units of simulation box length L with the same conditions as those depicted in system from Fig. 1. At small distances the repulsive interaction leads the distribution, however

at larger distances the crystallized configurations arise as signaled by the different peaks. Normalization of $g(r)$ is such that $\int_0^\infty n_I g(r) 4\pi r^2 dr = N_I - 1$.

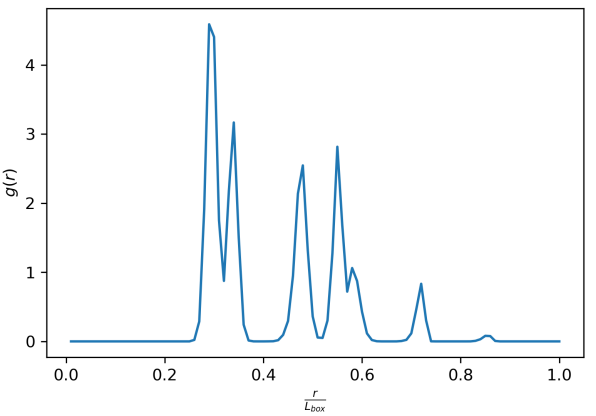

Fig. 2. Pair correlation function for $N_I = 50$ and same conditions as those in Fig. 1. Short range repulsion is shown along with the different peaks signaling the appearance of an ordered state with different neighbouring distances.

In Fig. 3 we show the energy per nucleon for a system of $N_I = 10$ ions with $A = 56$ at density $n_I = 0.0016$ fm^{-3}. Using the Ewald sum (we set $a = 2\ fm^{-2}$ and $a_{Ewald} = 10\ fm^{-2}$) we explore the convergence and actual value of energy per nucleon as the electron screening length changes. We use $\lambda = 10, 50, 100$ fm and we also test the Coulomb case where $\lambda \to \infty$. We show that the screened interaction in the infinite range converges to existing calculations using the raw Coulomb case.[8] In the depicted case the change can be nearly 50%, making the system less bound.

In Fig. 4 we show the pressure as a function of the mass density along with the non-diagonal stress tensor components. We use $a = 2\ fm^{-2}$ and $a_{Ewald} = 10\ fm^{-2}$ for a system of $N_I = 25$ ions with $Z = 26$, $A = 56$ at different densities. Pressure is obtained for the crystallized sytem as $P = \frac{1}{3} Tr \Pi_{\alpha\beta}$, but an additional electron pressure is present from the Fermi gas such that $P_e = \frac{\pi^3 \hbar^2}{15m} \left(\frac{3n_e}{\pi}\right)^{\frac{5}{3}}$ and $n_e = n_p$ in the charge neutral system. It is important to note that the true ground state of the system must provide a zero pressure crystal (as it does not exert external force per unit area) and this is fitted by considering a variable box length in our simulation. The off-diagonal components are zero as the crystal is not distorted from equilibrium (no shear).

We conclude that a careful evaluation of screening effects in the evaluation of the energies as well as forces is key to obtain the true binding of ion matter in the outer crust of NSs. We find that when the Ewald sum is implemented screened matter is less bound than the regular Coulomb lattice and this has an impact on forces

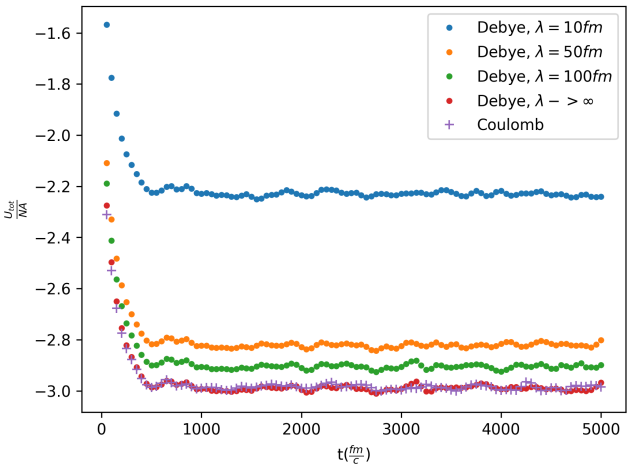

Fig. 3. Energy per nucleon as a function of simulation time for ions with $Z = 26$, $A = 56$, T=1 MeV and $n_I = 0.0016$ fm^{-3}. Colors represent simulations for different values of electron screening length λ, and for the Coulomb case. Ewald sums using Debye expressions in the limit $\lambda \to \infty$ provide results that converge to existing Coulomb calculations.[8]

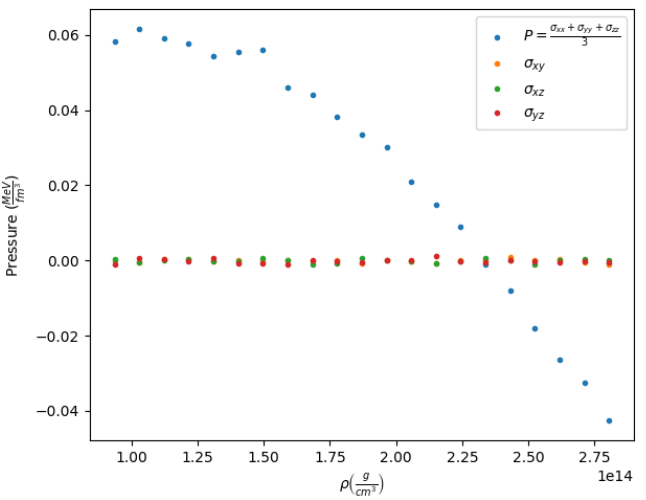

Fig. 4. Ion pressure and off-diagonal elements of the stress tensor as a function of mass density for ions with $Z = 26$, $A = 56$, T=1 MeV. It is seen that the total ion pressure is zero for a given value of the density. This is relevant to the definition of the true ground state of the system.

and thus on the mechanical properties derived from the stress tensor. In a future contribution we will detail how sizable this correction is with a complete analysis from density and temperature variation.

The concept of boson stars (BSs) was first introduced by Kaup and Ruffini and Bonazzola in the 1960s. Following this idea, we investigate an effect of self-interacting asymmetric bosonic dark matter (DM) according to Colpi et al. model for BSs (1986) on different observable properties of neutron stars (NSs). In this paper, the bosonic DM and baryonic matter (BM) are mixed together and interact only through gravitational force. The presence of DM as a core of a compact star or as an extended halo around it is examined by applying different boson masses and DM fractions for a fixed coupling constant. The impact of DM core/halo formations on a DM admixed NS properties is probed through the maximum mass and tidal deformability of NSs. Thanks to the recent detection of Gravitational-Waves (GWs) and the latest X-ray observations, the DM admixed NS's features are compared to LIGO/Virgo and NICER results.

Keywords: Bosonic Dark matter, Complex scalar field, Neutron Star, Gravitational-Wave

1. Introduction

The evidence for the existence of dark matter (DM) which constitutes up to 85% of the matter in the universe, is implied from various astrophysical and cosmological observations. However, despite the enormous experimental efforts in the past decades, the nature of these particles remains elusive. In addition to various terrestrial experiments, compact astrophysical objects such as neutron stars (NSs) can be served as valuable natural detectors to constrain the properties of DM. The presence

of DM in NS interior depending on the various hypothesis of introducing them and their features, could have signficant effects on the properties of NSs.[1–8]

There are different scenarios assuming existence of DM in the NS interiors, which are mostly based on the DM accumulation during different stages of stellar evolution. The main of these stages are : a) progenitor, b) main sequence star, c) supernova explosion with formation of a proto-NS, and d) equilibrated NS.[4,9–13] As an alternative way, DM can be produced during the supernova explosion or NS merger leading to presence of DM in the NSs.[2,3] High level of DM fraction inside NS is reachable through other mechanisms such as (i) dark compact objects or DM clumps as the accretion center of baryonic matter (BM),[3,14,15] (ii) DM captured by NS in a binary system including Dark star and Dark star–NS merger,[7,15,16] (iii) NS can pass through a region in the Galaxy with extremely high DM density leading to accumulation of vast amount of DM.[16–19]

Two main and qualitatively different pictures leading to potentially observable impact of DM on the NS properties are a) Self-annihilating DM affecting luminosity, effective temperature and cooling process of NSs[20–25] and b) Asymmetric DM (ADM) with negligible annihilation rate caused by particle-antiparticle asymmetry in the dark sector.[26–29] We consider the second possibility allowing stable and massive DM particles to reside in a core of the NS. It was pointed out that the presence of DM particles in stellar cores can significantly decrease the mass of a compact object.[18,19,30,31] However, it was shown that light DM particles form an extended halo around the NS and can increase its gravitational mass.[2,4] It is worth mentioning that both of the aforementioned cases for combination of DM and BM within NS are known as DM admixed NS.

Regarding the ADM model, generally two methods have been utilized so far to extract the properties of the DM admixed NS from the Tolman-Oppenheimer-Volkof (TOV) equations.[32,33] 1) Single fluid formalism, for which an Equation of State (EoS) is considered for the whole star by inserting DM-BM interactions.[1,7,34–37] 2) Two-fluid formalism, for which DM and BM interact only through gravitational force, and two individual EoSs have to be considered for the DM and BM fluids.[15,16,38–41]

In this research, we apply a two-fluid formalism for the DM admixed NS. Bosonic DM is described by a complex scalar field with repulsive self-interaction. Historically, this model has been applied to describe hypothetical self-gravitating objects composed of bosons, so called boson stars. The idea of BS was first proposed by Kaup[42] and Ruffini-Bonazzola[43] for non-interacting bosons. The Heisenberg uncertainty principle was the only source of pressure of the BS matter resisting gravitational contraction. This leads to much lower maximum mass of BS compared to the Chandrasekhar mass. The pressure of the BS matter was significantly increased by introducing repulsive self-interaction proposed by Colpi et al.[44] Within this approach, stellar mass objects are supported by the DM particle mass about hundreds MeV and dimensionless coupling constant is of order of unity (see a comprehensive

review on BSs in[45–47]). Another component, i.e. BM, is modeled by the induced surface tension (IST) EoS. It was successfully applied to describe the nuclear matter, heavy-ion collision data and dense matter existing inside NS.[48–50]

With this set up we study effects of self-repulsive bosonic ADM on the mass-radius (M-R) profile and tidal deformability parameter[2,3,13,36,37,51–54] inferred from the GW signals related to post-merger stages of NSs.[55–59] Such a combined analysis based on the recent LIGO/Virgo results[60,60,61,61] opens a new possibility to study the internal structure of compact objects which may contain DM.

To be specific, in this work we consider a model of Colpi et al.[44] with sub-GeV DM particles of mass $m_\chi \sim \mathcal{O}(100$ MeV) and self-coupling constant $\lambda = \pi$. We analyze two key observational constraints of NSs, i.e. maximum mass and tidal deformability. The first of them is based on the NICER observation of the heaviest known pulsar PSR J0740+6620 with mass $2.072^{+0.067}_{-0.066} M_\odot$[62] and corresponds to requiring the maximal stellar mass to be at least $M_{max} = 2M_\odot$. The merger event GW170817[63] leads to the second constraint on the dimensionless tidal deformability $\Lambda \leq 580$ for $M = 1.4M_\odot$.[64] Using these constraints we probe DM admixed NSs at various masses and fractions of DM.

The rest of the paper is organized as follows. In Sec. 2 the DM and BM EoSs are described. In Sec. 3 we explain the two-fluid TOV formalism, DM halo and DM core formations and their impacts on mass-radius profile of DM admixed NSs. Sec. 4 is devoted to probing the effect of DM halo/core configurations on the tidal deformability. Our conclusions will be presented in Sec.5. We use units in which $\hbar = c = G = 1$.

2. Bosonic DM and BM models

2.1. *Dark Boson Star*

In the following we apply a model of complex scalar field as the bosonic DM with repulsive self-interaction potential, $V(\phi) = \frac{\lambda}{4}|\phi|^4$, minimally coupled to gravity and described by the action

$$S = \int d^4x\sqrt{-g}\left[\frac{M_{Pl}^2}{2}R - \frac{1}{2}\partial_\mu\phi\partial^\mu\phi^* - \frac{1}{2}m_\chi^2|\phi|^2 - \frac{1}{4}\lambda|\phi|^4\right], \tag{1}$$

where m_χ is the boson mass, λ stands for the dimensionless coupling constant and M_{Pl} corresponds to the Planck mass.[44,65] In this setup a coherent scalar field is governed by both Klein-Gordon and Einstein equations which can potentially form Bose-Einstein Condensate (BEC) if the temperature is sufficiently low.[66,67] It has been assumed a spherically symmetric configuration for the scalar field $\phi(r,t) = \Phi(r)e^{i\omega t}$ and a static metric to rewrite Klein-Gordon-Einstein (K.G.E) equations to a set of ordinary differential equations.[44] This leads to the following EoS describing

a self-interacting and self-gravitating bosonic system so-called BS

$$P = \frac{m_\chi^4}{9\lambda}\left(\sqrt{1+\frac{3\lambda}{m_\chi^4}\rho}-1\right)^2 . \tag{2}$$

We recently presented an alternative derivation of this EoS in locally flat space-time by using the mean-field approximation (see appendix of[68]). This equation is valid in the parameter region for λ as

$$\lambda \gg 4\pi(m_\chi/M_{Pl})^2 = 8.43\times10^{-36}\left(\frac{m_\chi}{100\,\mathrm{MeV}}\right)^2 \tag{3}$$

In this limit which is called strong coupling regime, the system can be approximated as a prefect fluid and the anisotropy of pressure will be ignored.[45,69,70] Stellar mass BSs can be formed for $\lambda \sim \mathcal{O}(1)$ and $m_\chi \sim \mathcal{O}(100\ \mathrm{MeV})$,[45,71] in this section, we focus on this range of model parameters.

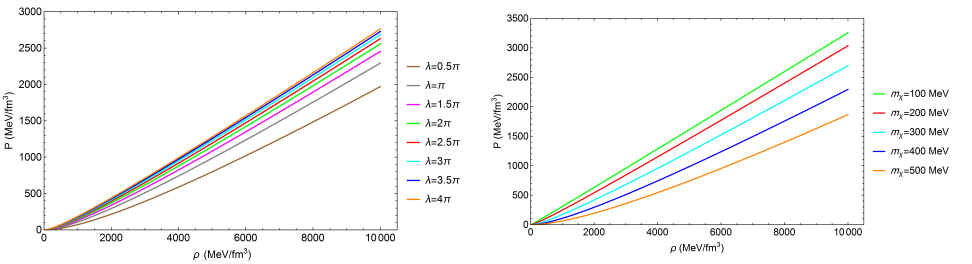

Fig. 1. Pressure as a function of density for bosonic matter obtained for $\lambda = \pi$ and various DM masses as labeled (right); for $m_\chi = 400$ MeV and different values of coupling constant (left).

Fig. 1 shows pressure of bosonic matter as a function of density for different masses and coupling constants as labeled. As it is shown in Fig. 1, (right panel) the pressure decreases with increasing of boson masses and (left panel) the pressure rises with the enhancement of the coupling constant or equivalently increasing the repulsive force between bosons.

In different density limits one can approximate Eq. (2) in a typical polytrope form $P = K\rho^\gamma$, where polytropic index at low density $\gamma \simeq 2$ and it smoothly reaches to $\gamma \simeq 1$ at high density. At low density regime, the bosonic DM EoS, Eq. (2), is reduced to

$$P \approx \frac{\lambda}{4m_\chi^4}\rho^2 . \tag{4}$$

However, for high density regime or correspondingly for very light bosons or high coupling constant, Eq. (2) reaches to radiation EoS with $P \approx \rho/3$. Similar equation to Eq. (4) has been obtained so far for a dilute self-interacting boson gas in a self-gravitating system (BS) known as Gross-Pitaevskii-Poisson (G.P.P) equation.[70,72,73] In fact, the G.P.P equation describes the BEC phase in a dilute

gas where only two-body mean field interaction is considered near zero temperature.[74–76]

In Fig. 2, we present the M-R diagrams of BSs obtained by solving TOV equation for Eq. (2). As it is indicated in the right panel, by decreasing the boson mass, the maximum gravitational mass of BSs increases and even goes above $2M_{\odot}$[62,77,78] and the corresponding radius goes well above typical NS radius. In the left panel, it is shown that higher self-coupling constant at fixed mass $m_{\chi} = 400$ MeV leads to higher maximum masses of BSs. Both the decreasing of boson mass and increasing of the coupling constant cause an enhancement in pressure of the system and consequently the rise of the maximum mass.

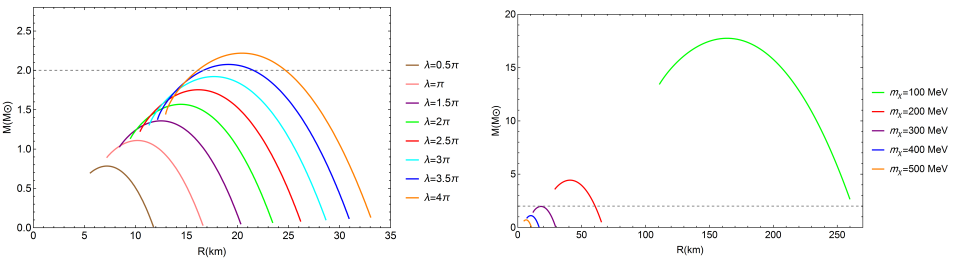

Fig. 2. M-R profile for BSs based on Eq. (2), (right panel) for the fixed value of coupling constant $\lambda = \pi$ and different boson masses. (Left panel) Calculations are made for fixed boson mass $m_{\chi} = 400$ MeV and different values of coupling constant as labeled at the figure. The gray dashed line shows the $2M_{\odot}$ limit.

Moreover, the variation of compactness $\mathcal{C} = M/R$ with respect to mass of BSs for different values of m_{χ} and λ is presented in Fig. 3. It shows the same dimensionless maximum compactness $\mathcal{C}_{(max)} \simeq 0.16$ for all cases. We see that the maximum compactness of a BS based on Eq. (2) is independent of free parameters of the model, namely m_{χ} and λ and for all the parameter space is well below the black hole formation limit $\mathcal{C} = 0.5$.[46,79]

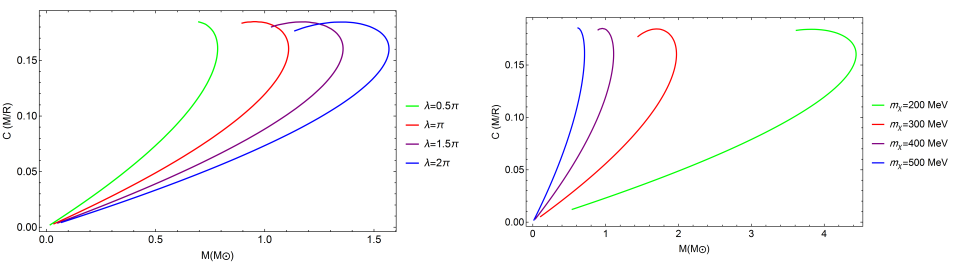

Fig. 3. Compactness of BSs as a function of their mass obtained for a fixed coupling constant $\lambda = \pi$ and different values of boson mass (right); fixed particle's mass $m_{\chi} = 400$ MeV and various λ values (left).

2.2. *Neutron Star*

For the baryon component (NS matter), we use the unified EoS with induced surface tension (IST) where both the short-range repulsion and long-range attraction between baryons have been taken into account.[49,50] The IST EoS reproduces the nuclear matter properties,[80] fulfills the proton flow constraint,[81] provides a high-quality description of hadron multiplicities created during the nuclear-nuclear collision experiments[82] as well as the matter inside compact stars.[48–50] The EoS is in a very good agreement with latest NS observations providing the maximum mass $M_{max} = 2.08 M_\odot$ and radius of the $1.4 M_\odot$ star equals to $R_{1.4} = 11.37$ km.[83] In our work the crust part of the NS's EoS is described via the polytropic EoS with $\gamma = 4/3$.[4] In Fig. 4, the change of pressure for a same density regime is plotted for BM and DM EoSs (left panel) and we show the M-R profiles of the NS and BS based on our considered EoSs (right panel).

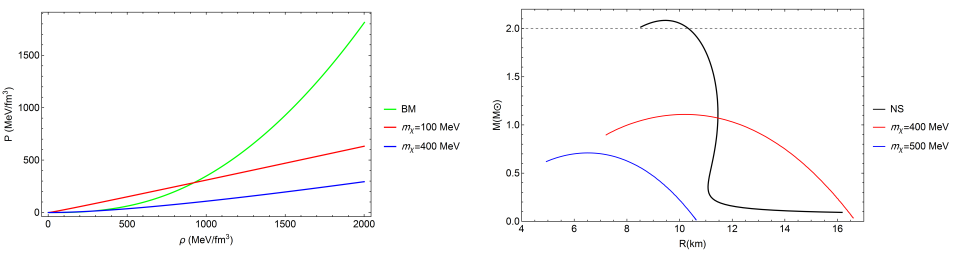

Fig. 4. Comparing BM and DM EoSs, left panel shows pressure vs. energy density for two different values of boson mass and $\lambda = \pi$. Right panel indicates M-R profiles for the NSs and BSs, considering $m_\chi = 400, 500$ MeV and the same coupling constant.

3. Two-fluid TOV equations and maximum mass

In order to study compact objects formed by the admixture of BM and DM that interact only through gravity, we use two-fluid TOV formalism[15,16] shown by Eqs. (5-6). Here $p = p_B + p_D$ and $M = M_T = \int_0^r 4\pi r^2 \epsilon_B(r) dr + \int_0^r 4\pi r^2 \epsilon_D(r) dr$. It can be seen that the total pressure and mass of the object have two contributions from BM and DM fluids shown by B and D indices. In order to solve two-fluid TOV equations

$$\frac{dp_{\rm B}}{dr} = -\left(p_{\rm B} + \epsilon_{\rm B}\right) \frac{M + 4\pi r^3 p}{r(r - 2M)}\,, \tag{5}$$

$$\frac{dp_{\rm D}}{dr} = -\left(p_{\rm D} + \epsilon_{\rm D}\right) \frac{M + 4\pi r^3 p}{r(r - 2M)}, \tag{6}$$

two central conditions related to both of the fluids have to be considered. By fixing two central pressures (p_B and p_D) together with the initial conditions at the center

of the star ($M_B(r \simeq 0) = M_D(r \simeq 0) \simeq 0$) the Eqs. (5-6) are numerically integrated up to the radius at which the pressure of one of the components vanishes. In principle this radius can be realized as DM radius R_D or BM radius R_B. In the former case the DM distributed only inside the core while BM extends to larger radius ($R_B > R_D$), then we set $p_D(r > R_D) = 0$ and continue the numerical integration to reach the visible radius of the star where $p_B(R_B) = 0$. When we have a BM core, DM can exist as an extended halo around the core with $R_D > R_B$, where $p_B(r > R_B) = 0$. It should be mentioned that for both DM core and DM halo cases, the core of the object is a mixture of DM and BM. Based on our extensive analysis there is another possibility of DM admixed NSs' configurations for which $R_B \approx R_D$ and DM distributed within the entire NS (see Fig. 5).

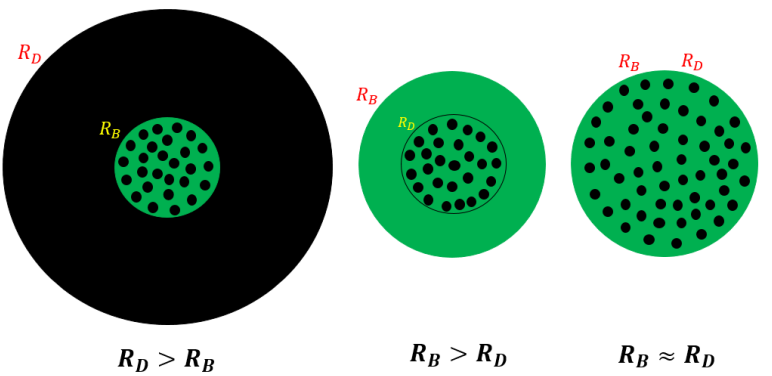

Fig. 5. Three possible configurations of a DM admixed NS, (left) DM halo, (middle) DM core and (right) DM is distributed in a whole NS. Note that for the DM core and halo cases the core of the object is a mixture of BM and DM. Green and black colors denote BM and DM, respectively.

For all of the possible DM admixed NSs' structures, the total gravitational mass of the mixed object is

$$M_T = M_B(R_B) + M_D(R_D). \tag{7}$$

However, the observable radius of the star is still defined by R_B, this is due to the visibility of R_B compare to R_D and technical difficulties of indirect detection of dark radius R_D. Furthermore, the DM fraction that determines the amount of DM in a DM admixed NS is defined as

$$F_\chi = \frac{M_D(R_D)}{M_T}. \tag{8}$$

Hereafter an effect of DM on NS properties is studied for m_χ of about hundreds MeV and and fixed coupling constant $\lambda = \pi$. Fig. 6 shows energy density profiles for a DM admixed NS where the BM (dashed red curves) and DM (solid red curves)

components are plotted separately. The energy density profiles for pure BM and DM stars are presented by solid black and green curves, respectively. Here we consider $\lambda = \pi$ and $F_\chi = 20\%$, while the central values of pressure for BM and DM components are chosen in such a way that a desired DM fraction F_χ has been obtained.

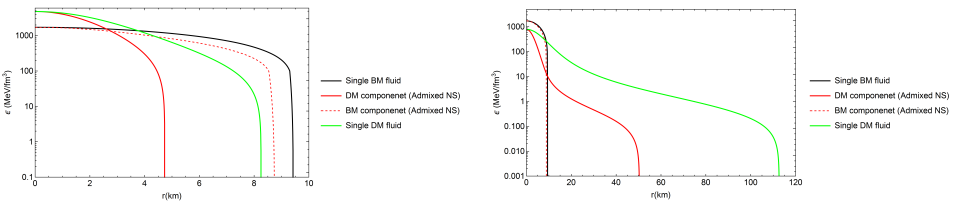

Fig. 6. Energy density profiles for pure BM and DM stars (black and green curves) shown together with the slitted DM and BM components of a DM admixed NS (solid and dashed red curves). Left panel corresponds to a DM core formation, while the right one to a DM halo, for $m_\chi = 400$ MeV and $m_\chi = 100$ MeV, respectively. For both of the cases, coupling constant is fixed at $\lambda = \pi$ and $F_\chi = 20\%$.

On the left panel which is obtained for $m_\chi = 400$ MeV, a DM core with $R_D \approx 5$ km is embedded in a BM structure with a larger radius. On the right panel, we fixed DM mass to $m_\chi = 100$ MeV which leads to the formation of a DM halo around the BM fluid with much larger radius. Interestingly, we see that for both DM core and DM halo formations, a reduction occurs in the energy density and the radius of DM and BM fluids in the mixed object compare to pure BM/DM star. This effect is much larger for the DM component and shows that the properties of the single DM fluid have significant effects in the admixed NS and in fact underly their features.

By comparing the left and right panels of Fig. 6, we see a transition from DM core to DM halo by changing m_χ from 400 MeV to 100 MeV. Therefore, by a thorough analysis of an effect of model parameters, as a general behaviour, we can conclude that light DM particles with $m_\chi < 200$ MeV, for low DM fractions, tend to form a halo around a NS, while heavier ones would mainly create a DM core inside a compact star (for more detailed analysis see[68]).

The M-R profiles for DM admixed NSs are shown in Fig. 7 in which $M = M_B + M_D$. Here R is the outermost radius of the star which is determined by R_B for the DM core and R_D for the DM halo. The solid black curve shows the M-R relation for the BM fluid (without DM), the gray dashed line indicates the $2M_\odot$ constraint on maximum mass of NSs and the shaded regions colored in magenta and cyan denote the causality and GR limits, respectively.

As it is shown in Fig. 7, two different boson masses, 100 MeV and 400 MeV lead to a DM halo and a DM core formations, respectively. In the left panel ($m_\chi = 400$ MeV), it is indicated that DM core formation causes a decrease of the maximum

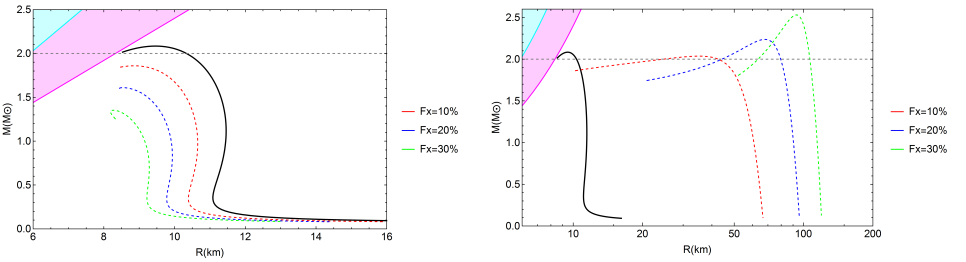

Fig. 7. Mass-Radius profiles for DM admixed NSs for $m_\chi = 400$ MeV (left) which corresponds to a DM core formation and $m_\chi = 100$ MeV (right) that represents an extended DM halo formation around a NS. Coupling constant is fixed to $\lambda = \pi$ and different F_χ are considered as labeled.

mass well below the $2M_\odot$ constraint,[62,77,78] and also a reduction of the corresponding radius. However, for $m_\chi = 100$ MeV (see the right panel in Fig. 7) for which a DM halo is formed around a NS, both maximum mass and radius are increased. Regarding the radius of the object for DM halo formation, it is increased significantly since is determined by R_D. It is seen that higher DM fractions enhance both of the above behaviours for DM core/halo structures. Note that for the cases in which a DM halo is formed ($R_D > R_B$), the visible radius of the star remains to be R_B.

To summarize, we see here that an effect of bosonic DM with repulsive self-interaction onto NSs is in agreement with previous studies which considered different DM models. Thus, an existence of a DM core decreases the maximum star's mass and the corresponding radius, while the formation of a DM halo increases these quantities.[2–4,30] In this regard, the most massive NS observed by NICER,[62] PSR J0740+6620 ($M_{max} \simeq 2M_\odot$) is compatible with the DM admixed NS scenario.

4. Tidal deformability of a DM admixed NS

GW signal from NS-NS mergers introduce tidal deformability as a new observable quantity to probe the internal structure of NSs and constrain their macroscopic features.[84–87] In this section, we analyse an impact of self-interacting bosonic DM on the tidal deformability of a DM admixed NS.

The idea of tidal deformability was first proposed by Tanja Hinderer in 2008[88,89] which comes from the fact that in a binary system of NSs both of the objects are deformed owing to the imposed tidal forces.[90–92] The tidal deformability expresses the ability of the gravitational field to change the quadrupole structure of a NS which alter the rotational phase of the binary system. Therefore, the GW signal is influenced during the inspiral phase due to the deformation effects of NSs when the binary orbital radius becomes comparable to the radius of NS. In fact, taking tidal deformability into account produces a phase shift in GW signal and accelerates the inspiral which leads to an earlier merging.[37,85,93]

The induced quadrupole moment Q_{ij} of a NS due to the external tidal field of its companion $\mathcal{E}_{ij}$ can be parameterized as follows[88,90]

$$Q_{ij} = \lambda_t \mathcal{E}_{ij} \,, \tag{9}$$

where λ_t is the tidal deformability parameter and can be defined based on k_2, the tidal love number, which is calculated from the system of equations including the TOV one. As is evident, k_2 and the tidal deformability strongly depend on the star's EoS.[88–90]

$$\lambda_t = \frac{2}{3} k_2 R^5 \tag{10}$$

Unlike λ_t which has dimension, dimensionless tidal deformability Λ can be defined as,

$$\Lambda = \frac{\lambda_t}{M^5} = \frac{2}{3} k_2 \left(\frac{R}{M}\right)^5 . \tag{11}$$

where R and M are the radius and mass of the compact star. It should be mentioned that R in a DM admixed NS is the outermost radius of the object which for a DM halo $R = R_D$ and for a DM core $R = R_B$. As an observational constraint on the tidal deformability, we take $\Lambda_{1.4} = 190^{+390}_{-120}$ reported by[64] for $M = 1.4 M\odot$ in the case of GW170817.

In the following, we investigate the effect of self-interacting bosonic DM, as a DM core or a DM halo, on the tidal deformability Λ of a mixed object at various m_χ and F_χ. In Figs. 8 and 9 the variation of Λ is shown in terms of total mass and radius of DM admixed NSs. In these figures the gray horizontal dashed lines indicate the LIGO/Virgo upper bound $\Lambda_{1.4} = 580$,[64] the gray solid vertical lines show $M_T = 1.4 M_\odot$ and the colored dashed and solid vertical lines stand for $R_{1.4}$ radius for the corresponding model parameters. The tidal deformability calculated for the pure baryonic EoS is denoted by the solid black curve and its $\Lambda_{1.4}$ value is about 285 which is well below the LIGO/Virgo constraint.

As a general behaviour in these plots, it can be seen that tidal deformability is a decreasing function of total mass and rises by increasing the radius which is related to the definition of this parameter as a function of R/M through Eq. (11). It follows from the M-R profile of a combined system NS+DM, that approaching the maximum mass of the equilibrium sequence decreases the stellar radius and, consequently, R/M. In other words the lowest value of Λ corresponds to the maximum mass and minimum radius of the DM admixed NS.

The effect of variation of Λ caused by changing the DM mass at fixed coupling constant $\lambda = \pi$ and DM fraction $F_\chi = 10\%$ is shown on Fig. 8. It is seen that for low DM masses $m_\chi = 100, 120, 150$ MeV, leading to formation of the DM halo, $\Lambda_{1.4}$ is higher than in the cases of higher m_χ and purely baryonic NS. Indeed, the corresponding $R_{1.4}$ significantly exceeds the values obtained for purely baryonic NS. For $m_\chi = 300, 400, 500$ MeV, however, the situation is different. Formation of the

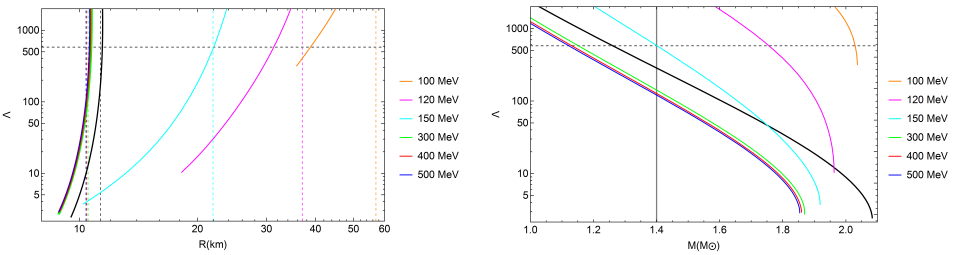

Fig. 8. Tidal deformability (Λ) in terms of total mass (right) and outermost radius (left) for stable sequences of DM admixed NSs. Various boson masses are considered, $m_\chi = 100, 120, 150$ MeV correspond to a DM halo formation while for $m_\chi = 300, 400, 500$ MeV a DM core is formed inside NS. Coupling constant and DM fraction are fixed at π and 10%, respectively.

DM core reduces the corresponding tidal polarizability, for which the $\Lambda - R$ curves are very similar to purely baryonic case. Regarding Fig. 8, we can conclude that DM halo yields large $\Lambda_{1.4}$, which even can exceed the observational constraint, while the DM core lowers Λ making it consistent with $\Lambda_{1.4} \leq 580$. This is related to the effect, which was mentioned in the previous section. Namely, DM halo increases the mass and radius of DM admixed NSs while DM core decreases these quantities. It is worth mentioning that GW observations during the inspiral phase of NS-NS coalescence correspond to lower frequencies detectable by Ad. LIGO. At this regime typical interstellar separation is $r < 150$ km. In order to prevent the technical difficulties caused by the overlap of DM halos we restrict their radii as $R_D \leq 75$ km.[2,3]

To give more insight, Fig. 9 shows modification of tidal polarizability due to variation of the DM fraction from 5% to 15% calculated at fixed $\lambda = \pi$ and $m_\chi = 100, 400$ MeV, corresponding to DM halo and DM core, respectively. As it is seen, higher F_χ increases $\Lambda_{1.4}$ and $R_{1.4}$ at $m_\chi = 100$ MeV and decreases theses parameters at $m_\chi = 400$ MeV. Remarkably, for $m_\chi = 100$ MeV (solid lines) tidal polarizability of the $M = 1.4 M\odot$ star exceeds 580 even at $F_\chi = 5\%$ since in this case Λ is more sensitive to DM fraction than at $m_\chi = 400$ MeV. Despite at this later case depicted by the dashed lines $\Lambda_{1.4}$ is in agreement with the upper observational constraint, the reduction of tidal deformability and $R_{1.4}$ should be consistent with the lower observational limits $\Lambda_{1.4} \gtrsim 70$ and $R_{1.4} \gtrsim 11$ km.[64,94–97]

As the final remark of this section, in Fig. 10, we show the effect of increasing and decreasing tidal deformability in a NS with DM halo/core and purely baryonic one. It was explained in the beginning of this section that tidal deformability parameter shows how much the compact object is deformed due to the gravitational potential of its companion. Thus in this illustration, we see that DM admixed NS with a DM halo can be more deformed since it has higher values of Λ compared to purely baryonic NS and the DM admixed one with the DM core. In addition, considering tidal love number k_2 we note that mixed compact objects with stiffer EoS are more deformable due to the DM halo compared to the ones with softer EoS producing the DM core.

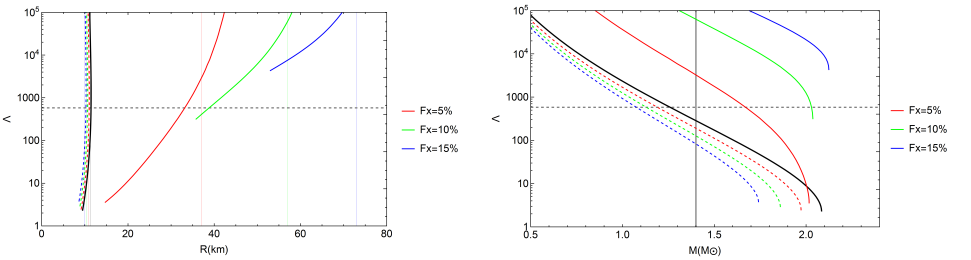

Fig. 9. Tidal deformability (Λ) in terms of total mass (right) and outermost radius (left) for stable sequences of DM admixed NSs. Two boson masses are considered, $m_\chi = 100$ MeV (solid lines) and $m_\chi = 400$ MeV (dashed lines) which correspond to DM halo and DM core formations, respectively. Various DM fractions are considered as labeled.

In summary, we note that in full agreement with the previous studies[2,3] DM halo increases tidal deformability, while DM core decreases it. Meanwhile, upper constraint on tidal deformability, $\Lambda_{1.4} = 580$, related to GW170817 event,[64] has been considered.

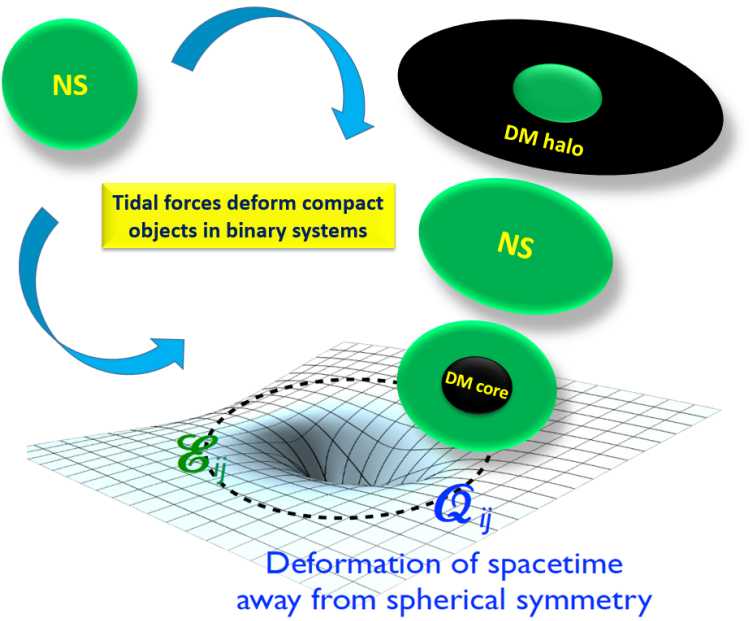

Fig. 10. The effect of increasing and decreasing of tidal deformability on DM admixed NS's deformation is compared with the pure BM object (NS). It is shown that higher value of Λ indicates more deformation in the compact object, therefore a DM halo deforms more in comparison with a pure NS and DM admixed NS with a DM core.

5. Conclusion and Outlook

Treating DM as a self-repulsing complex scalar field, various properties of single fluid BSs and two-fluid NSs has been studied within the TOV formalism. It is shown that for $\lambda = \pi$, light DM particles ($m_\chi \lesssim 200$ MeV) form BSs with much larger maximum mass and radius compared with typical NSs, while heavy DM particles lead to formation of BSs with much smaller radius and mass. Furthermore, we showed that for low DM fractions ($F_\chi < 20\%$), light bosons create a halo around the DM admixed NSs, while heavier DM particles form a DM core inside the BM component.

The effect of bosonic DM as a halo/core has been examined by considering the maximum mass, radius and tidal deformability of a DM admixed NS. We have indicated that DM halo formation causes an increase in the aforementioned observable quantities while a DM core reduces all of them. Considering various m_χ and F_χ, the maximum mass and tidal deformability of the mixed object has been compared to the latest upper observational bounds, $M_{max} = 2M\odot$ and $\Lambda_{1.4} \leq 580$ inferred from NICER (PSR J0740+6620) and LIGO/Virgo (GW170817) detections.

Regarding the impact of DM halo and DM core formations on NS's observable parameters and applying the observational limits for NSs' features, one could constrain the parameter space of DM model such as mass and coupling constant and also the amount of DM inside the compact object. In this regard, an extensive investigation has been done recently in[68] by the same authors of the present paper in which a constraint has been imposed on F_χ for sub-GeV DM particles by taking M_{max} and $\Lambda_{1.4}$ bounds. Moreover, as DM core decreases the visible radius of the DM admixed NS (R_B) and DM halo increases the invisible dark radius of the object (R_D), radius constraint for typical NSs ($M \approx 1.4M\odot$) and most massive ones ($M \approx 2M\odot$)[62,96,97] could be utilized to impose more stringent limits on DM parameter space and its fraction. In addition, any unusual observational results of NSs' properties could be explained by the DM admixed NS model. For instance, there are many effort among the community to explain the nature of the secondary compact object in the GW190814[98] event with the mass about $2.6M\odot$ being higher than the maximum NS one. There are some works explaining the mass of this strange object by the DM core or halo formation within the DM admixed NS scenario.[52,99,100] Regarding our model, as an example, $m_\chi = 50$ MeV, $\lambda = \pi$ and $F_\chi \approx 20\%$ lead to formation of a DM admixed NS with $M_T = 2.6M\odot$ and detectable radius about 10 km. As a final remark, upcoming modern facilities such as X-ray (NICER,[101] ATHENA,[102] eXTP[103] and STROBE-X[104]) and radio (MeerKAT,[105] ngVLA[106] and SKA[107]) telescopes, as well as GW (LIGO/Virgo/KAGRA[108] and Einstein[109,110]) detectors, shown in Fig. 11, would provide vast numbers of promising results for NSs' features bringing us to a golden age of NS investigations and consequently could help us to shed light on the nature of DM and its possible existence in compact objects.

Fig. 11. Applying various innovative telescopes covering all kinds of observations from GW and X-ray to radio waves provide a unique opportunity for compact objects' research which may solve the puzzle of DM.

With recent observations of gravitational wave signals from binary neutron star mergers (BNSM) by LIGO-Virgo-KAGRA (LVK) Collaboration and NICER, the nuclear equation of state (EoS) is becoming increasingly testable by analysis with numerical simulations. Numerous simulations currently exist exploring the EoS at different density regimes for the constituent neutron stars. In this paper we summarize the GR three-dimensional hydrodynamics based simulations of BNSMs for EoSs with a specific emphasis on quark matter EoS at the highest densities.

Keywords: Neutron star binaries; Gravitational waves; Nuclear equation of state.

1. Introduction

Neutron stars are an ideal laboratory in which to probe the properties of matter at very high density. The microphysics of nuclear interactions in a neutron star reflects in its large structural features like its mass and radius. This results in modulation of the evolution of their binaries. This amplification of subatomic physics makes probing the physics at scales 10^{-14} m plausible at neutron star size 10^4 m scales. In particular, neutron star binary systems provide a means to analyze the pressure of nuclear matter at all domains of nuclear densities. Indeed, the first detection of gravitational waves from the binary neutron star merger GW170817 by the LIGO-Virgo Collaboration and the pulsar PSR J0740 by NICER has provided fundamental new insights into the nature of dense neutron-star matter.[1,2] The detected gravitational wave signal depends upon the tidal distortion of the neutron stars as they approach merger. For example, in the LIGO analysis[1,3] the tidal polarizability[4,5] was deduced from post-Newtonian dynamics implying that the radius of the stars of 1.4 $M_\odot$ is in the range 10.5 km $\leq R \leq$ 13.3 km. This has placed tight constrains on the equation of state (EoS) for nuclear matter as the stars approach merger.

Here we summarize the work done in the regime of quantum chromodynamics (QCD) formed during the merged neutron star binaries. The detection of the gravitational radiation during the postmerger could be used as a sensitive probe of both the order of the quark-hadron phase transition and the properties of matter in the non-perturbative regime of QCD.

The prospect of the postmerger evolution being used to explore EoS issues has been proposed for some time.[6] Indeed, there have been several investigations into the effects of the formation of quark matter in the BNSM.[7–10] For the most part these

studies have considered effects of a first-order phase transition and the formation of a mixed quark-hadron phase. In this case the first-order transition can soften the EoS and hasten the formation of the black hole.

The neutron star-ringdown occurs in a frequency range 2-5 kHz and thus the strain strength for a binary at 50 Mpc is not easily accessible to aLIGO/aVirgo/KAGRA. However, the third generation GW observatories, the Einstein Telescope and the Cosmic Explorer, will have enhanced sensitivities in this frequency range and will be susceptible to observing postmerger evolution of a BNSM. Further, there is a suggestion in the literature (see Refs. 11, 12) of post merger energy output in gravitational radiation from the GW170817 event that appears to be an extended ringdown (see however Ref. [13].) In Ref. [12] it was hypothesized that such extended emission might result from spin down of a magnetar.

2. Equation of state

To describe the evolution of matter completely, the hydrodynamics equations require an additional constraint that relates the various state variables of the matter, i.e. pressure, density, electron fraction, chemical potentials, etc. in a neutron star.[14,15] Constraints on the equation of state (EoS) have been placed by aLIGO based upon the tidal polarizability deduced from the chirp associated with event GW170817.[1,3] Any realistic description of the equation of state (EoS) of matter formed in the merger of neutron stars must also include the consequences of a transition between hadronic matter and quark matter. As the merged system collapses to a black hole it unavoidably encounters all dense phases of matter, particularly the transition to quark matter.

It is worth noting that as the baryon density and chemical potential increase the QCD strong coupling constant α_s approaches unity and a nonperturbative approach to QCD is imperative. In particular, There is rich physics in this region of the quark-matter phase diagram including the generation of constituent quark masses, due to chiral symmetry breaking,[16] and quark pairing leading to color superconductivity.[17] The evolution of these effects until the asymptotic regime must be described during the collapse.

The transition from hadronic matter to quark matter is not yet fully understood.[18] However, people have proposed many interesting models to describe the transition from hadronic matter to quark matter at densities between 2-5 ρ_{nuc}.[19,20] Considering strongly interacting quark states for the crossover density region, people could have made the EoSs satisfying 2 times solar mass observational bound.[21] Also, many models having the first order phase transition features have been proposed to describe the transition.

3. Power spectral density of the gravitational waves

In addition to f_{max} which could be obtained from the instantaneous change of the phase of h, the power spectral density (PSD) of the strain, h, poses to reveal further

features about the star's EoS. Refs. [22, 10] shows the presence of high frequency spectral features in the f_1, f_2 and f_3, as defined in Ref. [22] modes for binaries with different EoS description. The positioning and strength of the frequencies depends on the nature of the EoS. One of the important aspects about the power spectra of the mergers is that the strength of the PSD at 2 kHz to 5 kHz frequencies is weak enough that the current LVK detectors are unable to discern them from the noise. It is also pointed out that the third generation gravitational wave interferometers, the Einstein Telescope and the Cosmic Explorer, would have higher sensitivities at these frequencies making them more likely to resolve the f-modes. Further, Ref. [22] notes the occurrence of 'quasiuniversal' relations relating f-modes with compactness and the maximum frequency of chirp with tidal deformability of a single stable NS for the given EoS. These relations can be explained partially by the stiffness of the equation of state, softer EoSs leading to higher f-modes. Recent studies of the BNSM with the phase transtion have examined whether the features of the phase transition could be imprinted in the f-mode frequencies, for example, the shift of the peak frequencies.[8,23] We are currently investigating the spectral features of the BNSM with a specific crossover EoS and have found some interesting postmerger behaviour showing elongated duration owning to the stiffened EoS.[18,19,24]

4. Conclusion

We have briefly summarized some recent studies on the BNSM with quark matter. An observation of the postmerger and the collapse in a BNSM could be used to determine the nature of the phase transition and the physics at the crossover densities. The next generation GW detectors will probe and unveil the physics of this dense matter physics with their highly improved power of detectabilities at higher GW frequencies.

Finally, noting a caveat that there have been no studies fully considering such as MHD and neutrino transport for the simulations, however, we expect that essential features of the non-perturbative characters of the QCD would be revealed and confirmed without taking these considerations into account.

Recent observational data on transiently-accreting neutron stars has unequivocally shown fast-cooling sources, such as in the case of neutron star MXB 1659-29. Previous calculations have estimated its total neutrino luminosity and heat capacity, as well as suggested that direct Urca reactions take place in 1% of the volume of the core. In this paper, we reproduce the inferred luminosity of this source with detailed models of equations of state (EOS) and nuclear pairing gaps. We show that three superfluidity gap models are inconsistent with data for all EOS and another three are disfavoured because of fine tuning arguments. We also calculate the total heat capacity for all constructed stars and show that independent observations of mass and luminosity could set constraints on the core superfluidity of a source as well as the density slope of the symmetry energy, (L). This is an important step towards defining a universal equation of state for neutron stars and therefore, towards a better understanding of the phase diagram of asymmetric matter at high densities.

Keywords: Symmetry energy; neutron star composition; direct Urca; transiently-accreting neutron stars

1. Introduction

The composition of the core of neutron stars is still unknown. Their extreme densities make it impossible for similar conditions to be reproduced experimentally in laboratories, and their strongly-coupled hadronic nature represents a serious challenge for first-principles calculations. Therefore, there is a lot of uncertainty when it comes to the particle content and matter organization in neutron star cores. Even in the simplest model of neutron stars made only of neutrons, protons, electrons and muons, there is no agreement on the star's proton fraction – which determines electron and muon fractions, by the charge neutrality requirement – or how to describe proton superconductivity and neutron superfluidity, both expected to happen in matter at high densities.[1] The proton fraction is important because it determines whether neutrino cooling occurs via modified Urca or direct Urca reactions, which differ by orders of magnitude in emissivity.

Although BCS theory with polarization corrections [2,3] can describe superfluidity and superconductivity in a low density medium, at high densities, in-medium effects

prevent an accurate description of neutron and proton pairing. This uncertainty forbids a precise determination of the critical temperatures as a function of density, that is, the gap amplitude and width of the pairing gap in neutron star cores. Nonetheless, a wide range of theoretical calculations of superfluidity at high densities exist, which have been summarized in the functional analytic form in Ref. 4. Its parameters mimic the effect of in-medium interactions, and thus define a range of possible models for nucleon pairing at high densities, each one with their specific amplitudes and widths.

These different gap models will predict different stellar cooling rates, as shown in Ref. 4, because both superfluidity and superconductivity suppress neutrino production through direct or modified Urca reactions.[5] Furthermore, Cooper pair formation produces pair-breaking-formation (PBF) cooling reactions, which enhance the star's cooling when its temperature is close to the superfluid critical temperature.[5] The suppression or enhancement of neutrino emission due to superfluidity depends on density, and therefore location within the neutron star core. By comparing these predictions with the star's observed luminosity, one can exclude or favor specific gap models.

Transiently-accreting neutron stars are ideal systems to perform these observations. These stars periodically accrete matter from a companion star, in cycles of accretion outbursts followed by periods of quiescence, in which accretion halts.[6,7] By observing X-ray emissions after the accretion period, the surface temperature of the star can be found. Combining that information with the mass accretion rate, one can obtain a consistent estimate of the star's neutrino luminosity and determine whether fast cooling reactions (such as direct Urca) or slow cooling reactions (such as modified Urca) are taking place in the neutron star's core.[7]

The source MXB 1659-29 is particularly interesting because it has shown more than one accretion-quiescence cycle, which allows for repeated measurements of accretion rates during outburst, luminosity and temperature during quiescence. Analysis of the energy balance between accretion-driven crustal heating in outburst and neutrino cooling during quiescence leads to the conclusion that this source is undergoing fast cooling processes in its core.[7,8] Furthermore, it has been suggested in Ref. 8 that measuring the decrease of external temperature of the neutron star MXB 1659-29 over an interval of ten years, combined with the observation of its neutrino luminosity, could set constraints on its total heat capacity, and therefore on its composition. This analysis would represent another avenue for finding, for example, the relative contribution of leptons to the total heat capacity of a specific source based on direct observations, which could set further constraints on its superfluidity.

Other transiently accreting sources such as KS 1731-260 have inferred neutrino cooling luminosities inconsistent with fast cooling, implying that they have slow cooling processes operating in their cores.[9] To explain this data, one should consider a combination of equation of state (EOS) describing a star's particle content, and a collection of nuclear pairing gap models that accommodate both fast and slow

cooling processes. In this paper, we create detailed realistic scenarios for MXB 1659-29, to determine how the observed neutrino cooling rate of that source constrains the input physics. We use gap models described in Ref. 4, and a family of relativistic mean-field (RMF) EOS[10] based on FSUGold2, first described in Ref. 11. Their particularities are discussed in section 2. In section 3, we investigate the agreement of the calculated luminosities with data and we verify the suggestion made in Ref. 8 that direct Urca processes occur in approximately 1% of the volume of the star's core. Finally, in section 4, we discuss which gap models accurately describe this scenario and compute predictions for the neutron star heat capacity in each case.

2. Formalism

To determine the particle composition of the core of neutron stars, we use a family of equations of state (EOS) that are developed from the RMF model FSUGold2.[11] The original FSUGold2 model was created to reproduce the ground-state properties of finite nuclei such as binding energy and charge radii, their monopole response, and the maximum observed neutron star mass. In particular, the original model predicts both a stiff symmetry energy and a soft equation of state for symmetric nuclear matter, that is, matter with equal number of protons and neutrons. The symmetry energy is an essential ingredient of the EOS that strongly impacts the structure, dynamics, and composition of neutron stars and has received considerable attention over the last decade .[12,13] Customarily, one expands the total energy per nucleon $E(\rho,\alpha)$ at zero temperature—where $\rho=\rho_{\rm n}+\rho_{\rm p}$ is the total baryon density and $\alpha=(\rho_{\rm n}-\rho_{\rm p})/\rho$ is the neutron-proton asymmetry parameter—around the energy of isospin symmetric matter with $\alpha=0$,

$$E(\rho,\alpha)=E_{\rm SNM}(\rho)+E_{\rm sym}(\rho)\cdot\alpha^2+\mathcal{O}\left(\alpha^4\right) \tag{1}$$

where $E_{\rm SNM}(\rho)\equiv E(\rho,0)$ is the energy per nucleon in symmetric nuclear matter (SNM) and $E_{\rm sym}(\rho)$ the symmetry energy, which represents a correction of second order in parameter α, to the symmetric limit. No odd powers of α appear in the expansion above because the nuclear force is assumed to be isospin symmetric. To characterize the behavior of both $E_{\rm SNM}(\rho)$ and $E_{\rm sym}(\rho)$ near the nuclear saturation density $\rho_{\rm sat}\approx 0.15$ fm^{-3}, one can further expand these quantities in a Taylor series,[14]

$$E_{\rm SNM}(\rho)=B+\frac{1}{2}Kx^2+\cdots \tag{2}$$

$$E_{\rm sym}(\rho)=J+Lx+\frac{1}{2}K_{\rm sym}x^2+\cdots \tag{3}$$

where $x=(\rho-\rho_{\rm sat})/3\rho_{\rm sat}$ is a dimensionless parameter that quantifies the deviations of the density from its value at saturation, B is the energy per nucleon and K is the incompressibility coefficient of SNM. Similarly, J and $K_{\rm sym}$ represent the symmetry energy and the incompressibility coefficient of symmetry energy at saturation density and serve as corrections to the binding energy and incompressibility.

Unlike in SNM, whose pressure vanishes at saturation density, the slope of the symmetry energy L, and consequently, pressure of pure neutron matter, do not vanish at $\rho_{\rm sat}$.

Since L is poorly constrained experimentally, we generated a family of the FSUGold2 models that are identical in their predictions for the EOS of SNM but vary in their predictions for the symmetry energy. It is well known that, at a sub-saturation density of $\rho \approx 0.1$ fm^{-3}, which represents an average value between the central and surface densities, the symmetry energy is well constrained by the binding energy of heavy nuclei with a significant neutron excess.[15–17] By fixing this value of the symmetry energy, we obtain a family of models with differing (J, L) values that are identical in their predictions for the ground state properties of finite nuclei but predict a range of the neutron skin thicknesses and neutron star radii consistent with the current experimental and observational data.[18–22]

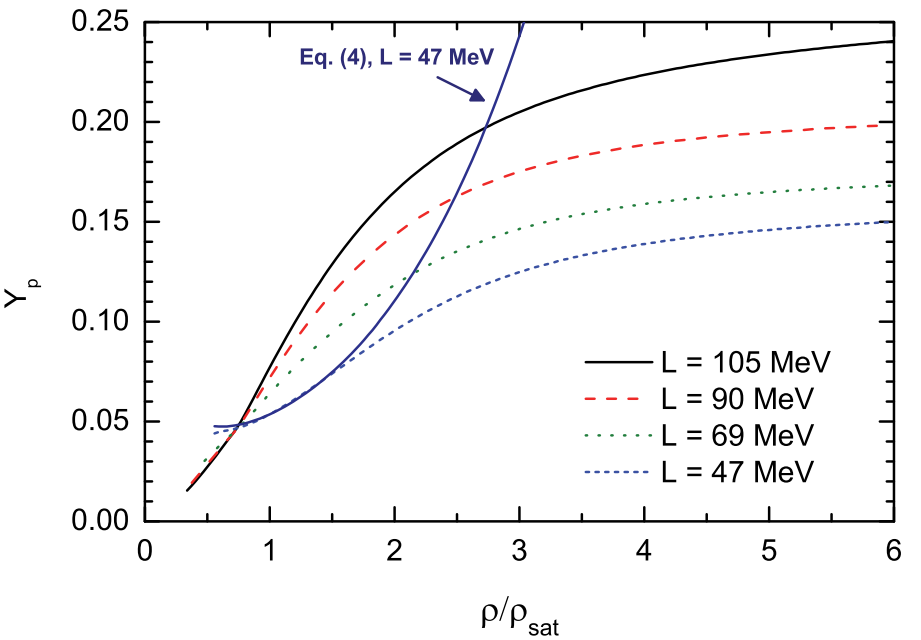

Fig. 1. Proton fraction $Y_{\rm p}$ versus baryon density ρ normalized by saturation density for EOS in the FSUGold2 family. Different curves correspond to EOS with different L values, in MeV. The blue solid curve shows the analytic approximation (Eq. 4).

Cold-catalyzed matter in neutron stars, ie. matter in the ground state with lowest energy per nucleon, is in a state of chemical equilibrium and is assumed to be electrically neutral. Therefore one must impose a charge neutrality and chemical equilibrium condition to obtain an EOS of neutron-star matter. We consider a

minimal model in which neutrons, protons, electrons and muons are present inside neutron stars. Increasing the parameter L leads to a larger symmetry energy at supersaturation densities. This in turn makes it difficult for protons to convert into neutrons and thus increases the proton fraction $Y_{\rm p} = \rho_{\rm p}/\rho$ in the innermost region of the star, as shown in Fig. 1. For matter composed of neutrons, protons and electrons, Ref. 23 shows this proportionality explicitly by writing the beta equilibrium condition as a function of the proton fraction, such that for low proton fraction,

$$Y_{\rm p} \simeq \frac{64}{3\pi^2\rho_{\rm sat}\,(3x+1)}\left(\frac{J+Lx+\frac{1}{2}K_{\rm sym}x^2}{\hbar c}\right)^3 . \tag{4}$$

As displayed in Fig. 1, this approximation is only valid up to about $1.5\rho_{\rm sat}$, where proton fractions are small. Here we used the predicted bulk parameters of symmetry energy at saturation density $\rho_{\rm sat} = 0.15$ fm^{-3}, $J = 30.6$ MeV, $L = 47.0$ MeV and $K_{\rm sym} = 54.0$ MeV to generate the blue solid curve in Fig. 1.

The outer crust is described by the EOS from Ref. 24, whereas the EOS for the inner crust is described in Ref. 25. For the core we use the FSUGold2 family of EOS with different values of the slope of the symmetry energy L. We assume a non-rotating spherically-symmetric neutron star, and solve the Tolman-Oppenheimer-Volkoff (TOV) equations

$$\frac{{\rm d}P}{{\rm d}r} = -\frac{\mathcal{E}(r)}{c^2}\frac{Gm(r)}{r^2}\left[1+\frac{P(r)}{\mathcal{E}(r)}\right]\left[1+\frac{4\pi r^3P(r)}{m(r)c^2}\right]\left[1-\frac{2Gm(r)}{c^2r}\right]^{-1} , \tag{5}$$

$$\frac{{\rm d}m}{{\rm d}r} = 4\pi r^2\frac{\mathcal{E}(r)}{c^2} , \tag{6}$$

$$\frac{{\rm d}\phi}{{\rm d}r} = -\frac{1}{\mathcal{E}(r)+P(r)}\frac{{\rm d}P}{{\rm d}r} \tag{7}$$

where $m(r)$ is the mass within radius r, $P(r)$ is the pressure, $\mathcal{E}(r)$ is the energy density and $\phi(r)$ is the gravitational potential such that at the surface of the star, $r = R$ and $m = M$, the pressure vanishes, $P(R) = 0$ and $\phi(R) = \frac{1}{2}\ln(1-2GM/c^2R)$.

Since our goal is to reproduce the inferred neutrino luminosity of MXB 1659-29, we consider the fast cooling process of direct Urca only. If there are no muons participating, direct Urca cooling takes place through the reactions

$$n \to p + e^- + \bar{\nu}_e, \quad p + e^- \to n + \nu_e. \tag{8}$$

This process conserves momentum only if

$$k_{Fn} \le k_{Fp} + k_{Fe}, \tag{9}$$

which implies that for direct Urca reactions the proton fraction must exceed a threshold value

$$Y_p \ge Y_{\rm p\,dUrca} = \frac{\left[\left(3\pi^2\hbar^3\rho Y_n\right)^{1/3} - \left(3\pi^2\hbar^3\rho_e\right)^{1/3}\right]^3}{3\pi^2\hbar^3\rho}, \tag{10}$$

as explained in Ref. 5. Here, $k_{\rm Fx}$ are the Fermi momenta, a function of ρ_x, the number density for each species and the particle fraction Y_x. If there are no muons in the star at all, Eq. (10) can be simplified because of the star's charge neutrality condition $\rho_p = \rho_e$, hence $Y_{\rm p\,dUrca} = 1/9 \approx 0.11$. However, for the EOS studied here, $Y_{\rm p\,dUrca} \neq 1/9$ because even when muons are not participating in direct Urca reactions, they are present, such that the charge neutrality condition becomes $\rho_p = \rho_e + \rho_\mu$, thus, for our set of EOS, we have $0.131 \leq Y_{\rm p\,dUrca} \leq 0.138$.

The direct Urca neutrino luminosity is given by

$$L_{\nu_{\rm dUrca}} = \int_0^{R_{\rm core}} \frac{4\pi r^2 \epsilon_0^{\rm dUrca\ total}}{\left(1-(2Gm(r)/c^2 r)\right)^{1/2}} dr, \tag{11}$$

where the integral is over the neutron star core, and the local neutrino emissivity is[5]

$$\epsilon_0^{\rm dUrca\ total} = \epsilon_0^{\rm dUrca\ e^-} + \epsilon_0^{\rm dUrca\ \mu^-} \tag{12}$$

$$\epsilon_0^{\rm dUrca\ e^-} = \frac{457\pi}{10080} G_{\rm F}^2 \cos^2\theta_{\rm C} \left(1+3g_{\rm A}^2\right) \frac{m_n^* m_{\rm p}^* m_e^*}{h^{10}c^3} \left(k_{\rm B}T\right)^6 \Theta_{\rm npe}, \tag{13}$$

where we used the weak coupling constant $G_{\rm F} = 1.43610^{-62}{\rm Jm}^3$, the Cabibbo angle $\theta_{\rm C} = 0.227$, the axial vector coupling constant $g_{\rm A} = -1.2601\left(1 - \frac{\rho}{4.15(\rho_0+\rho)}\right)$. $\rm M_x^*$ represents the effective mass of species x and $\Theta_{\rm npe}$ is a step function specifying the densities where direct Urca reactions can happen, respecting momentum conservation. Note that, in general, muons can participate in these reactions at high densities, so that

$$n \to p + \mu^- + \bar{\nu}_{\mu^-}, \quad p + \mu^- \to n + \nu_{\mu^-} \tag{14}$$

Their emissivities are

$$\epsilon_0^{\rm dUrca\ \mu^-} = \epsilon_0^{\rm dUrca\ e^-}. \tag{15}$$

Including superfluidity and superconductivity in the neutron star core model changes the neutrino luminosity calculations. The formation of Cooper pairs reduces the number of neutrons and/or protons available for participating in direct Urca reactions, therefore the rate $\epsilon^{\rm dUrca}$ is exponentially reduced, as described in Ref. 5, according to

$$\epsilon^{\rm dUrca} = \epsilon_0^{\rm dUrca} R \tag{16}$$

$$R = \exp\left(-v^*_{\rm triplet/singlet}\right) \tag{17}$$

$$\text{for } v^*_{\rm triplet} = 2.376\left(\rm T_c/T\right), \text{where } \rm T_c = 0.1187\Delta(k_{Fx}) \tag{18}$$

$$\text{and } v^*_{\rm singlet} = 1.764\left(\rm T_c/T\right), \text{where } \rm T_c = 0.5669\Delta(k_{Fx}). \tag{19}$$

Here T_c is the critical temperature, calculated according to each gap model parametrization, and T is the local temperature of the core, $T = \tilde{T}\exp(-\phi(r))$, where $\tilde{T}$ is the temperature of the isothermal core as seen at infinity. The heat

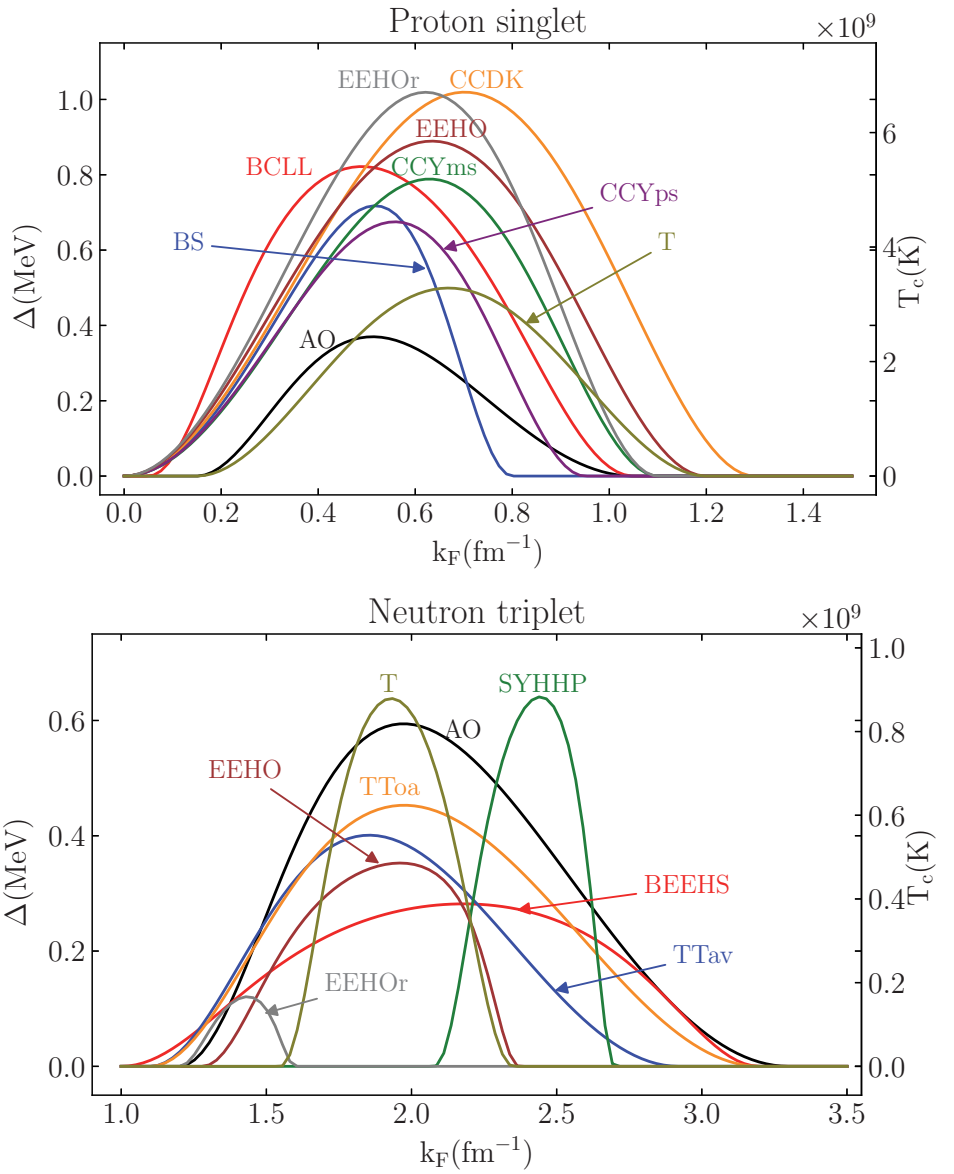

Fig. 2. Gap model parametrizations Δ (MeV) as a function of Fermi momenta k_F (fm^{-1}) for all models studied here (see Ref. 4 and references therein). (a) Proton singlet superconductivity (b) Neutron triplet superfluidity.

capacity of neutrons and protons is similarly reduced when they are superfluid or superconducting, $C_{p,n}^{\text{superfluid}} = C_{p,n}\ R$.

Equations (17)–(19) are simplifications of the results of full calculations, that find the proper quantum state rearrangements in the energy levels of the matter once

neutron and proton pairing are taken into account.[5] We acknowledge the difference in the reduction rates between the full calculation and the approximations (Eq. (17)–(19)), especially at $T \ll T_c$ and when superconductivity and superfluidity are simultaneously present in the star's core. This difference becomes large only well-below the critical temperature T_c, where the neutrinos are already suppressed, thus our results are not expected to change qualitatively. Results of full calculations will be explored in a forthcoming paper.

To characterize the different gap models, we work with the polynomial parametrizations for the superfluid gap[4]

$$\Delta\left(k_{\mathrm{Fx}}\right) = \Delta_0 \frac{\left(k_{\mathrm{Fx}} - k_0\right)^2}{\left(k_{\mathrm{Fx}} - k_0\right)^2 + k_1} \frac{\left(k_{\mathrm{Fx}} - k_2\right)^2}{\left(k_{\mathrm{Fx}} - k_2\right)^2 + k_3}, \tag{20}$$

where Δ_0, k_0, k_1, k_2 and k_3 are free parameters fitted to adjust the amplitudes and widths of each gap model. The resulting superfluid gaps are shown in Fig. 2 and their parameters can be found in Ref. 4.

3. Results

3.1. *Direct Urca cooling and the dependence on gap model*

We first calculated neutron star models without the effects of pairing, to determine when direct Urca reactions are kinematically allowed, as a function of the neutron star mass M and slope of the symmetry energy L. The direct Urca threshold for all EOS is shown in Fig. 3. All stars with masses above the $\mathrm{M_{dUrca}}$ curve can have part or the entirety of their core emitting neutrinos through direct Urca reactions. For low L EOS, only stars with large masses ($M \geq 1.8 M_\odot$) have a proton fraction large enough to allow direct Urca. On the right hand side of the plot, high L EOS, which have a larger proton fraction, can accommodate direct Urca reactions even for very low mass neutron stars ($M \leq 1.0 M_\odot$). Note that we include neutron stars with $M < 1.0 M_\odot$ to show the full parameter space, although it is not expected that such low mass neutron stars are formed in reality.

The range of parameter space in which direct Urca cooling can occur may change once we include superfluidity, as a consequence of the exponential suppression of direct Urca rates in the presence of Cooper pairs. Depending on the range of density over which superfluidity occurs, there can be different effects on the direct Urca parameter space. For example, shown in Fig. 4, the gap model NT_{T} predicts that for $L \geq 60\,\mathrm{MeV}$, part of the core of all neutron stars with masses $M \leq (1.7\text{–}1.8)\, M_\odot$ will be superfluid, thus reducing their total neutrino luminosity. Therefore, owing to the combination of the direct Urca threshold and the suppression by superfluidity, in this case only high mass stars $M \geq (1.7\text{–}1.8)\, M_\odot$ can significantly cool through direct Urca reactions, even for large values of L. In all figures where superfluidity gap models are taken into consideration, we also plot their closing curves, which are obtained by finding the densities for which the predicted gap model $T_c(\rho)$ matches

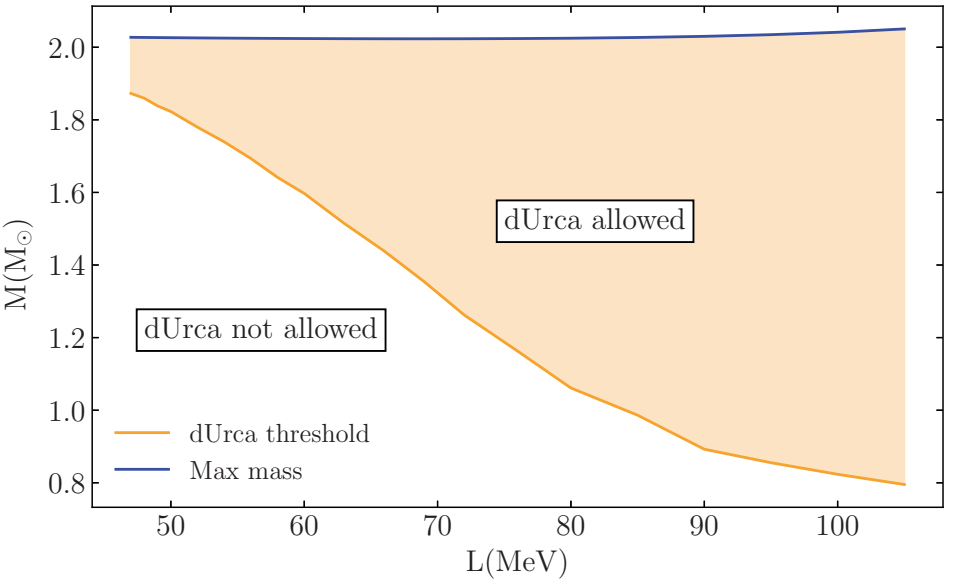

Fig. 3. Direct Urca threshold calculation (orange curve) for all EOS without nuclear pairing. The shaded area corresponds to the phase space where direct Urca reactions are allowed, the maximum mass reached for each EOS is also shown (blue curve).

the star's core temperature T, for $\tilde{T} = 2.5 \times 10^7$K, the inferred core temperature for MXB 1659-29.[8]

Another interesting situation is when there is a late opening of the superfluid gap, as in the case of $NT_{\rm SYHHP}$, Fig. 5. In this situation, for large L ($L \geq 70\,$MeV) and low mass stars ($M \leq 1.3M_\odot - 1.4M_\odot$), direct Urca reactions are allowed to happen because there is no superfluidity in the core yet. Cooper pair formation happens for larger mass stars or lower L, when direct Urca is suppressed, until there is no more superfluidity, that is, the gap closes, at higher masses. Therefore, direct Urca reactions are allowed again, close to maximum mass stars. In this situation, there are two regions of the phase diagram where direct Urca processes are significant: large L and low mass stars or very high mass stars ($M \approx 2.0M_\odot$) for all L.

There are also cases in which the superfluid part of the core is in a region where direct Urca reactions do not happen. Then, superfluidity does not change the calculations of neutrino luminosity shown in Fig. 3. This is the case for gap models $\rm NT_{EEHOr}$, $\rm PS_{BS}$ and $\rm PS_{CCYps}$. The last possible situation is represented by gap models $\rm NT_{AO}$, $\rm NT_{BEEHS}$ and $\rm NT_{TToa}$, which predict that the whole core of the neutron star is superfluid, severely suppressing direct Urca for all EOS and all masses.

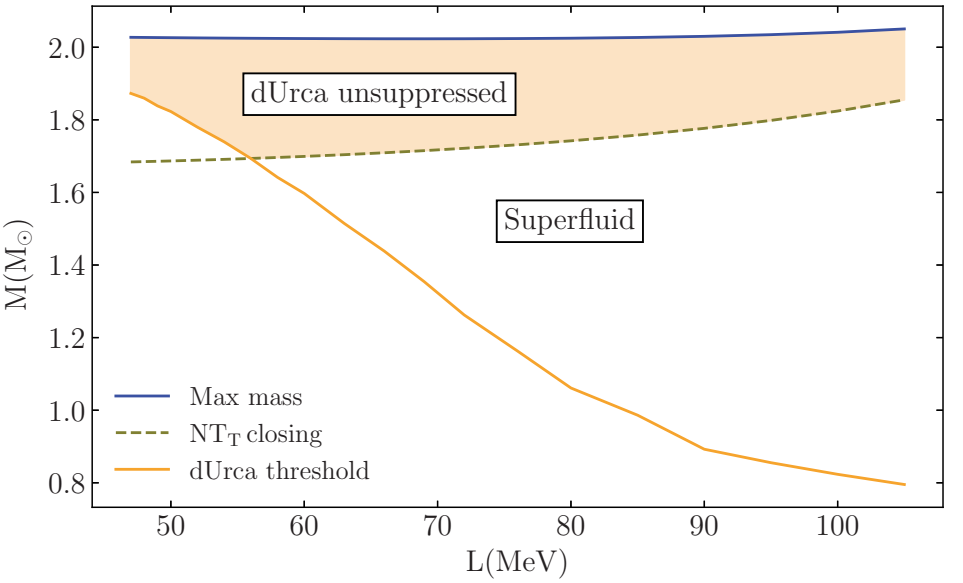

Fig. 4. Direct Urca threshold calculation (orange curve) and closing curve of superfluid gap model NT_T (dashed olive). The area between the orange and dashed olive lines corresponds to exponential suppression of direct Urca reactions. Above the dashed line, there is no suppression.

3.2. *Application to MXB 1659-29*

We now discuss the predictions of our model for the accreting neutron star MXB 1659-29. As described in Ref. 8, knowing the total mass accreted onto the neutron star during an outburst, one can estimate the total energy deposited in the crust. Assuming this energy is almost completely conducted into the core, and, after the core reaches thermal equilibrium, radiated away by neutrinos, we get an estimate of the star's neutrino luminosity. For the source MXB 1659-29, this luminosity is estimated to be $L_\nu \approx 3 \times 10^{27}$ J/s $= 3 \times 10^{34}$ erg/s.

This estimate was shown[8] to be insensitive (less than a factor of two) to variations in accretion rate during outburst and the outburst recurrence time, neutron star mass or EOS, for a core temperature of $\tilde{T} = 2.5 \times 10^7$ K and a light element envelope composition. As detailed in Ref. 9, the envelope composition is a crucial parameter in modelling the relationship between the internal temperature of the star and its surface temperature. For this source, a heavy element envelope would correspond to a core temperature of $\tilde{T} = 5 \times 10^7$ K, which increases the star's predicted total neutrino luminosity by two orders of magnitude, however, this scenario is inconsistent with the measured accretion rates. Ref. 8 also found that the envelope's impurity parameter and distance uncertainties can change the inferred luminosity above by an additional factor of $\lesssim 2$. For this study, we will take the value $L_\nu = 3 \times 10^{34}$ erg/s as the correct value of neutrino luminosity.

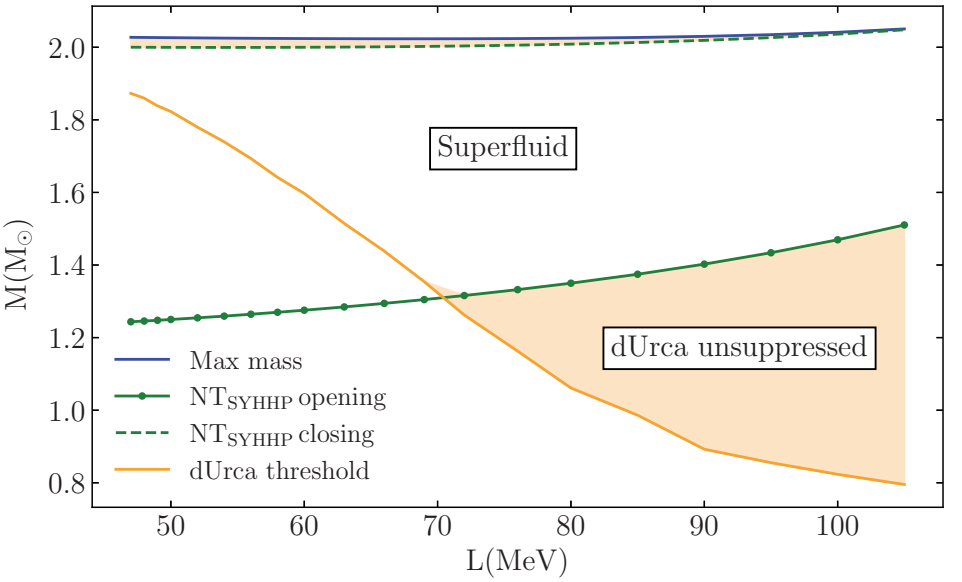

Fig. 5. The direct Urca threshold (orange curve), and the opening (dotted green) and closing (dashed green) curves of superfluid gap $\mathrm{NT_{SYHHP}}$. The area bounded by the orange, the dotted green and the dashed green lines corresponds to exponential suppression of direct Urca reactions. In all highlighted areas, there is no suppression.

To attempt to match the inferred neutrino luminosity of the source MXB 1659-29, we calculate the masses of stars with that total luminosity, for all combinations of EOS and gap models. The results are shown in Fig. 6. Panel (a) displays only the no superfluidity case, whereas panel (b) contains the predictions for neutron triplet superfluidity and panel (c), for proton singlet superconductivity. In all cases, we observe that only a small fraction of the volume of the core, from 0.10% to 1.07% depending on the EOS, is involved in unsuppressed direct Urca cooling. These volume fractions are shown in the bottom panel of panel (a).

We also calculated the total neutron star heat capacity, for all combinations of EOS and gap models. The results are shown in Fig. 7. Note that larger mass stars have larger heat capacities, which is a trend one observes in the figure above and in Fig. 8. Specifically, for proton superconductivity, high L EOS have lower mass stars achieving the observed luminosity of $L_\nu = 3 \times 10^{34}$ erg/s, thus Fig. 7a shows a general trend of lower heat capacities for higher Ls. The opposite trend happens for neutron superfluidity, where most heat capacity curves increase with increasing L, reflecting that higher mass stars are produced in that region. The C-shaped curves on the right bottom of Fig. 8b are a consequence of this phenomenon. Note that different L EOS can generate stars with the same mass and luminosity, for a given gap model. The fact that we are not comparing same size stars on Fig. 7 explains

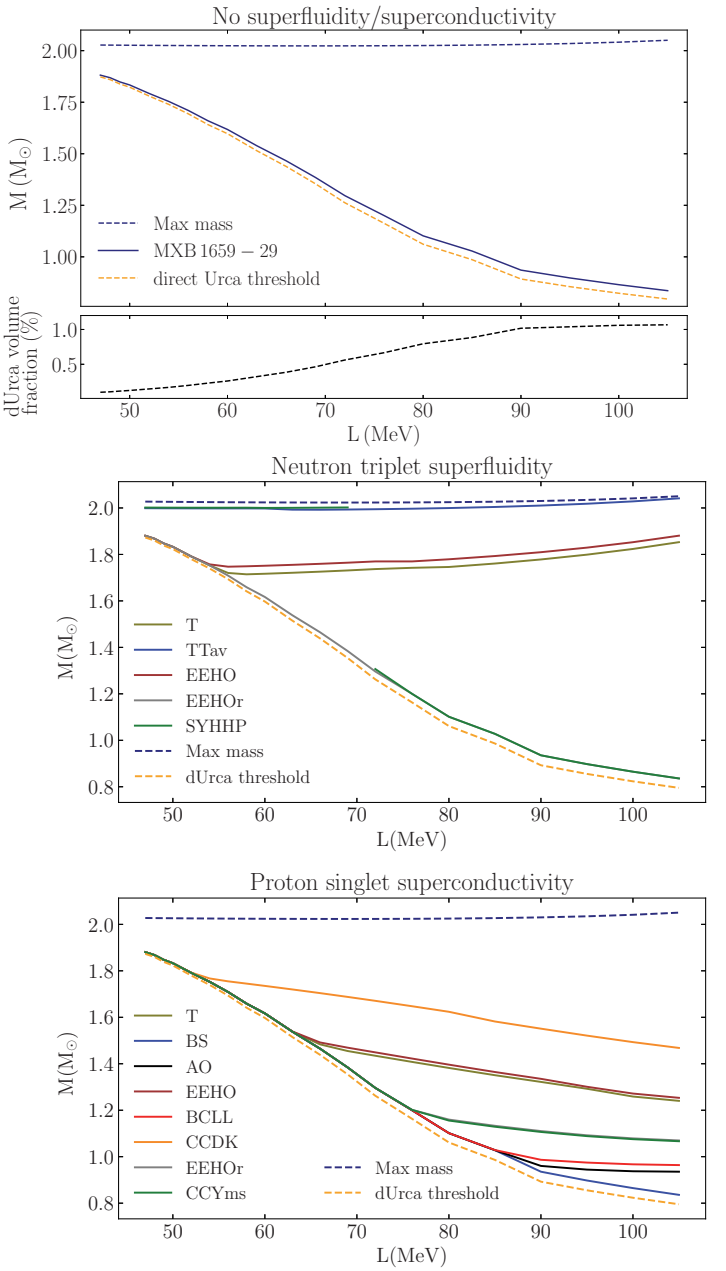

Fig. 6. Masses of stars with luminosity $L_\nu = 3{\cdot}10^{27}$ J/s, corresponding to MXB 1659-29 source, for all EOS. (a) No superfluidity/superconductivity (dark blue curve). The bottom panel displays the percentage of the core volume involved in unsupressed direct Urca reactions. (b) For all gap models of neutron triplet superfluidity. The curve displayed in panel a is under the gap model $\mathrm{NT_{EEHOOr}}$ curve. (c) For all gap models of proton singlet superconductivity. Gap models $\mathrm{PS_{CCYps}}$ and $\mathrm{PS_{BS}}$ predict the same curve.

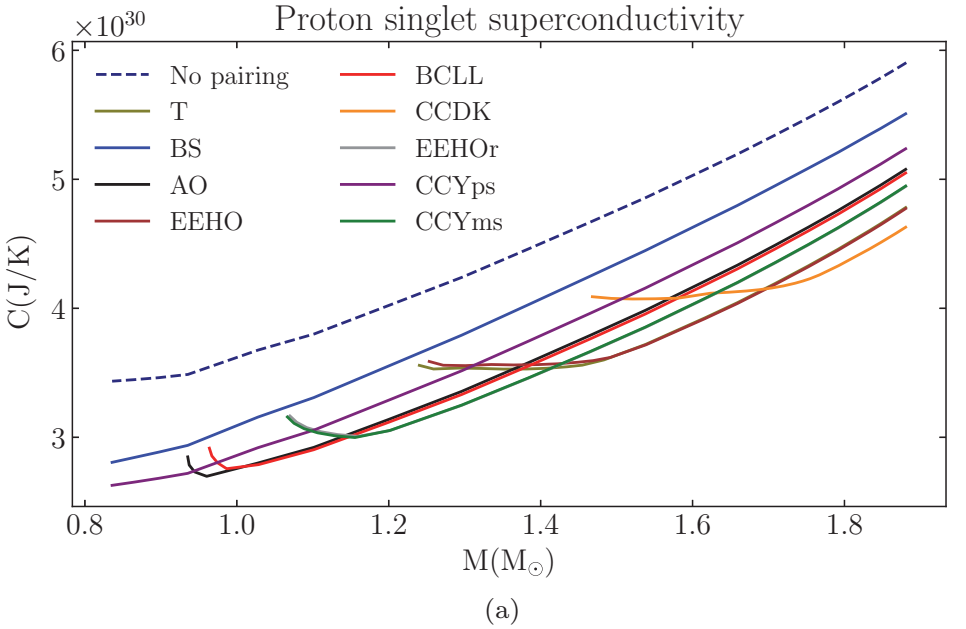

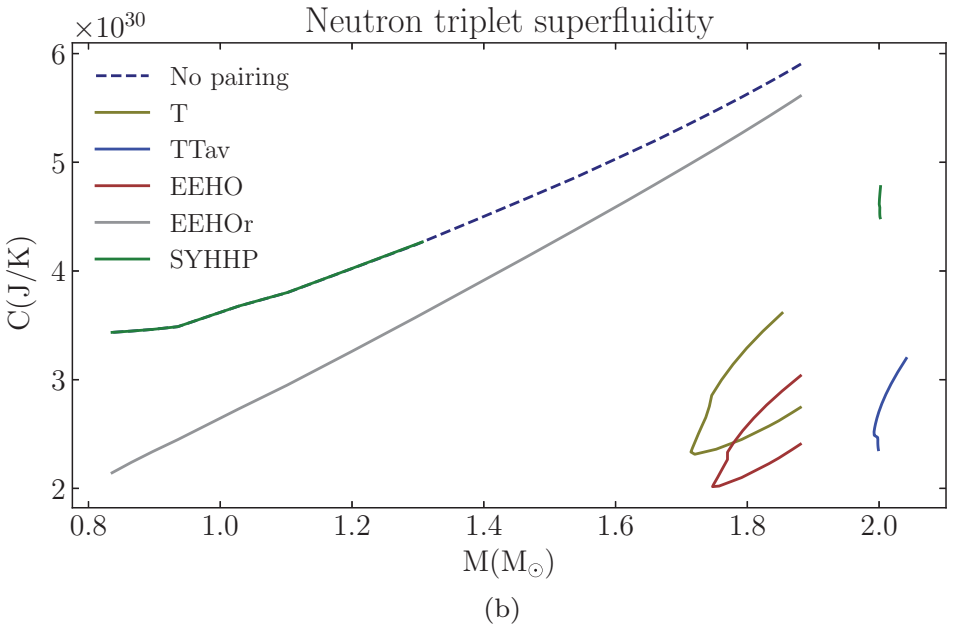

Fig. 8. Total heat capacity C (J/K) versus total mass M ($M_\odot$) for stars with luminosity $L_\nu = 3 \cdot 10^{27}$J/s for all EOS studied here. (a) Proton singlet superconductivity (b) Neutron triplet superfluidity.

why some heat capacity curves of superfluid stars overcome the heat capacity curve of stars without nuclear pairing. This situation does not happen in Fig. 8.

4. Discussion

Comparing the predictions of each gap model and EOS combination with the inferred neutrino luminosity of the accreting neutron star MXB 1659-29 (Fig. 6), we find that three models are disfavoured and can be excluded. $\mathrm{NT_{AO}}$, $\mathrm{NT_{BEEHS}}$ and $\mathrm{NT_{TToa}}$ predict that the whole core of the star will be superfluid at the core temperature of MXB 1659-29, hence direct Urca reactions are completely suppressed and we are not able to reproduce the inferred neutrino luminosity of MXB 1659-29. Other fast cooling processes would be equally suppressed by superfluidity, such that these models describe slow cooling stars for any EOS, thus, are inconsistent with the data. These gap models have similar opening and closing densities, but different amplitudes of the critical temperature T_c, suggesting that their location and width are the determinant factors in the luminosity prediction. This result is a consequence of the low temperature of MXB 1659-29's core in comparison with the models' T_c (Fig. 2). Therefore, we expect that any gap models with similar opening and closing densities will be unable to reproduce the data.

The other gap models can reproduce the observed neutrino luminosity. However, gap models $\mathrm{NT_{EEHOr}}$, $\mathrm{PS_{BS}}$ and $\mathrm{PS_{CCYps}}$ are disfavoured, particularly for high L EOS. These models close before the onset of direct Urca for all EOS, hence their predictions for neutrino luminosity are the same as in the case without superfluidity. Their calculated star masses are very close to the direct Urca threshold masses, and for high L ($L \geq 85$ MeV), they predict that all neutron stars will be fast cooling, which is in disagreement with observations. For low L, their predictions agree with data if less than 0.5% of the core volume of the star is involved in unsuppressed direct Urca reactions, which suggests fine-tuning because it requires that the neutron star mass happens to lie within a narrow range of masses near the dURCA threshold.

Of the remaining gap models, we highlight NT_{SYHHP}, which predicts that only very high mass stars have unsuppressed direct Urca for low and intermediate L ($L \leq 70\,\mathrm{MeV}$), whereas for high L, both low mass stars and very high mass stars cool through this fast process. This superfluid model is the only one predicting direct Urca cooling in low mass stars ($M \leq 1.3\,M_\odot$), thus, a future observation consistent with this situation would favour this model and $L \geq 70\,\mathrm{MeV}$. At the same time, it is able to accommodate slow cooling for stars with masses $2.0\,M_\odot \geq M \geq 1.3\,M_\odot$, in agreement with luminosity data from other transiently-accreting and isolated sources, for example, the ones studied in Refs. 26, 27.

Proton superconductivity models $\mathrm{PS_{AO}}$, $\mathrm{PS_{BCLL}}$, $\mathrm{PS_{EEHOr}}$ and $\mathrm{PS_{CCYms}}$ also predict fast cooling for low mass stars with $L \geq 70\,\mathrm{MeV}$, but, differently from the superfluid model NT_{SYHHP}, by themselves they do not accomodate slow cooling for stars with masses $M \geq 1.3\,M_\odot$, thus are inconsistent with data from other sources. However, a more realistic description of a neutron star would include a

combination of neutron superfluidity and proton superconductivity, which can significantly change the results shown here. Therefore, the proton superconductivity models above can not be excluded under this argument.

On Reference 9, it was discussed that the heat capacity and luminosity ratio can be written as

$$\frac{C_{38}}{L_{\nu,35}} = \left(\frac{\Delta\tilde{T}/\tilde{T}}{0.3\%}\right)^{-1} \left(\frac{t_q}{10\mathrm{yr}}\right) \tilde{T}_8^{-1} \tag{21}$$

where $\Delta\tilde{T}$ corresponds to the difference in temperature measurements after a quiescence time interval t_q, $C_{38} = C/10^{38}$ and $L_{\nu,35} = L_\nu/10^{35}$. Therefore, knowing $\Delta\tilde{T}/\tilde{T}$ and the inferred luminosity of a source, one can find its total heat capacity, which is intrinsically dependent on the star's particle composition. In Figure 9, we show our calculations for the heat capacities and luminosities of stars with different masses and gap models. For better visualization, only neutron triplet results for two EOS are shown. We display $\Delta T_{\mathrm{eff}}^{\infty}/T_{\mathrm{eff}}^{\infty}$, which is related to $\Delta\tilde{T}/\tilde{T}$ through $\Delta\tilde{T}/\tilde{T} = 1.8\,\Delta T_{\mathrm{eff}}/T_{\mathrm{eff}}$.

The difference between heat capacities for each triplet gap model is a factor of 2 at most, thus, one needs a few percent precision in observations of temperature variation to discriminate between particle composition scenarios.[8] Note that the intersection between $\Delta\tilde{T}/\tilde{T}$ curves and the vertical line marking the luminosity of source MXB 1659-29 is only relevant for $\Delta\tilde{T}/\tilde{T} < 2\%$. Bigger temperature variations for that luminosity would imply that the star is completely superfluid, such that the heat capacity is dominated by leptonic contributions. That is an unrealistic scenario, as discussed before.

Knowing L with precision can eliminate or favour certain gap models. However, the current predictions from gravitational waves[21,22] and nuclear experiments, such as PREX-II[10] are in tension, thus, unable to set reliable constraints on L. For this reason, we chose to investigate the whole phase space of L for the EOS family studied here. At the moment, our results are unable to set constraints for the EOS, however, with independent measurements of luminosity and mass of a neutron star source, this goal could be achieved. In this scenario, it will be particularly relevant to include more fast cooling processes in this framework, beyond direct Urca, as well as other equations of state, potentially with exotic components like hyperons, pions or free quarks.

We highlight that, for all cases studied here, the fraction of the core volume undergoing unsuppressed direct Urca is around 1%, which suggests that neutron stars with even higher neutrino luminosities and lower core temperatures should exist. Candidates for such cold stars are the sources SAX J1808.4-3658 and 1H 1905+000.[6] Further research is necessary to confirm whether the cooling of these sources is consistent with direct Urca reactions. Alternatively, one can speculate whether source MXB 1659-29 is actually a neutron star with a quark core or if it cools through exotic processes, such as neutrino emission from pion or kaon condensates. In some

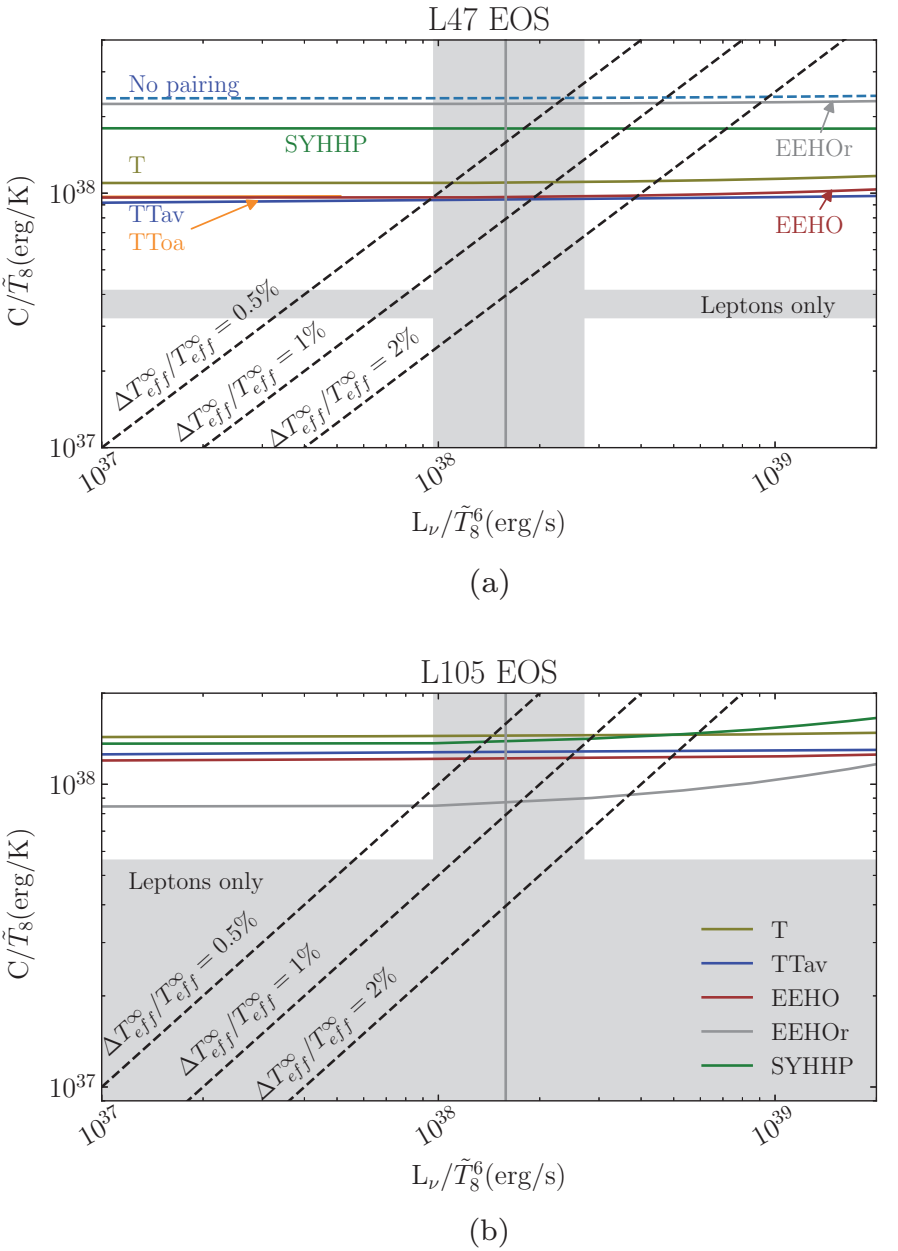

Fig. 9. Total heat capacity $C/\tilde{T}_8$ (erg/K) versus neutrino luminosity $L_\nu/\tilde{T}_8^6$ (erg/s) for neutron triplet gap models studied here. Only stars able to cool through direct URCA are displayed. $C_{leptons}$ is the lower limit of only electrons and muons contributing, mimicking a completely superfluid star. The vertical line and grey region around it correspond to the inferred luminosity of $L_\nu = 3 \times 10^{34}$ erg/s and uncertainty for source MXB 1659-29, more details on Ref. 8. The diagonal lines $\Delta T^{\infty}_{eff}/T^{\infty}_{eff}$ indicate temperature variation of the star's effective temperature after a period of ten years in quiescence. (a) *L*47 EOS (b) *L*105 EOS. The "no pairing" curve is under the *SYHHP* curve.

of these cases, their emissivities could be lower by up to 3 orders of magnitude, as shown in Ref. 5, resulting in larger fractions of the core volume cooling through direct Urca emission.

5. Summary

In this paper, we studied a family of hadronic EOS with different values of the slope of the symmetry energy, L, combined with several models of proton superconductivity and neutron superfluidity in the neutron star core. Comparing the direct Urca neutrino luminosity calculations with data from transiently-accreting source MXB 1659-29, we can rule out gap models that predict superfluidity in the whole star's core, $\mathrm{NT_{AO}}$, $\mathrm{NT_{BEEHS}}$ and $\mathrm{NT_{TToa}}$. We predict that pairing models with similar opening and closing densities can also be excluded. Gap models $\mathrm{NT_{EEHOr}}$, $\mathrm{PS_{BS}}$ and $\mathrm{PS_{CCYps}}$ are able to describe the observed luminosity but are disfavoured, because, for high L, they predict all neutron stars will be fast cooling and for low L, the masses need to be close to the direct Urca threshold. In a forthcoming paper, we will investigate neutron superfluidity and proton superconductivity simultaneous presence in the star's core.

We also calculated the total heat capacities for all stars which match the inferred neutrino luminosity of MXB 1659-29. Their values are within a factor of 2, hence one needs to distinguish between 1% and 2% of a variation of temperature over a decade[8] to differentiate between the particle composition scenarios. If independent observations of mass and luminosity can be made, they could be used to determine an accurate gap model description of the star's nuclear pairing, as well as the L parameter of its EOS. Furthermore, we were able to construct several detailed realistic scenarios where MXB 1659-29's estimated luminosity was obtained, consistent with direct Urca cooling at around 1% core volume, as previously estimated. This low percentage implies that stars with even larger neutrino luminosities and colder cores should exist. Alternatively, other fast cooling processes from exotic components with a lower emissivity could be operating over a larger fraction of the core.

QED's predictions that photons propagating in a magnetized vacuum should feel the vacuum birefringence are still standing. Magnetars have strong magnetic fields and may give us signals of this effect through the delay of photons travelling from this source to detectors and the polarization position or by the angle and degree of polarization of the radiation emitted. Starting from non linear electrodynamics, we analyze and discuss for weak and strong field approximations the theoretical predictions for both using a toy model of rotating neutron stars with dipolar magnetic field shape and photon trajectories that lie radial.

Keywords: Magnetic field, Neutron stars, Polarization, Magnetized vacuum.

1. Introduction

Quantum Electrodynamics is a very well-established and successful theory with great numbers of experimental test. The theory conceives that fluctuations from the virtual electron-positron pairs, the vacuum, give rise to very interesting phenomena, becoming a magnetized vacuum in non-linear interaction theory. One of these properties is birenfrigence, which means that electromagnetic waves propagating perpendicular to a constant electric or magnetic field suffer changes in their speed of propagation. This velocity is a function of the external field. As incredible as it seems, this phenomenon has not been detected experimentally yet. It is not clear the reason behind that. It could be due to the smallness of the effect of the magnetic fields generated in the lab, but it is not ruled out that it represents a manifestation of new physics.

One of the most relevant experiment designs for getting birefringence is the Polarization of Vacuum with Laser (PVLAS) experiment.[1] A magnetic field of 5.5×10^4 G was used in this experiment. The PVLAS-team blamed axions[a] as responsible for the discrepancy between the established theoretical QED birefrigence and the null experimental signal.[1]

[*] Departamento de Física Teórica, Instituto de Cibernética Matemática y Física (ICIMAF), Calle E esq 15 No. 309, Vedado, La Habana 10400, Cuba.

[a] hypothetical elementary particles with low mass, candidates for dark matter, and in this context, photons could decay in axions and a new physics may appear.

However Astrophysics could give information about birefringence and other exotic phenomena of the QED-vacuum. The Universe is our main lab, while experiments on Earth are being improved.Very exotic objects like neutron stars have huge magnetic fields that could give us signals of birefrigence of the vacuum but also the inestability of the vacuum and pair production. Neutron stars have magnetic fields of the order of Schwinger's critical field $B_c = 4.41 \times 10^{13}$G,[2] and beyond for magnetars.[3] The birefringence signal from these objects could be measured through the time delay that should undergo the emitted polarized radiation of NS to be detected.

Our work is focused on obtaining a theoretical estimate of the angle of polarization as a consequence of vacuum birefringence, considering that the pulsar magnetosphere is a magnetized vacuum. In that case, we analyze the propagation of photons in two limits, weak and strong magnetic fields, and consider the dipolar shape of the magnetic field.

We started using effective Euler Heisenberg Lagrangian[4] to obtain the modes of polarization of photons traveling perpendicular to the magnetic field ($k \perp B$). This calculation is equivalent to the previous one obtained by solving the photon dispersion equation, considering the radiative corrections given by the magnetized photon self-energy.[5]

2. Euler Heisenberg non-linear electrodynamics

The non linear Euler Heisenberg Lagrangian for the weak $B \ll Bc$,$E \ll Ec$ and strong limits $B \gg Bc$, $E \gg Ec$ is presented in this section. Despite the fact that this formulation does not cover all microscopic photon-photon interactions, it is very useful because it describes vacuum as a non-linear optical medium allowing us to investigate specific phenomena using traditional techniques and interpretation of non-linear optics in media.

For the approximation $B \ll B_c$ the EH lagrangian[4] has the form

$$\mathcal{L}_{EH}^{W} = \mathcal{L}_0 + \xi(\mathcal{L}_0^2 + \frac{7\epsilon_0^2 c^2}{4}(\boldsymbol{E}.\boldsymbol{B})^2), \;\; \mathcal{L}_0 = \frac{\epsilon_0}{2}(E^2 - c^2 B^2), \tag{1}$$

$\mathcal{L}_0$ is the linear Lagrangian density and ϵ_0 and c are the dielectric constant and the speed of light in the vacuum respectively. QED vacuum corrections emerge through the constant $\xi = \frac{8\alpha^2\hbar^3}{45 m_e^4 c^5}$ which encloses the interaction of virtual pairs with magnetic field and depends on charge and mass of electrons. The vacuum: electron-positron virtual pairs have an indirect photon interaction responsible of non linearity of lagrangian Eq. (1). In the limit $B \gg B_c$ we have for the EH Lagrangian the following expression[4,6]

$$\mathcal{L}_{EH}^{S} = -\frac{B^2}{2} + \frac{m^4}{24\pi^2}\frac{B}{B_c}\left(ln\left(\frac{B}{2B_c}\right) + \frac{6}{\pi^2}\xi^{i\prime}(2)\right). \tag{2}$$

where $\frac{6}{\pi^2}\xi^{i\prime}(2) = -0.5699610$ with $\zeta(x)$ the Riemann zeta-function. This limit is important in astrophysics because compact objects, such as neutron stars (magnetars),

have a surface magnetic field of order $10^{13}-10^{15}$ G[7] which is higher than the critical magnetic field of B_c.

We start off from Lagrangian in two limits: weak and strong magnetic field to study the photon propagation perpendicular to a constant magnetic field B_e (in the direction x_3) in a vacuum. The photon can be described as electromagnetic wave with electric and magnetic field E_w and B_w which are orthogonal each other. Therefore, the total electric and magnetic fields are $E_t = E_w$, $B_t = B_w + B_e$.[8] The modified Maxwell equation solutions will be determined by whether the external magnetic field B_e is aligned with or orthogonal to the wave magnetic field B_w ($B_e \perp B_w$, $B_e \parallel B_w$), resulting in two physical polarization modes.[9,10] According to the case, we label along the paper $i = \perp, \parallel$ perpendicular and parallel respectively. Assuming E_w and B_w as plane wave $\sim exp(i(kz - \omega t)$ to solve modified Maxwell equations, doing some algebra and retaining only first term corrections, we may get the dispersion equations.[11] For the weak and strong field approximation reads as

$$\omega_{\parallel}^{W} = \mid \boldsymbol{k} \mid \sqrt{(1 - \frac{\xi}{4}(\boldsymbol{B_e} \times \hat{\boldsymbol{k}})^2)}, \quad \omega_{\perp}^{W} = \mid \boldsymbol{k} \mid \sqrt{(1 - \frac{7}{4}\xi(\boldsymbol{B_e} \times \hat{\boldsymbol{k}})^2)}, \tag{3}$$

$$\omega_{\parallel}^{S} = \mid \boldsymbol{k} \mid \sqrt{(1 - \frac{\alpha}{3\pi}(\hat{\boldsymbol{b}} \times \hat{\boldsymbol{k}}))}, \quad \omega_{\perp}^{S} = \mid \boldsymbol{k} \mid \sqrt{(1 - \frac{\alpha}{3\pi}\frac{B_e}{B_c}(\hat{\boldsymbol{b}} \times \hat{\boldsymbol{k}}))}. \tag{4}$$

For photon propagation perpendicular to the external magnetic field $\theta = \pi/2$. For weak field, both modes depend on the square of the external magnetic field. However, the strong magnetic field limit (SFL) has different behavior. In that case, we obtain where only the perpendicular mode depends on the magnetic field but linearly, while the mode parallel is independent of the magnetic field.

We define $\Delta n^{S,W} \equiv n_{\perp} - n_{\parallel}$ as the difference between the refraction indices of the two polarization modes,

$$\Delta n^{S} = \frac{\alpha}{4\pi}\frac{2}{15}\left(\frac{B_e}{B_c}\right)^2, \qquad \Delta n^{W} = \frac{\alpha}{4\pi}\frac{2}{3}\left(\frac{B_e}{B_c} - 1\right). \tag{5}$$

Let us note that in a magnetized vacuum, not only do photons acquire different velocities according to their polarization, but also the polarization changes once a photon has travelled a certain distance. Initial photon linear polarization becomes elliptical and the angular rotation of the polarization plane of the electromagnetic wave travelling a path length L is $\phi = \Delta n^{S,W} \omega L$.

3. Polarization radiation of neutron stars

Our focus in this section is to revisit the polarization that would occur when photons propagate in the magnetosphere of a neutron star, considering only the effects of a magnetized vacuum. As we mentioned before, NS are very exotic astronomical objects, characterized by huge densities and magnetic fields. The surface magnetic field could be around 10^{12-15} G, but its geometry is complicated, and it is impossible to consider it constant and uniform throughout the star.

Therefore, to do our study we have to make three important approximations: photons propagate in a magnetosphere considered as a magnetized vacuum, the magnetic field shape is dipolar and photon trajectories are radial. These assumptions allow us to calculate the polarization degree (PD) of radiation using the evolution equation, $\frac{\partial \mathbf{s}}{\partial \hat{r}} = \hat{\mathbf{\Omega}} \times \mathbf{s}$, $|\hat{\mathbf{\Omega}}| = \frac{\omega}{c}\Delta n^{W,S}$, where $\hat{r}$ is the direction of propagation of the photons, $\mathbf{s} = \{S_1/S_0, S_2/S_0, S_3/S_0\}$ is the normalized Stokes vector and $\hat{\mathbf{\Omega}}$ is related to the refraction index (defined in Eq (5)). We estimate the polarization degree PD of photons consider the adiabatic approximation $\hat{\mathbf{\Omega}}\left(\frac{1}{|\hat{\mathbf{\Omega}}|}\frac{\partial|\hat{\mathbf{\Omega}}|}{\partial\hat{r}}\right)^{-1} \gtrsim 1/2$, obtained in.[13] This condition allows us to calculate the polarization-limiting radius r_L at which the degree of polarization begins to be constant and the polarization becomes elliptical. We consider a dipolar shape configuration for the magnetic field as $B_e(r) = B_0\left(\frac{r_0}{r}\right)^3$, with B_0 and r_0 are the surface magnetic field and radius of the neutron star respectively. Because, regardless of the value of the surface magnetic field B_0, the important values of magnetic field strength are those where decoupling of polarization modes occurs, whether far or close to the neutron star, our calculations will be performed for the entire range of magnetic fields using the weak and strong field approximations. If the decoupling modes occur far enough from the star's surface, $r_L \gg r_0$, as the magnetic field goes as r^{-3}, the magnetic field will be significantly smaller. Then, $\Omega \sim \Delta n^W \sim B_e^2$. When decoupling arises for $r_0 \leq r_L < 2r_0$ the strong field approximation, $B_0/B_c \gtrsim 1$, is suitable, and $\Omega \sim \Delta n^S \sim B_e$. We assume rotating NS for both magnetic field regimes. Then, the angle ϕ is given by the relation $r_L - r_0 = \phi\frac{P}{2\pi}$ where P is the period of the pulsar.[12] The computed polarization angle is given by the equations

$$\phi(\omega, B, P) = \begin{cases} \frac{2\pi}{cP}\left(\left[\frac{\alpha}{90\pi}\frac{\omega}{c}\left(\frac{B_0}{B_c}\right)^2 r_0^6\right]^{1/5} - r_0\right), & B < B_c \text{ (weak)} \\ \frac{2\pi}{cP}\left(\left(\frac{\alpha}{9\pi}\frac{\omega}{c}\frac{B_0}{B_c}r_0^3\right)^{1/2} - r_0\right), & B > B_c \text{ (strong)} \end{cases} \tag{6}$$

and polarization degree is $\Pi(\omega, B, P) = 4\pi/cP\left((3/r_L)^2 + (4\pi/cP)^2\right)^{-1/2}$. For higher frequencies, the radiation from neutron stars' magnetosphere is substantially polarized (fig. 1). Furthermore, neutron stars or magnetars with a higher magnetic field, release strongly polarized radiation. The polarization degree (PD) of radiation of a pulsar is inversely related to its period; millisecond pulsars have more polarization than second period pulsars. The behavior of angle and polarization degree with the magnetic field is depicted in fig. 1 for weak and strong field approximations. For magnetic fields greater than $2B_c$, strong field approximation contributes to an increase the polarization degree and polarization angle compared to weak field approximation.

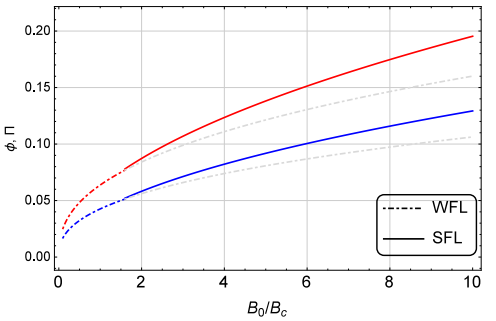

Fig. 1. Comparison of the polarization degree (Blue line) and polarization angle (Red line) for weak field limit (dotdashed line) and strong field limit (solid line) as function of the surface magnetic field of the pulsar. We take typical neutron star parameters, a radius $r_0 = 10$ km, a period of $P = 1$ s and radiation of $\omega = 2$ MeV of energy.

Our results are in agreement with previous obtained by Heyl et al[13] when weak field approximation is taken into account. Furthermore, studies on $RXJ1856.5-3764$ for polarization of visible and X radiation revealed that it is essential to include the influence of magnetized vacuum to explain the observational data of polarization of this source.[14]

For photon energy of $\omega = 1MeV$ and typical values of the parameters $B_0 = 1.5 \times 10^{13}G$, $M = 1.4M_{\odot}$, radius $r_0 = 12km$, and $P = 7.06s$, the angle and degree of polarization for $RXJ1856.5-3764$ owing to simply the effect of magnetized vacuum give $\phi = 6.4 \times 10^{-3}$ and $\Pi = 0.42\%$.[15,16] Obviously, when geometric factors are taken into account, this value rises.[14]

4. Conclusions

From non-linear electrodynamics we have obtained the refraction index and different phase velocity of photon propagating in strong magnetic field according to the polarization modes. We have also obtained the polarization angle that the radiation acquires as a consequence of crossing a magnetized vacuum. The calculations have been done in weak and strong field approximation for a constant magnetic field.

In addition, we investigated the influence of a magnetized vacuum on the polarization of radiation emitted by rotating NS. To do so, we considered the magnetosphere to be a magnetized vacuum with a dipolar magnetic field and photons traveling along radial trajectories.

Our findings are consistent with previous results based on weak field approximation.[13] More energetic photons have a greater polarization degree than the lower ones. Besides, the polarization degree is strongly dependent on the period of rotation of neutron stars since this can raise or decrease the polarization limiting radii, causing the couple or decouple of the propagation modes.

The authors of the work[14] claim that there is no way of explaining the polarization data from visible and X rays of the pulsar $RXJ1856.5-3764$ without

considering the effect of magnetized vacuum. As a consequence, it might be a test of vacuum birefringence, albeit we expect it will be tested in terrestrial laboratories.

However, not all regarding vacuum birefringence has been said, and the door is opened for new physics. This work was undertaken as a starting point for developing more realistic models of polarization radiation emission of NS which will allow us to identify in robust way those linked to vacuum birefringence and may validate the QED prediction.

We present our studies on the neutrino pairs annihilation into electron-positron pairs ($\nu\bar{\nu} \to e^- e^+$) near the surface of a neutron star in the framework of extended theories of gravity. The latter modifies the maximum energy deposition rate near to the photonsphere and it might be several orders of magnitude greater than that computed in the framework of General Relativity. These results provide a rising in the Gamma-Ray Bursts energy emitted from a close binary neutron star system and might be a fingerprint of modified theories of gravity, changing our view of astrophysical phenomena.

Keywords: Extended theories of gravity, GRB, Neutrino energy deposition, Black Holes, Neutron Stars

1. Introduction

General Relativity (GR) is without any doubt the best theory of gravitational interaction. Its predictions have been tested with high accuracy on scales of the solar system (for example, the precession of the Mercury perihelion, the photons deviation and the gravitational leasing effect), on astrophysical scales (the gravitational waves), and cosmological scales (the cosmic microwave background radiation (CMBR) and the formation of primordial light elements (Big Bang Nucleosynthesis)). Despite these results, there are still open questions that make GR incomplete. The latter arise at short distances and small time scales (black hole and cosmological singularities, respectively), or at large distance scales, the rotational curve of the galaxies and the observed accelerated phase of the present Universe, for which any predictability is lost.

To solve these issues, deviations from the GR (hence from the Hilbert-Einstein action on which GR is based) are needed, and new ingredients, such as dark matter and dark energy, are required for fitting the present picture of our Universe.[1–6] Indeed, in the last years, several *alternative* or *modified* theories of gravity have been proposed, which try to answer all the opened questions of GR and the Cosmological Standard Model. To give an example, higher-order curvature invariants than the simple Ricci scalar R, allow getting inflationary behaviour, removing the primordial singularity, as well as explaining the flatness and horizon problems[7,8] (for further applications, see Refs.[9–37]). On the other hand, one can tend to preserve the GR and the Hilbert-Einstein action, adding only some two unidentified components: dark matter and dark energy. These two different approaches try to solve the same

problems but at the moment there is not a final solution for that (modified gravity theories do not manage to solve all the problems while dark matters elements are still missing). One of the consequences of these approaches is that the metric tensor $g_{\mu\nu}$ describing the gravitational field generated by a massive source gets modified with respect to GR metric, in particular, the Schwarzschild or Kerr metric. The latter are recovered in the limit in which the parameters characterizing some specific theory of gravity beyond GR are set to zero.

In this proceeding, we highlight the differences between GR and extended theories of gravity arising from the mechanism of generation of Gamma-Ray Bursts (GRBs). We focus, in particular, on GRBs powered by neutrino annihilation processes $\nu\bar{\nu} \to e^+e^-$.[a]

The neutrinos annihilation process is relevant in many astrophysical frameworks: in the stellar envelope, as well as on the delay shock mechanism into the Type II Supernova (at late time, from the hot proto-neutron star, the energy is deposited into the supernova envelope via neutrino pair annihilation and neutrino-lepton scattering). These processes augment the neutrino heating of the envelope generating a successful supernova explosion.[44] Moreover, the neutrino annihilation process has been also proposed as the mechanism that power GRB in a binary neutron star system, which is the topic of this work. Simulations and analytical estimations performed within GR show that the mechanism is not sufficient to generate the required energy for explaining short GRB. Such a conclusion changes, as we will show, if the gravitational background is described by modified theories.

2. Neutrino energy deposition formulation

In this section we recall the main features to treat the energy deposition in curved spacetimes.[45,46] Previous calculations of the $\nu\bar{\nu} \to e^-e^+$ reaction in the vicinity of a neutron star have been first based on Newtonian gravity,[47,48] then the effect of gravity has been incorporated for static stars,[44,49] and then extended to rotating stars.[45,50] We consider the spacetime around a black hole described by the following diagonal metric

$$g_{\mu\nu} = \mathrm{diag}\left(-f(r), h(r), r^2, r^2\sin^2\theta\right) , \tag{1}$$

The energy deposition per unit time and per volume is given by (considering $c = \hbar = 1$)[51]

$$\begin{aligned}\dot{q}(r) = &\iint f_\nu(\mathbf{p}_\nu, r) f_{\overline{\nu}}(\mathbf{p}_{\overline{\nu}}, r) \\ &\times \left[\sigma|\mathbf{v}_\nu - \mathbf{v}_{\overline{\nu}}|\varepsilon_\nu\varepsilon_{\overline{\nu}}\right]\frac{\varepsilon_\nu + \varepsilon_{\overline{\nu}}}{\varepsilon_\nu\varepsilon_{\overline{\nu}}} d^3\mathbf{p}_\nu d^3\mathbf{p}_{\overline{\nu}} ,\end{aligned} \tag{2}$$

[a] Indeed the state of the art of NS-NS merger simulations is special relativistic, axisymmetric hydrodynamic simulations for the final black hole-torus systems[38–43] from which emerge that neutrino-pair annihilation in ordinary GR models seems to be not efficient enough to power GRBs and the Blandford-Znajek process is currently considered a more promising mechanism for launching. In extended theories of gravity, the situation can be different as we will show in this proceeding.

where $f_{\nu,\overline{\nu}}$ are the neutrino number densities in phase space, $\mathbf{v}_\nu$ the neutrino velocity, and σ is the rest frame cross section. Since the term $\sigma|\mathbf{v}_\nu - \mathbf{v}_{\overline{\nu}}|\varepsilon_\nu\varepsilon_{\overline{\nu}}$ is Lorentz invariant, it can be calculated in the center-of-mass frame, and turns out to be

$$\sigma|\mathbf{v}_\nu - \mathbf{v}_{\overline{\nu}}|\varepsilon_\nu\varepsilon_{\overline{\nu}} = \frac{DG_F^2}{3\pi}(\varepsilon_\nu\varepsilon_{\overline{\nu}} - \mathbf{p}_\nu \cdot \mathbf{p}_{\overline{\nu}}c^2)^2\,, \tag{3}$$

with $G_F = 5.29 \times 10^{-44}$ cm^2 MeV^{-2} the Fermi constant,

$$D = 1 \pm 4\sin^2\theta_W + 8\sin^4\theta_W\,, \tag{4}$$

$\sin^2\theta_W = 0.23$ the Weinberg angle, and the plus sign for electron neutrinos and antineutrinos while the minus sign for muon and tau type. $T(r)$ is the temperature measured by the local observer and $\Theta(r)$ is the angular integration factor. At these energies, the mass of the electrons can be neglected and it is possible to obtain that the general expression of the rate per unit time and unit volume of the $\nu\bar{\nu} \to e^+e^-$ process[44]

$$\dot{q} = \frac{7DG_F^2\pi^3\xi(5)}{2}[kT(r)]^9\Theta(r)\,. \tag{5}$$

The evaluation of $T(r)$ and $\Theta(r)$ account for the gravitational redshift and path bending. To write the latter in terms of observed luminosity L_∞ one has to has to consider that temperature, like energy, varies linearly with red-shift and following the procedure of Ref.[44], one finds that:

$$\Theta(r) = \frac{2\pi^3}{3}(1-x)^4(x^2+4x+5)\,, \tag{6}$$

$$T(r) = \frac{\sqrt{f(R)}}{\sqrt{f(r)}}T(R)\,, \tag{7}$$

$$L_\infty = f(R)L(R)\,, \tag{8}$$

$$L(R) = L_\nu + L_{\overline{\nu}} = \frac{7}{4}\,a\pi R^2T^4(R)\,. \tag{9}$$

Here R is the neutrinosphere radius (the spherical surface where the stellar material is transparent to neutrinos and from which neutrinos are emitted freely), $L(R)$ is the neutrino luminosity, a the radiation constant, $x = \sin^2\theta_r$, θ_r is the angle between the trajectory and the tangent velocity in terms of local radial and longitudinal velocities[45] for which one can obtain that[46]

$$\cos\theta_r = \frac{R}{r}\sqrt{\frac{f(r)}{f(R)}}. \tag{10}$$

This relation comes from the fact that the impact parameter b is constant on all the trajectory and is related to $\cos\theta_r$ by the relation

$$b = \left(\frac{f(r)}{r\cos\theta_r}\right)^{-1}\,. \tag{11}$$

Moreover, photosphere radius R_{ph} exists below which a massless particle can not be emitted tangent to the stellar surface. The present discussion is therefore restricted to $R > R_{ph}$. The neutrino emission properties hence mainly depend on the geometry of spacetime. From the equation of the velocities

$$\dot{r}^2 = \left(E\dot{t} - L\dot{\phi}\right) f(r)\,, \quad \dot{\phi} = \frac{L}{r^2}, \quad \dot{t} = -\frac{E}{f(r)},$$

where E and L are the energy and angular momentum at the infinity, one gets the effective potential V_{eff}, such that the photonsphere radius follows from the condition $\frac{\partial V_{\rm eff}}{\partial r} = 0$. The circular orbit is derived by imposing $\dot{r}^2 = 0$. We note en passant that these results reduce to ones derived in the case of the Schwarzschild geometry, $R_{ph} = 3M$, as calculated in.[44]

The integration of $\dot{q}$ from R to infinity gives the total amount of local energy deposited by the neutrino annihilation process (for a single neutrino flavour) for time units

$$\dot{Q} = 4\pi \int_R^\infty dr \frac{r^2}{\sqrt{f(r)}}\,\dot{q}\,. \tag{12}$$

According to,[44] the total energy deposition from the neutrinosphere radius R_6 to infinity (for a symmetric spherical star that emits neutrinos from a spherical neutrinosphere) is given by

$$\dot{Q}_{51} = 1.09 \times 10^{-5} \mathcal{F}\left(\frac{M}{R}\right) D L_{51}^{9/4} R_6^{-3/2}\,. \tag{13}$$

Here $\dot{Q}_{51}$ is expressed in units of 10^{51} erg s^{-1}, L_{51} is neutrino luminosity in units of 10^{51} erg s^{-1}, $D = 1 \pm 4\sin^2\theta_W + 8\sin^4\theta_W$, $\sin^2\theta_W = 0.23$ and the plus sign is for electron neutrinos and antineutrinos while the minus sign is for muon and tau type, R_6 is the radius in units of 10 km and, for a generic diagonal metric of the form $g_{\mu\nu} = \left(g_{00}, -1/g_{00}, -r^2, -r^2\sin^2\theta\right)$, the function $\mathcal{F}\left(\frac{M}{R}\right)$ is given by

$$\mathcal{F}\left(\frac{M}{R}\right) = 3g_{00}(R)^{9/4} \int_1^{\rm R_{ch}} (x-1)^4(x^2+4x+5)\frac{y^2 g_{11}(yR)^{1/2} dy}{g_{00}(yR)^{9/2}}\,. \tag{14}$$

In the Newtonian limit one gets $\mathcal{F}(0) = 1$ so that it is convenient, for our analysis, to consider the ratio $\dot{Q}_{\rm GR}/\dot{Q}_{\rm Newt} = \mathcal{F}(M/R)$. Usually, almost all energy is carried out by electron neutrino thus we can approximate Eq. (13) considering $D = 1.23$.

Equations (13) and (14) allow obtaining the deposited energy of neutrinos and the energy that can be emitted to powering GRB. In the next Section, we will study the ratio (14) for astrophysical objects in various modified gravity theories.

3. Neutrino deposition in modified gravity

In what follows, we present three relevant cases that explain how relevant could be the modification to GR in this context. First of all, we take into consideration the

Einstein dilaton Gauss-Bonnet gravity. The action is[52]

$$S = \frac{1}{8\pi}\int d^4x\sqrt{-g}\left(\frac{R}{2} - \frac{1}{2}\partial_\mu\psi\partial^\mu\psi + \alpha\psi L_{GB}\right) \ , \tag{15}$$

where ψ is a scalar field and L_{GB} is the Gauss-Bonnet invariant: $L_{GB} = R^2 - 4R^{\alpha\beta}R_{\alpha\beta} + R^{\alpha\beta\gamma\delta}R_{\alpha\beta\gamma\delta}$. The solution considered is the Sotiriou-Zhau solution(solution in perturbation theory[53]), which lead to results in Fig. 1[46]:

$$ds^2 = -f(r)dt^2 + h(r)dr^2 + r^2d\Omega^2 \ , \tag{16}$$

with

$$f(r) = \left(1 - \frac{2m}{r}\right)\left(1 + \sum_n A_n\bar{a}^n\right) \ ;$$
$$h(r) = \left(1 - \frac{2m}{r}\right)^{-1}\left(1 + \sum_n B_n\bar{a}^n\right) \ .$$

where, to the second order:

$$A_1 = B_1 = 0 \ ;$$
$$A_2 = -\frac{49}{40m^3r} - \frac{49}{20m^2r^2} - \frac{137}{30mr^3} - \frac{7}{15r^4} + \frac{52m}{15r^5} + \frac{40m^2}{3r^6} \ ;$$
$$B_2 = \frac{49}{40m^3r} + \frac{29}{20m^2r^2} + \frac{19}{10mr^3} - \frac{203}{15r^4} - \frac{436m}{15r^5} - \frac{184m^2}{3r^6} \ .$$

The maximum value taken for α, considering the perturbative regime of the solution, shown an increase of the 50% for the maximum amount of energy deposition respect to GR.

The second case that we want to analyze is the Brans Dicke theory. It represents a generalization of general relativity, where gravitational effects are in part due to geometry, in part due to a scalar field. The action is[54]

$$S = \int d^4x\sqrt{-g}\left[\psi R + \frac{16\pi}{c^4}L - \omega(\psi)\right] \ , \tag{17}$$

where L is the Lagrangian density of all the matter, including all non-gravitational field, ψ is a scalar field and ω is its Lagrangian density.

With this Lagrangian, expressing the line element in the isotropic form, we obtain the solution[54]

$$ds^2 = -e^{2\alpha}dt^2 + e^{2\beta}\left[dr^2 + r^2d\Omega^2\right] \ , \tag{18}$$

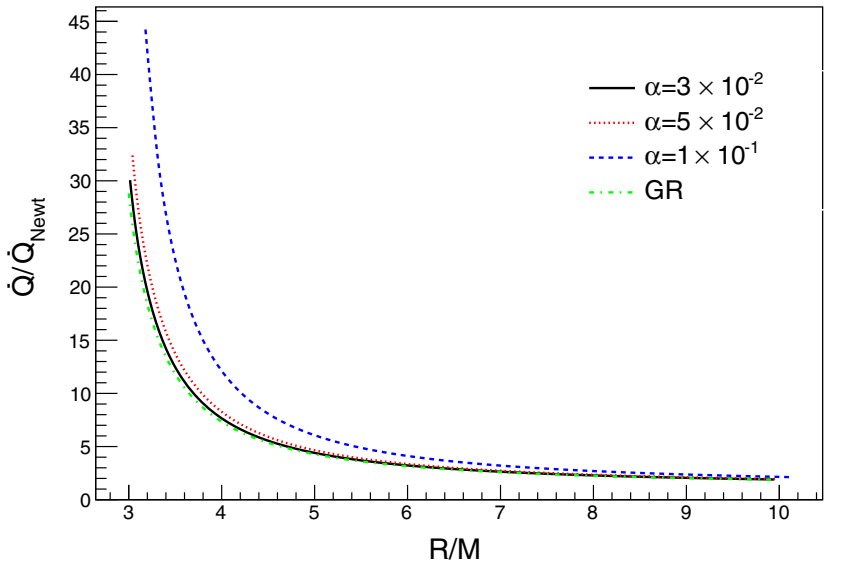

Fig. 1. Ratio of energy deposition $\dot{Q}$ for the the Sotiriou-Zhau metric to total Newtonian energy deposition $\dot{Q}_{\rm Newt}$ for different values of α. The green curve shows the GR energy deposition for comparison.

where

$$\lambda = \sqrt{(C+1)^2 - C(1-\frac{C\omega}{2})}$$

$$e^{2\alpha} = e^{2\alpha_0}\left[\frac{1-\frac{B}{r}}{1+\frac{B}{r}}\right]^{\frac{2}{\lambda}} ,$$

$$e^{2\beta} = e^{2\beta_0}\left(1+\frac{B}{r}\right)^4\left[\frac{1-\frac{B}{r}}{1+\frac{B}{r}}\right]^{\frac{2(\lambda-C+1)}{\lambda}} ,$$

$$\psi = \psi_0\left[\frac{1-\frac{B}{r}}{1+\frac{B}{r}}\right]^{-\frac{C}{\lambda}} ,$$

with ω positive constant and

$$\alpha_0 = \beta_0 = 0 \ ,$$
$$\psi_0 = \frac{4+2\omega}{3+2\omega} \ ,$$
$$C \sim -\frac{1}{2+\omega} \ ,$$
$$B \sim \frac{M}{2\sqrt{\psi_0}} \ .$$

Using this metric, we obtain the shape for energy deposition in Fig. 2. Even with this model we have an enhancement of about 50% respect to the maximum value of $\dot{Q}/\dot{Q}_{\rm Newt}$ 30 in GR.

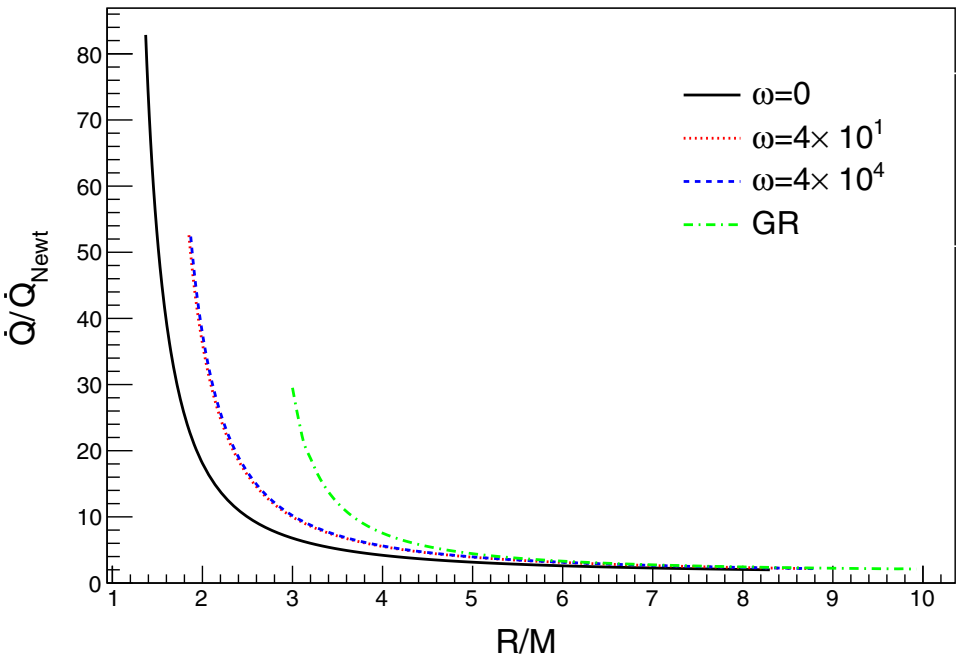

Fig. 2. Ratio of energy deposition $\dot{Q}$ for metric in Eq. (18) to total Newtonian energy deposition $\dot{Q}_{\rm Newt}$ for different value of ω. The green curve shows the GR energy deposition for comparison.

Finally, we discuss the case of a BH surrounded by quintessence field. In this case

$$g_{00}(r) = 1 - \frac{2M}{r} - \frac{c}{r^{3\omega_q - 1}} \ , \tag{19}$$

where c is a positive constant and $-1 < \omega_q < -1/3$. The quintessence parameter is constrained by the fact that increasing c, the model passes from describing a black hole with an event horizon to representing a naked singularity.

We chose to show only the case with $\omega = -0.4$, for which we obtain results in Fig. 3 and an enhancement of a factor 25 with respect to GR.

3.1. *GRB enhancement*

The above results show that modified gravity provides an enhancement of the neutrino annihilation process as compared to GR. Such an enhancement is relevant

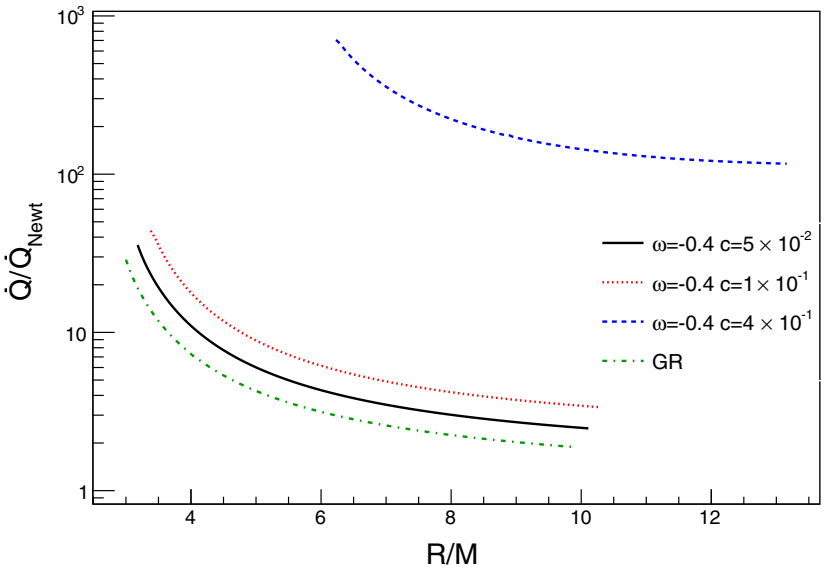

Fig. 3. Ratio of total energy deposition $\dot{Q}$ for $\omega = -0.4$ to total Newtonian energy deposition $\dot{Q}_{\rm Newt}$ for three values of the parameter c. The green curve shows the GR energy deposition for comparison.

for powering GRBs for the model given by a closed neutron stars binary merging system. Neutrino emission happens in the last phase of the merging and the final configuration is a black hole (or neutron star) with an accretion disk. With the developed formalism, we can not describe the disk emission (we are considering a spherical system), so we restrict ourselves to the central BH. Taking into account total energy emitted into neutrinos from the central BH of $\mathcal{O}(10^{52})$ erg, a radius of $R = 20$ km, the maximum possible total energy released in GRB is

$$Q_{\rm GR} \sim 2.5 \times 10^{49} \text{ erg}\,, \tag{20}$$

which is too small to explain the short GRB from neutron star merging. Instead, considering the maximum enhancement that modified gravity induces shown in Figs. 1, 2 and 3, we have that the total possible energy released in GRB can exceed the maximum energy of $\mathcal{O}(10^{52})$ erg (we have to remind that we are considering only the neutrino emission from the central BH and therefore the true emitted energy is larger considering the whole BH+disk configuration). Moreover, considering that the deposited energy is converted very efficiently to the relativistic jet energy, we infer a constraint on the quintessence model. It is possible to obtain that the maximum allowed value of $\mathcal{F}(R_{ph})$ is $\mathcal{O}(10^4)$. The contour plots given in Figs. 4 and 5 show the value of $\mathcal{F}(R_{\rm ph})$ for allowed value of ω_q and c. Therefore, one can infer, for $\mathcal{F}(R_{\rm ph}) \sim \mathcal{O}(10^4\text{-}10^5)$, the values of the parameter c that are not allowed in the considered scenario.

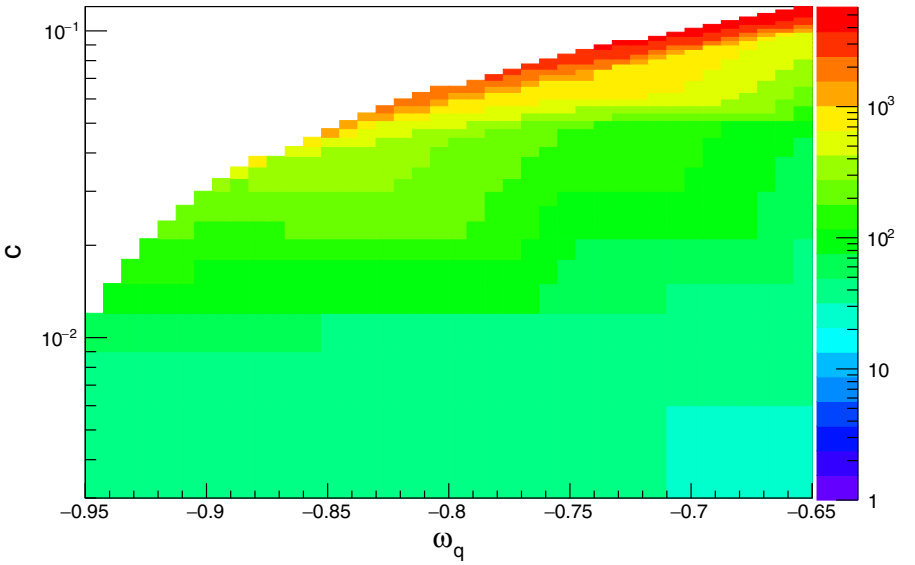

Fig. 4. Contour plot for $\omega_q \in]-1, -0.65[$. On the y axis are reported the excluded values of c due to the creation of a naked singularity (white part) and, on the right, the values of $\mathcal{F}(R_{\rm ph})$. It can be also seen the values of the parameter c, for which $\mathcal{F}(R_{\rm ph}) \sim \mathcal{O}(10^4\text{-}10^5)$, that are excluded by the energy deposition bounds.

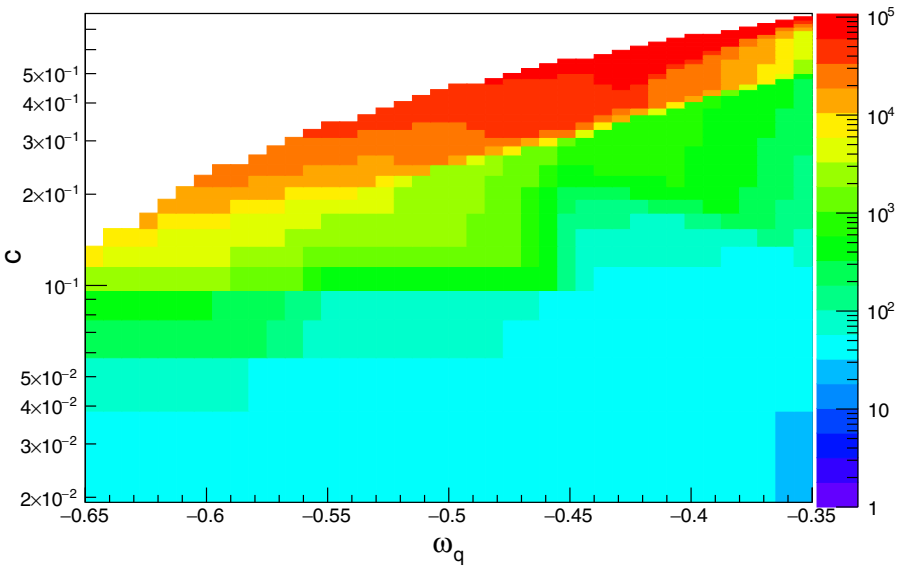

Fig. 5. Contour plot for $\omega_q \in]-0.65, -0.35[$. On the y axis are reported the excluded values of c due to the creation of a naked singularity (white part) and, on the right, the values of $\mathcal{F}(R_{\rm ph})$. It can be also seen the values of the parameter c, for which $\mathcal{F}(R_{\rm ph}) \sim \mathcal{O}(10^4\text{-}10^5)$, that are excluded by the energy deposition bounds.

4. Conclusion

In conclusion, we have analyzed the neutrino pair annihilation process $\nu\bar{\nu} \to e^+e^-$ near a BH in some modified gravitational theories. We have shown that, owing to a shift of the photosphere radius, there is an enhancement of the deposited energy rate ratio with respect to GR. Such an enhancement could be a relevant mechanism for the generation of GRBs in close neutron star binary merging, for which neutrino pairs annihilation has been proposed as a possible source. Moreover, the released energy may be larger than the Short GRB maximum energy observed of $\mathcal{O}(10^{52})$ erg as it happens in the quintessence model (cfr. Ref.[55]). In that case, one can constrain the value of ω and c such that the released energy is inferior to $\mathcal{O}(10^{52})$ erg. The $\nu\bar{\nu} \to e^+e^-$ processes are of great importance in astrophysics, as well as in modified gravity, since they lead to considerable differences with respect to GR and its phenomenology. Therefore, the results presented in this proceeding could provide a new astrophysical framework to search for a signature of gravitational theories beyond GR.

We provide an update on the ongoing monitoring and study of the highly-relativistic double neutron star binary system PSR J1757–1854, a 21.5-ms pulsar in a highly eccentric, 4.4-hour orbit. The extreme nature of this pulsar's orbit allows it to probe a parameter space largely unexplored by other relativistic binary pulsars. For example, it displays

one of the highest gravitational wave (GW) luminosities of any known binary pulsar, as well as the highest rate of orbital decay due to GW damping. PSR J1757–1854 is also notable in that it is an excellent candidate for exploring new tests of General Relativity and other gravitational theories, with possible measurements of both Lense-Thirring precession and relativistic orbital deformation (through the post-Keplerian parameter δ_θ) anticipated within the next 3–5 years.

Here we present a summary of the latest interim results from the ongoing monitoring of this pulsar as part of an international, multi-telescope campaign. This includes an update of the pulsar's long-term timing and post-Keplerian parameters, new constraints on the pulsar's proper motion and corresponding Shklovskii kinematic correction, and new limits on the pulsar's geodetic precession as determined by monitoring for secular changes in the pulse profile. We also highlight prospects for future work, including an updated timeline on new relativistic tests following the introduction of MeerKAT observations.

Keywords: Gravitation; binaries: close; pulsars: individual: PSR J1757–1854

1. Introduction

For many decades, relativistic binary pulsars have been one of the key tools for studying different theories of gravity in the strong field regime, the current paradigm being Einstein's theory of General Relativity (GR). Discovered in 2016 as part of the HTRU-S Galactic Plane pulsar survey,[1,2] the 21.5-ms pulsar PSR J1757–1854 ranks as one of the most extreme examples of this class. Its high eccentricity ($e \simeq 0.606$) and compact orbit (measured via the projected semi-major axis, $x \simeq 2.24\,\mathrm{lt\text{-}s}$) around a neutron star companion combine some of the best properties of other notable relativistic binary pulsars, including the high eccentricity of PSR B1913+16[3] (the 7.75-hr orbital period *'Hulse-Taylor pulsar'*, with $e \simeq 0.617$) and the compact orbit of PSR J0737–3039A/B[4,5] (the 2.45-hr orbital period *'Double Pulsar'*, with $x \simeq 1.42\,\mathrm{lt\text{-}s}$). The extreme nature of PSR J1757–1854 is further demonstrated by multiple records set by the pulsar, including the highest acceleration ($\sim 700\,\mathrm{m\,s^{-2}}$) and highest relative velocity ($\sim 1000\,\mathrm{km\,s^{-1}}$) seen in a binary pulsar, as well as the highest rate of orbital decay due to gravitational wave damping and one of the shortest predicted merger times of any Galactic double neutron star system ($\sim 76\,\mathrm{Myr}$). Together, these properties make PSR J1757–1854 a highly promising candidate for providing new insights into theories of gravity.

Here, we describe some of the ongoing aspects of the work involving this pulsar, in advance of a more detailed peer-reviewed publication anticipated by mid-2022.

2. Current timing and post-Keplerian tests

Since its discovery in 2016, PSR J1757–1854 has been observed by multiple radio telescopes as part of an international collaboration, including the Parkes[a] (Australia), Effelsberg (Germany), Lovell (UK), Green Bank (GBT; USA) and MeerKAT (South Africa) telescopes. This data was analysed using a standard pulsar timing

[a] Also known by its indigenous Wiradjuri name *'Murriyang'*.

technique,[6] wherein summed, average pulse profiles are cross-correlated against high signal-to-noise (S/N) template profiles to produce a dataset of high-precision pulse 'times of arrival' (TOAs). Each TOA represents the mean arrival time of an integrated pulse profile from the pulsar. These are then iteratively fit using a *timing ephemeris* in order to develop a high-precision model of the pulsar's behaviour.

Currently, the GBT accounts for the overwhelming majority of PSR J1757–1854's TOAs, having produced over 22,000 TOAs since it began observing in mid-2016. Data from the GBT is recorded in a full-Stokes coherent search mode at both L and S-bands (800 MHz bandwidth centered at 1500 and 2000 MHz respectively). We currently record one 4.4-hr orbit at each frequency every two months.

Table 1. Latest timing parameters for PSR J1757–1854, based on data from the GBT and Parkes between MJD 57405–59363 and employing the DDH[7] binary model. Values in parentheses give the 1-σ uncertainties on the final digit.

Inclination angle, i (°)	85.0(2)

The most recent timing ephemeris for PSR J1757–1854 is given in Table 1. This includes five theory-independent post-Keplerian (PK) relativistic parameters, from which we can derive three independent tests of gravity. A mass-mass diagram showing the mass constraints imposed by each PK parameter under GR is shown

in Figure 1. By fixing a solution for the masses of the pulsar and the companion neutron star using the intersection of $\dot{\omega}$ and γ (the most precisely measured PK parameters), the further intersection of each remaining PK parameter provides one additional test of consistency. Both the orthometric amplitude and ratio parameters of the Shapiro delay[7] (h_3 and ς) are consistent to within 3.7% and 1.9% of their GR-predicted values respectively, and are approximately consistent with the $\dot{\omega} - \gamma$ intersection. However, although the observed value of the orbital period derivative $\dot{P}_\mathrm{b}$ is also consistent with GR to within at least 1%, its location on the mass-mass diagram is inconsistent with the constraints set by $\dot{\omega}$ and γ under the assumption of GR being correct. This is further discussed in Section 2.1.

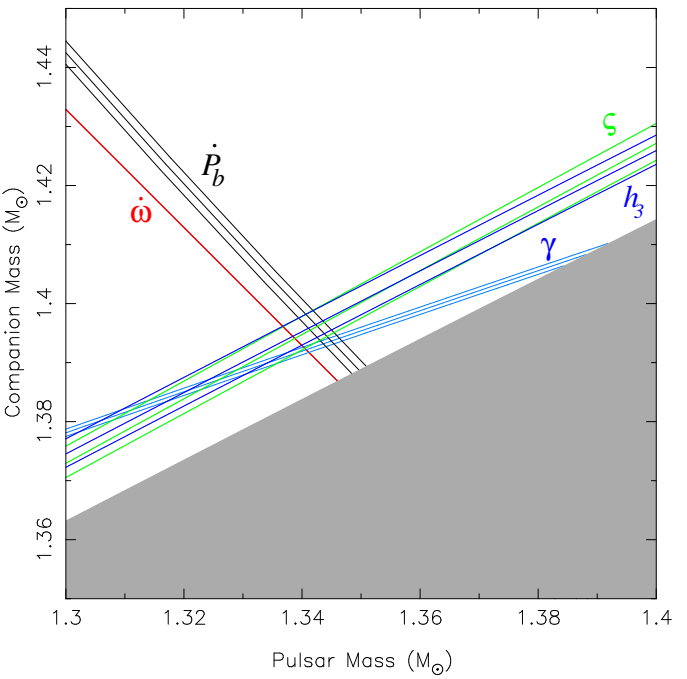

Fig. 1. Mass-mass diagram for PSR J1757–1854. Each coloured triplet of lines shows the constraints (with 1-σ uncertainty) placed by each of the measured PK parameters in Table 1 on the mass of the pulsar and the companion neutron star, in this case according to GR. The measured uncertainty of $\dot{\omega}$ is so small that it cannot be seen at this scale. The grey region in the bottom right is excluded due to orbital geometry.

2.1. *Proper motion and the radiative test of gravity*

A recent development in the timing of PSR J1757–1854 has been the first constrained measurement of the pulsar's proper motion, which is also listed in Table 1. The component in right ascension (μ_α) is detectable at approximately 36 σ, while the component in declination (μ_δ) remains poorly constrained, although its contribution

to the total proper motion remains small given its value relative to μ_α. Together, these values indicate a total proper motion of

$$\mu_{\rm T} = \sqrt{\mu_\alpha^2 + \mu_\delta^2} = 4.4\,(3)\ {\rm mas\,yr^{-1}}. \tag{1}$$

This allows us to attempt to quantify the contributions contaminating the observed value of the orbital period derivative, $\dot{P}_{\rm b,obs}$. We define the excess contribution as

$$\dot{P}_{\rm b,exs} = \dot{P}_{\rm b,obs} - \left(\dot{P}_{\rm b,GR} + \dot{P}_{\rm b,Gal} + \dot{P}_{\rm b,Shk}\right), \tag{2}$$

where $\dot{P}_{\rm b,GR}$ is the expected intrinsic contribution from GR (here calculated using the mass values derived from the observed $\dot{\omega}$ and γ as given in Table 1); $\dot{P}_{\rm b,Gal}$ is the contribution from the acceleration of the pulsar within the Galactic potential[8] (dependent on position, distance and the chosen model of the Galactic potential); and $\dot{P}_{\rm b,Shk}$ is the contribution from the Shklovskii effect[9] (dependent on distance and proper motion).

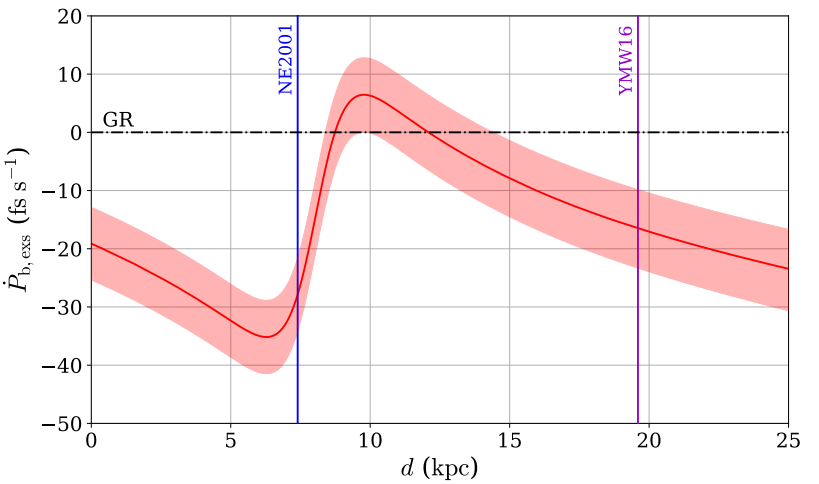

Fig. 2. The excess contribution to the orbital period derivative $\dot{P}_{\rm b,exs}$ as calculated by Equation 2, plotted (red) as a function of distance. The shaded region shows the 1-σ uncertainty. $\dot{P}_{\rm b,Gal}$ was calculated using the McMillan Galactic potential.[10] The vertical blue (left) and magenta (right) lines indicate the NE2001[11] and YWM16[12] DM-distance estimates respectively. The horizontal dashed black line shows the GR expectation of $\dot{P}_{\rm b,exs} = 0$.

For the radiative $\dot{P}_{\rm b}$ test of GR to be considered 'passed', $\dot{P}_{\rm b,exs}$ must be consistent with zero, given that the other contributions have been accurately accounted for. However, although we have now quantified the pulsar's proper motion, we still lack an accurate estimate of the pulsar's distance. This is demonstrated in Figure 2, where we show how $\dot{P}_{\rm b,exs}$ depends on the distance to PSR J1757–1854.

Assuming GR, the distance to PSR J1757–1854 should fall between approximately 8.5–14.5 kpc. Therefore, available distance estimates based on the pulsar's dispersion measure (DM), including both the NE2001[11] (7.4 kpc) and the YMW16[12] (19.6 kpc) electron density models, are currently excluded. This is also shown in Figure 2. However, we note that these DM-distance estimates typically come with large uncertainties,[13] making a definitive determination difficult. Additionally, the McMillan Galactic potential model[10] we have used in our analysis has known shortcomings at distances of approximately 7–9 kpc in the central regions of the Galaxy near PSR J1757–1854's position, further complicating this assessment.

Without an accurate distance to PSR J1757–1854, the utility of the radiative test of gravity is unfortunately limited. As seen in Figure 2, the unknown distance introduces an approximate uncertainty to $\dot{P}_{\rm b,exs}$ of at least $\pm 20 \times 10^{-15}$, more than three times the current uncertainty of $\dot{P}_{\rm b,obs} = 6 \times 10^{-15}$, such that the precision of the radiative test of GR is limited to about 0.4 %. We are currently exploring ways of further refining the estimated distance to PSR J1757–1854 (e.g. through VLBI astrometry). However, by assuming GR, we will still be able to inform our understanding of the pulsar's evolution. For example, the currently allowed distance range indicates a transverse velocity based on $\mu_{\rm T}$ between 180–300 $\mathrm{km\,s^{-1}}$, well in agreement with simulations of the neutron star kick associated with the second progenitor supernova.[2]

3. Attempts to detect the presence of geodetic precession

Our current understanding of the binary evolution of PSR J1757–1854 suggests the strong likelihood of a misalignment between the pulsar's spin vector and the orbital angular momentum vector.[2] As a result, we anticipate the presence of geodetic precession at a rate of $\Omega_{\rm geod} \simeq 3.07\,^\circ\,\mathrm{deg\,yr^{-1}}$, which if detected may serve as another test of GR. We have therefore analysed the current GBT dataset for evidence of changes in the pulse profile, which would indicate a changing line-of-sight through the emission cone of the pulsar as expected from geodetic precession.[14]

Our method adapts an approach previously applied[15] to PSR J1022+1001. Each GBT observation (at both L and S-bands) spanning greater than 80% the orbital period is summed in time, frequency and polarisation before being fit by a template composed of three component Gaussian curves. We then normally re-sample each profile bin using the off-pulse root-mean-squared noise value to generate at least 1,000 randomly 're-noised' profiles, to which the template is re-fit. From each new fitted template, the positions and amplitudes of the major and minor peaks are then measured, as well as the intercept positions at 10% and 50% of the profile's maximum amplitude. The mean and standard deviation of each parameter's statistical distribution across all fitted templates are then taken as the nominal value and its uncertainty.

This approach has for the first time confirmed the presence of statistically significant profile change. An example of this is given in Figure 3, which shows that

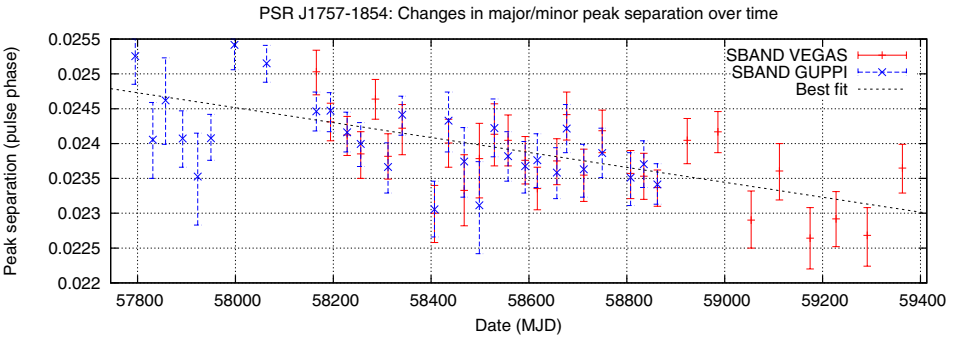

Fig. 3. Change in phase separation of the major and minor peaks of PSR J1757–1854's pulse profile, as measured by the GBT at S-band using the GUPPI and VEGAS backends. The line of best fit corresponds to a decreasing separation of $0.14\,(2)\,^{\circ}\,\mathrm{yr}^{-1}$.

the separation between the two peaks of PSR J1757–1854's profile (termed the 'major' and 'minor' peaks) is decreasing (i.e. moving closer together) by an average rate of approximately $0.14\,(2)\,^{\circ}\,\mathrm{yr}^{-1}$. The width of the profile at both 10% and 50% also appears to be shrinking at a commensurate rate, with all trends most pronounced at S-Band due to the decreased influence of scattering (with respect to lower-frequency L-band observations). The precise physical implications of these changes are to be explored in a future publication, but their detection provides fundamental evidence for the presence of geodetic precession, as well as evidence for the suspected spin/orbit misalignment present in the binary system.

4. Searches for the companion neutron star

If PSR J1757–1854's neutron star companion was confirmed to be an active radio pulsar, it would immensely enhance the scientific utility of this pulsar and its binary system. This is most obviously demonstrated by the prior example of the Double Pulsar, where the presence of the second pulsar PSR J0737–3039B allowed additional tests of gravity beyond those normally available, including the detection of geodetic precession[16] and an independent determination of the mass ratio.[17]

We have therefore conducted an ongoing search for evidence of pulsations from the neutron star companion to PSR J1757–1854. This search has focused on observations from the GBT, which are recorded in a coherently-dedispersed search mode so as to allow for optimal search sensitivity across all pulse periods. Given our precise knowledge of PSR J1757–1854's orbit as detailed in Table 1, each observation is re-sampled using the inferred orbit of the companion via the custom software package PYSOLATOR.[18] This allows the companion to appear stationary such that any pulsations would appear as a single narrow peak in a resulting Fourier spectrum. To account for the small degree of uncertainty in the companion orbit, different

re-sampled trials are produced using values of the mass ratio $q = m_{\rm p}/m_{\rm c}$ between $0.9554 < q < 0.9661$ in increments of 0.00005. The resulting Fourier power spectra from each observation are then stacked and summed, boosting the total S/N of any pulsations.

To date, this search has unfortunately returned negative results, although the complete GBT dataset has yet to be analysed. In total, approximately 389.7 hr of GBT observations are currently on file, although there is significant overlap in this dataset between the VEGAS and GUPPI backends during intervals when both were recorded simultaneously. Ongoing searches for the companion neutron star will continue, as the companion may become detectable in the event that it precesses into view in the near future, given the expected precession rate of $\Omega_{\rm geod} \simeq 2.97\,^\circ\,{\rm deg\,yr^{-1}}$.

5. Future observations and anticipated tests of gravity

5.1. *Addition of MeerKAT*

Although observations with South Africa's MeerKAT telescope have been ongoing since 2019 as part of the MeerTIME program,[19] all these observations took place with MeerKAT's L-band receiver, which has a large 856 MHz bandwidth centered at 1283.5 MHz. This frequency band is located at lower frequencies than those of the GBT L-band receiver and therefore is much more susceptible to pulse broadening via scattering than the GBT L-band.[20] As a consequence, even though MeerKAT can achieve about twice the S/N of the GBT for this target, the available timing precision from both telescopes is roughly equivalent.

These effects are expected to be mitigated as part of the ongoing rollout of a fleet of MeerKAT S-band receivers (with a bandwidth of approximately 1750 MHz centred at 2625 MHz), designed by the MPIfR. The decreased influence of scattering at these higher frequencies combined with the wider bandwidth and the pulsar's relatively flat spectral index suggest an improvement in TOA precision to within 10 μs or better (compared with a typical TOA precision of 25–30 μs currently achievable using similar TOA integration times with the current GBT and MeerKAT receivers). This will provide a significant advantage in the ongoing timing of the pulsar.

5.2. *Future tests of gravity*

PSR J1757–1854 is expected to provide new insight into two rarely-explored tests of gravity within the next few years. The first of these is the *relativistic orbital deformation*, characterised by the PK parameter δ_θ, which describes the deviation of the orbit from a pure Keplerian ellipse due to the effects of relativity. The measurability of δ_θ scales with both eccentricity and $\dot{\omega}$, positioning PSR J1757–1854 as an ideal system for providing constraint in the short-term. Meanwhile, the Hulse-Taylor pulsar[21] (lower $\dot{\omega}$) and the Double Pulsar (lower eccentricity) have to date only weakly constrained δ_θ despite having been studied for far longer.

The second anticipated test involves the detection of Lense-Thirring precession, which to date has not been detected in a double neutron star binary system. We intend to detect this effect via the measurement of a change in the semi-major axis,[22] $\dot{x}_{\rm LT}$. Although in general $\dot{x}_{\rm LT}$ becomes negligible for small misalignment angles between the pulsar spin and orbital angular momentum vectors, our recent detection of geodetic precession confirms that a significant misalignment is likely. The Lense-Thirring effect is also proportional to the neutron star moment of inertia; should the Lense-Thirring effect be detected here, it would lead to a rare measurement of this quantity and thereby provide insight into the neutron star equation of state.

The timescale over which each of these parameters is anticipated to be constrained was determined by a simulation of the anticipated timing campaigns. A simulation was produced by extrapolating the current GBT timing campaign until the end of 2024, and including an equivalent MeerKAT S-band campaign comprising one full orbit recorded every two months, starting in 2022. Timing ephemerides were fit to the data at set intervals, while averaging the results of 30 realisations of the dataset. Based on these simulations, we anticipate the achievement of a 3-σ constraint of δ_θ between approximately 2024–2025, and of $\dot{x}_{\rm LT}$ between 2025–2026.

Acknowledgments

The Parkes radio telescope is part of the Australia Telescope National Facility which is funded by the Australian Government for operation as a National Facility managed by CSIRO. On the origin of the unique isolated X-Ray pulsar 1E 161348-5055 with 6.7 hr. spin period

V. Yu. Kim

Fesenkov Astrophysical Institute

A scenario for the formation of an isolated X-ray pulsar 1E161348-5055 with an anomalously long period of 6.7 hours is proposed. It is shown that this pulsar can be a descendant of a massive X-ray binary system, which disintegrated about 2000 years ago after a supernova explosion caused by the core collapse of a massive component. X-ray radiation of this object in the present epoch is generated as a result of accretion of matter onto (about 10 million years old) neutron star from the residual non-Keplerian accretion disk. The pulsar's nebula RCW 103 is a supernova remnant formed by the explosion of its massive companion in the final evolutionary phase of a massive binary system.

Keywords: X-Ray pulsar, isolated neutron star, accretion, stellar evolution

Introduction

X-ray pulsar 1E 161348-5055 (hereinafter 1E 1613) was discovered in 1979 by means of the Einstein cosmic observatory, as a point X-ray source in the supernova remnant RCW 103.[1] The distance to RCW 103 was approximately estimated as $d \simeq 3.2 \pm 0.1$ kpc from the analysis of absorption of radio emission by neutral hydrogen in the 21 cm line.[2] The estimated age of RCW 103 from the expansion rate and size of the nebula is about $\tau \simeq 2000 \pm 1000$ yr.[2] The nebula is an atypical remnant of a SN II type. It has an almost rounded shape with a fibrous structure, a low expansion rate (~ 1100 km/s) and it has a relatively small spatial size 7.7 pc for its age.[3] Nebulae with such parameters account for less than 20 % of the currently known SN II supernova remnants, the explosion of which apparently occurred in a high-density gaseous medium.[4] After the discovery of this pulsar, it was suggested that this object is an isolated cooling neutron star in the peculiar supernova remnant RCW 103.[5] However, in the period 1997-1999, during the study of 1E 1613 by the ASCA space observatory, significant variations in the source brightness were detected and the thermal component emitted by a hot spot $kT \sim 0.6 - 0.8$ keV with a radius of $a_{\rm p} \sim 600$ m,[6,7] was found. It is not typical for a cooling neutron star, but typical for magnetized neutron stars accreting matter on their surface. This served as the basis for the hypothesis that 1E 1613 is a neutron star accreting matter in the area of the magnetic poles. The average X-ray luminosity of the source is $L_{\rm x} \sim 10^{34}$ erg/s.[6,7] The report about the possible X-Ray variability of 1E 1613 with a period of ~ 6 hours, discovered from the results of observations

of this source by the "Chandra" observatory, stimulated the search for an optical companion of the neutron star. Observations made for this purpose with the ESO VLT telescope in the near infrared, however, allowed to establish only the upper limit of the luminosity of a hypothetical companion $L_{\rm ir} \sim 10^{31}$ erg/s, which could be a star of a later spectral class than M4.[8] This result became a strong argument in favor of the fact that 1E 1613 is not part of a close binary system and it is an isolated neutron star, whose radiation is caused either by accretion of matter from the residual disk or by the rapid dissipation of a superstrong magnetic field.[9]

In 2006, by means of the XMM-Newton space telescope, it was possible to establish the spin period of 1E 1613 $P_{\rm s} \simeq 6.67 \pm 0.003$ hr.[10] None of the known pulsars had such a long spin period. Almost immediately after the discovery of the period, several hypotheses were put forward about the nature of object 1E 1613. One of the first idea was the assumption that this object is a unique magnetar accreting matter from the surrounding residual (fall-back) disk, with a magnetic field $> 10^{15}$ G.[9,10] It was also hypothesized that 1E 1613 is a magnetar in a low-mass close binary system.[5] Subsequently, it was suggested that 1E 1613 is a millisecond pulsar in a close binary system, where the observed period (6.7 hours) was assumed as an orbital period (the so-called period mimicry).[11]

In 2011, from the analysis of the pulsation profiles obtained from space observatories: "Swift", "Chandra", "XMM-Newton", the upper limit of the rotation deceleration was calculated $\dot{P}_{\rm s} \leq 1.6 \times 10^{-9}$ s/s or $\dot{\nu}_{\rm s} \leq -2.8 \times 10^{18}$ Hz/s (here $\nu_{\rm s} = 1/P_{\rm s}$ - spin frequency).[12] Analyzing their result, the authors of this discovery noted that the moment of force applied to a neutron star in the present epoch is significantly less than the value expected in all previously proposed models of this source. The high stability of pulsations apparently indicates that the spin period of the star at the present epoch is close to the equilibrium period of its spin rotation, the value of which weakly depends on changes in the accretion rate in the residual disk. It was shown in the article[13] that such a situation is realized in the scenario of Magnetic Levitation accretion, in which a neutron star with a magnetic field 10^{12} G accrets onto its surface matter from the residual non-Keplerian magnetic disk.

1. Formation of an isolated pulsar during the decay of a binary system

We consider a situation in which 1E 1613 is a neutron star, born in a close massive binary system during the first supernova explosion. We assume that this did not lead to the disintegration of the system and the neutron star formed a close pair with its massive companion. The initial rotation period of the neutron star was fractions of a second and increased as the star successively passed the ejector and propeller states. Upon completion of this phase, the star passed into an accretor state, in which it remained until the second supernova explosion, caused by the collapse of the core of its massive companion.This event most likely led to the disintegration of the system,[14] and the old neutron star passed into the state of an isolated pulsar,

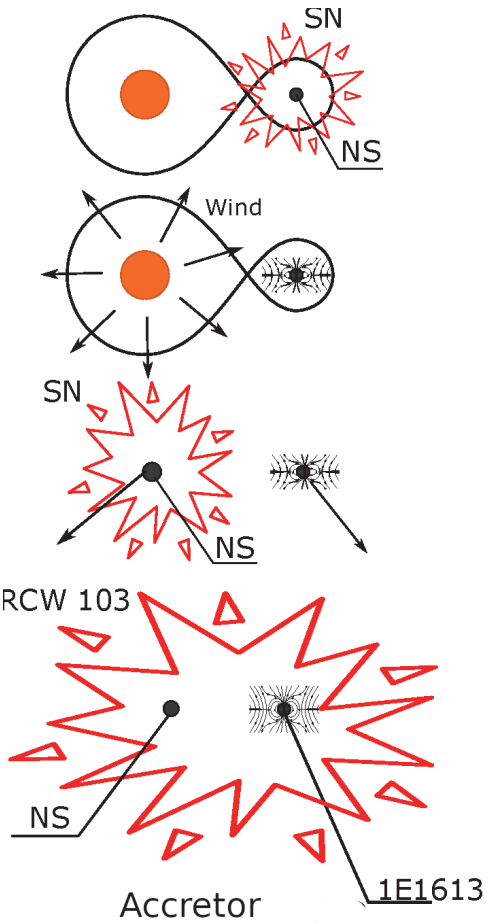

Fig. 1. Possible way of formation of isolated X-ray pulsar as a descendant of high-mass X-ray binary system

immersed in the remnant of its companion supernova, observed in the present epoch as the RCW 103 nebula.

2. Magnetorotational evolution

The scenario of the evolution of a high-mass X-ray binary system (HMXB) described above has been sufficiently studied by now and is perceived by most authors as canonical (see the article [Postnov et al., 2014][15] and the literature cited there). The lifetime of such a system is estimated by the evolution time of its optical component on the main sequence with mass $M_{\rm opt}$ corresponds to[16]:

$$t_{\rm ms} \simeq 6 \times 10^6\, yr \times \left(\frac{M_{\rm opt}}{M_\odot}\right)^{-5/2} \qquad (1)$$

Numerical modeling of the magnetorotational evolution of a neutron star in the framework of such a scenario with allowance for the dissipation of its magnetic field was carried out by Urpin et al.[17] According to the results of their calculations, the magnetic field of the star during $t_{\rm ms}$ decreases by an order of magnitude due to diffusion and accretion screening.[18] In particular, with an initial value of $\sim 10^{13}$ G, the magnetic field on the surface of a star that has evolved as part of HMXB system is $\sim 10^{12}$ G. Such a neutron star spends most of its evolution in the ejector state (see formula 17 in the paper[19]):

$$t_{\rm ej} \simeq 3 \times 10^6\, yr\ \times \mu_{30.5}^{-1}\, I_{45}\, \dot{M}_{14}^{1/2}\, \upsilon_7^{-1/2} \tag{2}$$

Here: $\mu_{30.5} = \mu_{\rm ns}/3 \times 10^{30}$ G cm^3 - normalized magnetic dipole moment of a neutron star, $I_{45} = I_{\rm ns}/10^{45}$ g cm^2 - its moment of inertia, $\dot{M}_{14} = \dot{M}/10^{14}$ g/s - normalized accretion rate, $\upsilon_7 = \upsilon_{\rm rel}/10^7$ cm/s - related velocity of a neutron star into surrounded medium. During this stage, its magnetic field decreases by an average of 3 times (the rapid cooling of the star during this phase significantly reduces the rate of diffusion of the magnetic field in its crust[17]).

As the rotation period of the star reaches a critical value (see formula 16 in the paper[19]), it passes into the propeller state.

$$P_{\rm ej} \sim 1.2\,{\rm s}\ \times \mu_{30.5}^{1/2}\, \dot{M}_{14}^{-1/4}\, \upsilon_7^{-1/4} \tag{3}$$

At this stage, the spin-down torque applied to the star by the penetrating under its Bondi radius gas is determined by the expression $K_{\rm sd}^{\rm pr} \sim \mu_{\rm ns}^2/r_{\rm m}^3$. The duration of the propeller stage substantially depends on the geometry and physical parameters of the accretion flow.

$$\tau_{\rm pr} = \frac{\pi\, I\, r_{\rm m}^3}{\mu_{\rm ns}\, P_{\rm ej}} \tag{4}$$

This parameter reaches its minimum possible value in the case of the scenario of Magnetic Levitation accretion:[13]

$$\tau_{\rm pr}^{\rm (ml)} \simeq 6 \times 10^3\, yr\ \times \alpha_{0.1}^{6/13}\, \mu_{30}^{-29/26}\, I_{45}\, m^{3/13}\, T_6^{-6/13}\, \dot{M}_{14}^{-35/52}\, \upsilon_7^{1/4} \tag{5}$$

In the paper[13] we showed that 1E 1613 could be in the accretor stage, the material for the accretion is supplied by the surrounding residual Magnetic Levitating disk or ML-disk formed from the supernova remnant RCW 103. The magnetic field strength 1E 1613 in this model (Magnetic Levitation accretion) corresponded to 10^{12} G, which corresponds to the canonical value of the magnetic field of neutron stars. For detailed explanation, see articles [Ikhsanov et al., 2013, 2015].[13,20]

3. Conclusions

The main conclusion of this study is to explain the origin of an isolated X-ray pulsar with a period of 6.7 hours within the canonical scenario of the evolution of a massive X-ray binary system without invoking the hypothesis of superstrong

magnetic fields on the surface of a neutron star. Our proposed model is consistent with modern concepts of a relatively small value of the initial rotation period of neutron stars and does not require invoking the additional assumption of fall-back accretion onto a neutron star after its birth.

The age of a neutron star 1E 161348-5055, manifesting itself in the present epoch as an isolated X-ray pulsar, is comparable to the lifetime of a massive X-ray binary system, estimated by Eq. (1) and amounts to several million years. The lifetime of this star in the state of an isolated X-ray pulsar, however, is much shorter. It corresponds to the time elapsed since the collapse of the massive X-ray binary, which is comparable to the age of the RCW 103 nebula and is about 2000 years (see also the article[20]).

The residual accretion disk surrounding the magnetosphere of a neutron star in the present epoch could have been formed during its evolution as part of a massive X-ray binary system or after the disintegration of the system during the capture of matter by an old neutron star from an envelope ejected by its massive component during a supernova explosion.

Isolated X-ray pulsars with long periods, within the framework of our model, are descendants of the widest pairs in which a massive component at the last stage of its evolution does not fill its Roche lobe and the capture of matter from the stellar wind remains the dominant mechanism of mass exchange between the components of the system at all stages of its evolution. The lifetime of such a pulsar depends on the mass of the residual disk and the physical parameters of the gas, which determine the rate of diffusion of the magnetic field in it. The main candidates for descendants of close binary systems are isolated X-ray pulsars located in the supernova remnants formed during the explosion of massive companions.

Even though Pulsar Timing Arrays already have the potential to detect the gravitational wave background by finding a quadrupole correlation in the timing residuals, this goal has not yet been achieved. Motivated by some theoretical arguments, we analyzed some advantages of including the millisecond pulsars within globular clusters, especially those in their cores, in current and future Pulsar Timing Array projects for detecting the gravitational waves emitted by an ensemble of supermassive black holes.

Keywords: Black Holes; Gravitational Waves; Pulsars.

1. Introduction

Within the context of the Albert Einstein theory of General Relativity,[1] gravitational waves (GWs) are space perturbations propagating at the speed of light in the vacuum. Due to the smallness of their amplitude, which in most cases is less than 10^{-16}[a], their detection is a challenging problem and, in fact, it took a hundred years since they were predicted for the first time. Nowadays, ground-based gravitational interferometers, such as those of the LIGO (Laser Interferometer Gravitational-Wave Observatory), KAGRA (Kamioka Gravitational Wave Detector) and VIRGO collaboration, are currently the only instruments capable of efficiently detecting GWs. Their sensitivity allows to detect high-frequency (i.e. in the range 10–10^3 Hz) GWs emitted by compact object systems, such as black hole binaries,[2] neutron star binaries[3] and neutron star-black hole binaries,[4] in the final phase of the merger. The detection of low-frequency (i.e. in the frequency range $\simeq 10^{-5}$–1 Hz) GWs is more challenging because it requires space-based gravitational interferometers such as LISA (Laser Interferometer Space Antenna), which is planned to be launched for 2034 and consists of a constellation of three satellites, separated by about 1.5×10^6 km, in a triangular configuration, orbiting with Earth around the Sun.[5,6] However, ultra-low frequency (i.e. in the frequency range $\simeq 10^{-10}$–10^{-6} Hz) GWs, that may be generated by sources relevant for astrophysics and cosmology, such as supermassive black hole binaries (SMBHBs)[7] and cosmic strings,[8] and form the gravitational

[a]This is a dimensionless quantity describing how a spatial dimension is stretched or squeezed by the passage of a GW.

wave background (GWB), are out of the range of any kind of gravitational interferometers and can only be detected by Pulsar Timing Arrays (PTAs)[b].

PTAs constantly monitor the pulsed radio emission from the most stable isolated and binary millisecond pulsars across the sky to detect variation between the observed pulse time of arrival (ToA) and the one expected from the timing model. Such variation, referred to as timing residuals, may be GW-induced. Indeed, GWs can modify the distance between the Earth and the MSP, causing advances or delays in the pulse ToAs.[10,11] As GWs, many other effects may induce timing residuals, so they must be distinguished from GWs. At present, the only way of doing this is by verifying that the cross-correlations between the timing residuals of each MSP pair follow the Hellings and Downs function, which is due to the quadrupole nature of GWs.[12]

The main PTA collaborations are the European Pulsar Timing Array (EPTA), the Indian Pulsar Timing Array (InPTA), the North American Nanohertz Observatory for Gravitational Waves (NANOGrav), and the Parkes Pulsar Timing Array (PPTA), and all of them are part of the International Pulsar Timing Array (IPTA). These PTAs have timed about forty MSPs for more than ten years with an accuracy that should be sufficient, in principle, to detect gravitational waves. Some clues of the presence of a common red process compatible with a GWB was found, but there is still not a strong enough evidence for or against it.[13–15] The reason behind that is yet unclear. Most likely, this could be due to the small number of MSPs available for PTAs, so continuing to add suitable MSPs should allow claiming detection, or to an insufficient observation time spawn, so it is essential to continue collecting data for many more years. Another option is that the standard GW search technique needs to be complemented by independent methods.

2. Back to the Theory

The GW-induced timing residuals are described, in a compact form, by[c]

$$r(t,\Omega^i) = \mathrm{Re}\left\{ \frac{h}{j\omega} \sum_{A=+,\times} \frac{1}{2} \frac{p^i p^j e^A_{ij}}{(1+\Omega_i p^i)} \left[e^{j(\omega\tilde{t}-\alpha^A)} - e^{j(\omega\tilde{t}-\omega\tau(1-\Omega_i p^i)-\alpha^A)} \right]_0^t \right\} \quad (1)$$

where h, ω, A, e^A_{ij}, and α^A indicate the GW amplitude, angular frequency, polarization state, polarization tensor, and the initial phase, respectively, $\tilde{t}$ is a mute variable, τ is the time distance between the Solar System Barycenter (SSB), Ω_i and p^i indicate the direction versors of the GW source and the MSP, respectively. The two terms in the square brackets are known as Earth[d] term and Pulsar term, and

[b]For a quick graphic overview of the different GW sources and GW detectors, see Ref. 9.
[c]For a complete theoretical description, see Ref. 16.
[d]The name "Earth" is a legacy of early work on PTAs.[17] In fact, since the Earth is not an inertial reference frame, the observer is assumed in SSB, whose position is known with great precision.

describe the metric in the proximity of the two objects[e]. Eq. (1) implies that, for an arbitrary MSP set, the Earth term is the same, while the Pulsar term changes. Since the latter term gives rise to an uncorrelated contribution in timing residuals, it is neglected in the standard GWB search[f]. This assumption is not entirely true if the MSP set is confined in a very small region, as in the case of globular clusters (GCs). Therefore, the GW-induced timing residuals of MSPs within GCs, especially those in their cores, should be strongly correlated, so considering these MSPs may offer a new instrument for GW detection.

3. Simulated Environment

The main target of the GW search with PTA is the GWBs produced by a hypothetical SMBHB population. Such a detection would give crucial information on the history of the Universe and, since that has not yet been achieved, it is worth considering improving PTAs by including MSPs within GCs.

We simulated the GW-induced timing residuals on GC core MSPs due to an SMBHB population. We arbitrarily assumed that the SMBHB chirp mass, distance, and GW emission frequency follow a log-normal distribution[g] and are in the ranges 10^8–10^9 $M_\odot$, 10^8–10^9 pc, and 10^{-9}–10^{-8} Hz, respectively, and that the SMBHB right ascension and declination follow a uniform distribution (see Fig. 1).

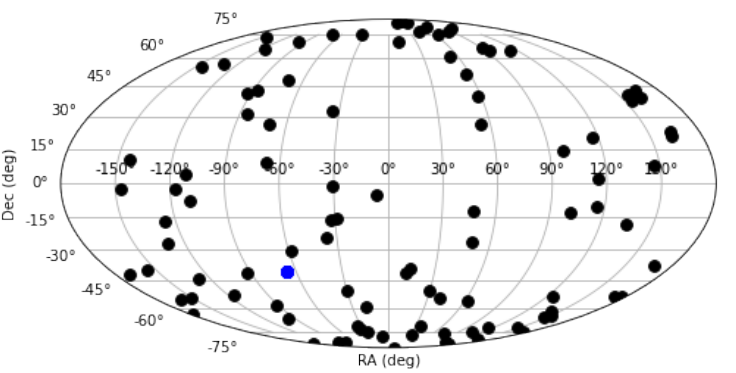

Fig. 1. Simulation of the SMBHB population. The position of 100 simulated SMBHBs, randomly scattered all over the sky is shown. The black dots indicate the SMBHB coordinates (RA and Dec), while the blue dot indicates the simulated GC coordinates.

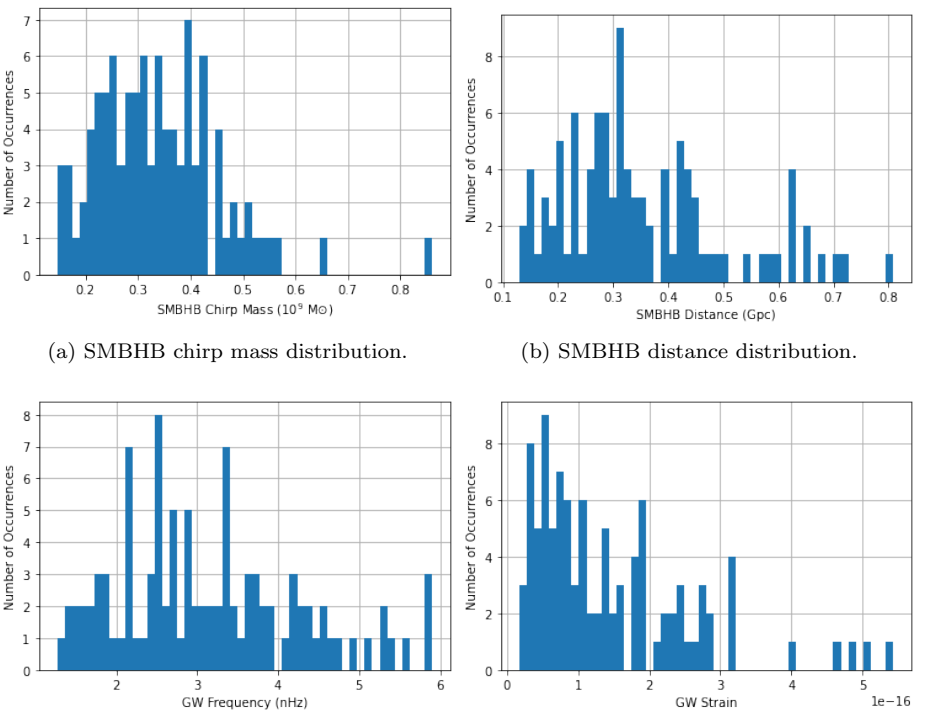
[e]In this paper geometrical units c=G=1 have been adopted.
[f]However, it is important to remark that the pulsar term may play an important role in the detection of GW emitted by single sources.
[g]The properties of the SMBHB population are still a matter of debate. However, this paper aims to explain how PTAs can be improved by including MSPs within GCs, so we took the results in Refs. 18–20 just as a guide for building SMBHB distributions compatible with the GW-induced timing residuals observable by PTAs.

The SMBHB strain is, in good approximation, given by:

$$h = \sqrt{\frac{32}{5}} \frac{\mathcal{M}^{5/3}}{D} \left(\frac{2\pi f}{1+z} \right)^{2/3} \tag{2}$$

where $\mathcal{M}$, D, z, and f indicate the SMBHB chirp mass, distance, cosmological redshift, and GW emission frequency, respectively. Eq. (2) allows to determine the GW strain distribution for our SMBHB population (see Fig. 2).



(a) SMBHB chirp mass distribution.

(b) SMBHB distance distribution.

(c) GW frequency distribution.

(d) GW strain distribution.

Fig. 2. SMBHB parameter simulation. Panel (a) shows the SMBHB chirp mass log-normal distribution, expressed in units of $10^9\ M_\odot$. Panel (b) shows the SMBHB distance log-normal distribution, expressed in Gpc. Panel (c) shows the GW frequency log-normal distribution, expressed in nHZ. Panel (d) shows the GW strain distribution, expressed in units of 10^{-16}. On the vertical axis of each panel is plotted the number of occurrences.

We also assumed that the GC core MSP distance[h], right ascension, and declination with respect to the GC center follow a uniform distribution[i]. To get a realistic

[h]In this paper, MSP distance refers to the distance with respect to the diametrical plane passing through the GC center and orthogonal to the line-of-sight.

[i]In accordance with what is described by the GC core mass-density distribution.[21]

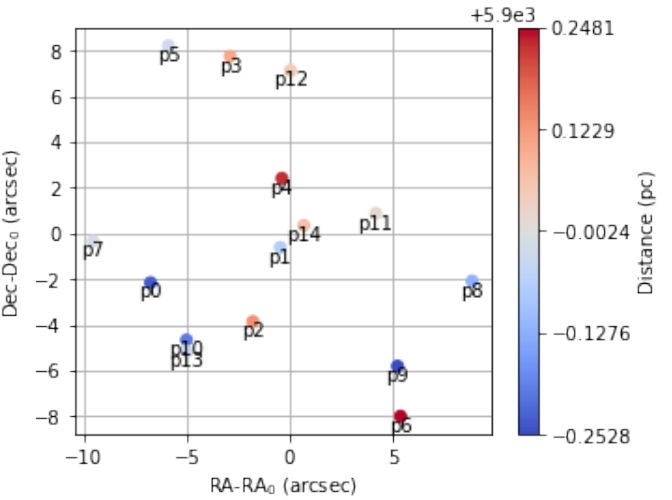


Fig. 3. Simulation of the MSP set. The position of 15 simulated GC core MSPs, randomly scattered within a GC core, whose distance and angular radius are 5.9 kpc and 0.16 arcmin, respectively, is shown. The dots indicate the MSP coordinates (RA and Dec), with respect to the GC center (RA_0 and Dec_0), expressed in arcsec, while the dot colors indicate, as described by the color bar, the MSP distance with respect to the GC core center, expressed in pc (the MSP distance with respect to the SSB can be obtained by summing the values expressed by the labels of the color bar with the quantity on its top).

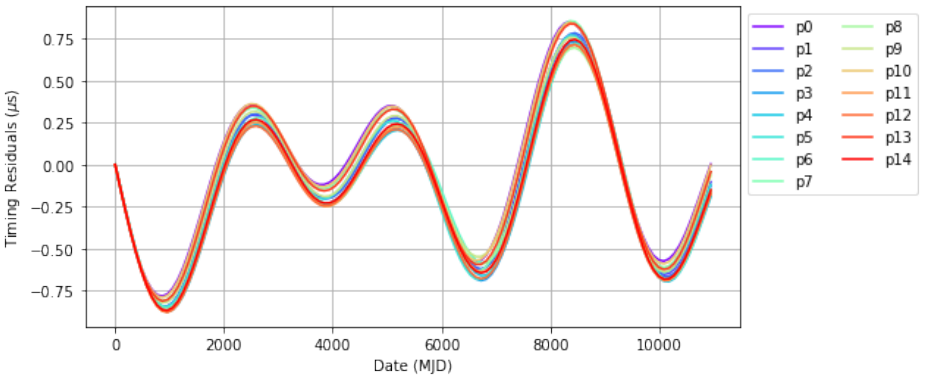
result, we took the GC core distance, angular radius, and MSP number of the Terzan 5 GC since it is one of the most populated by MSPs[22–24] (see Fig. 3).

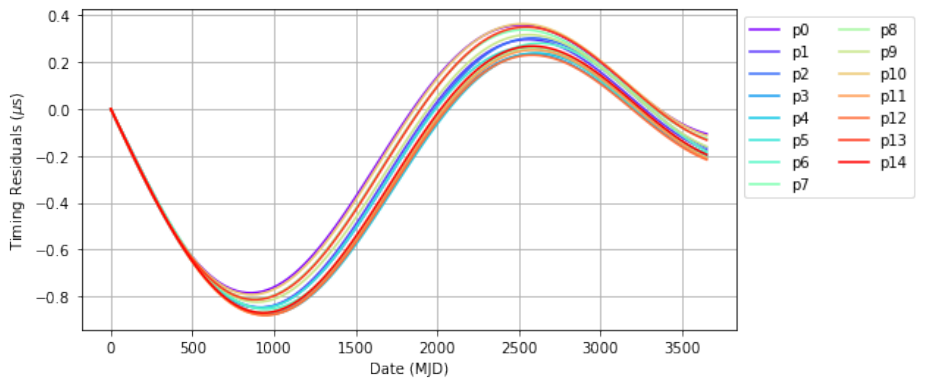
We finally calculated the simulated GW-induced timing residuals corresponding to each GC core MSP due to the overall contribution of the GW emission from each SMBHB (see Fig. 4).

4. Results

The simulation results (see Fig. 4) confirm what has been deduced in Sec. 2. In the PTA frequency band, the simulated GW-induced timing residual corresponding to each GC core MSP due to the overall contribution of the GW emission from each SMBHB appear to be strongly correlated. This property can be very useful in the GW search. Observing such correlation for the GC core MSPs would lead to a strong evidence for the GWB, especially if supported by stronger hints of a common red process compatible with a GWB. GC core MSPs can also be helpful for determining the quadrupolar nature of the cross-correlations between the timing residuals of each MSP pair. Indeed, the Hellings and Downs function has a global maximum when the angular distance between an MSP pair is null. Of course, it is unlikely to have an aligned MSP pair by chance, but this frequently happens in GCs due to physical reasons. Therefore, GCs offer the unique possibility of obtaining cross-correlation



(a) Simulated 30 years GW-induced timing residuals.



(b) Simulated 10 years GW-induced timing residuals.

Fig. 4. GW-induced timing residuals. Panel (a) shows the simulated GW-induced timing residuals corresponding to each GC core MSP due to the overall contribution of the GW emission from each SMBHB, plotted over a time interval of 30 years. Panel (b) shows the GW-induced timing residuals, plotted over a time interval of only 10 years. In both panels, the colored curves indicate the simulated GW-induced timing residuals, and have a different color for each GC core MSP, as described by the legend. On the horizontal axis of both panels the date measured from the arbitrary beginning of the simulated ToA observation, expressed in MJD, is plotted. On the vertical axis of both panels the timing residuals, expressed in μs, are plotted.

data for low angular separation MSPs, which can be very important because they might challenge or confirm the prediction of the Hellings & Downs function.

5. Conclusion

The proximity between the MSPs lying in a given GC, especially those in the GC core, can be exploited to get unique information about GWs and, for this reason, it is worth considering improving PTAs by including them.

It is important to note that, in the presented analysis, it has been considered an ideal situation to highlight some of the advantages of including MSPs within

GCs in PTAs. On the other hand, this class of MSPs is currently not timed with a precision adequate to detect GW-induced timing residual.[25,26]

Nevertheless, we expect that to change soon, thanks to new detectors, such as the Five hundred meter Aperture Spherical Telescope (FAST),[27] the MeerKAT radio telescope,[28] and the Square Kilometre Array (SKA).[29] SKA, in particular, will play a crucial role in ultra-low frequency GW detection. With its unprecedented sensitivity, it will be possible to time significantly better the GC MSPs, opening the possibility of adopting the strategy proposed in this paper, which is a summary of Ref. 30.

Searching for pulsars in globular clusters with the MeerKAT Radio Telescope

F. Abbate on behalf of the MeerTIME/TRAPUM Collaboration
Max Planck Institut für Radioastronomie,
Auf dem Hügel 69, D-53121, Bonn, Germany
E-mail: abbate@mpifr-bonn.mpg.de

Globular clusters are known to host an unusually large population of millisecond pulsar when compared to the Galactic disk. This is thanks to the high rate of dynamical encounters occurring in the clusters that can create the conditions to efficiently recycle neutron stars into millisecond pulsars. The result is a rich population of pulsars with properties and companions difficult or impossible to replicate in the Galactic disk. For these reasons, globular clusters have been and still are a prime target of searches for new and exciting pulsars. Because of their large distances, the limiting factor inhibiting these discoveries is the telescope sensitivity. The MeerKAT radio telescope, a 64-dish interferometer in South Africa, guarantees unrivalled sensitivity for globular clusters in the southern sky. Observations of well-studied globular clusters with MeerKAT have already returned more than 35 new pulsars with many more expected. These exciting discoveries will help us to understand more about the neutron star equation of state, stellar evolution, accretion physics and to hunt for intermediate mass black holes. In this talk I will present the prospects and current discoveries of the globular cluster working group in the MeerTIME and TRAPUM programmes.

Keywords: Pulsars; globular dusters.

1. Pulsars in globular clusters

Globular clusters contain a very rich population of pulsars with 232 known in 36 cluster[a] and this population is quite peculiar when compared with the one in the Galactic disk. The abundance of pulsars per unit of stellar mass in globular clusters is ~ 100 times higher than that of the disk and the vast majority of the pulsars are millisecond pulsars (MSP) with rotation periods shorter than a few tens of ms.

The difference between the population of pulsars in globular clusters and in the Galactic disk is caused by the starkly different environments. Globular clusters have no sign of recent star formation and have very high stellar densities in their cores that can reach up to $\sim 10^{4-5}$ $M_\odot\,pc^{-3}$ compared to $\sim 1-10$ $M_\odot\,pc^{-3}$ in the Solar neighbourhood. This high stellar density favours dynamical encounters between stars that can lead to exchange encounters where neutron stars become part of new binary systems. The exchanges of companions increase the chance of the neutron star going through an accretion phase boosting the number of low mass

[a]An up-to-date count can be found in the webpage `https://www3.mpifr-bonn.mpg.de/staff/pfreire/GCpsr.html`

X-ray binaries (LMXB) that evole into MSPs. Once a neutron star has been recycled into an MSP, it is likely to remain active for a time even longer than the Hubble time due to the low magnetic field.

Due to the peculiar environment within globular clusters, the possibility of going through multiple stages of recycling and the lack of recent star formation, the majority of pulsars have very fast rotational periods usually smaller than 20 ms. The fastest pulsar known, PSR J1748−2446ad,[1] with a rotational period of 1.395 ms resides in the globular cluster Terzan 5. Not all of the pulsars in globular clusters are, however, very fast. There is a small population of pulsars where the accretion process was interrupted before completion,[2] possibly by external encounters, with period between 20-100 ms called 'mildly recycled'. Furthermore, there is, in some specific clusters, a small number of slow pulsars with periods over 100 ms with the record of 1004.04 ms being held by B1718−19A in NGC 6342.[3] The presence of these apparently 'young' pulsars is in contradiction with the known formation scenarios and the lack of new star formation. Apart from dynamic disruption of LMXB[2] other possible explanations have been put forward like accretion-induced collapse, direct collisions with a main sequence star,[4] or electron capture supernova of an OMgNe white dwarf.[5]

The MSPs populations of globular clusters is also quite different from the one in the Galactic disk. The percentage of isolated to binary MSPs can vary a lot between clusters with some like NGC 6624 and NGC 6517 having mostly isolated pulsars and others like M62 and M5 having mostly binary pulsars. This is linked to the dynamical parameters of the clusters.[2]

The multiple dynamical interactions create a population of binary MSPs that are in some cases very different from the Galactic disk population. Eclipsing systems with non-degenerate companions like 'black widows' and 'redbacks' are common.[3,6,7] Binary systems can acquire high eccentricities and massive companions through successive interactions or through exchange encounters like M15C,[8] NGC 1851A,[9] NGC 6544B,[10] and NGC6652A[11] . A very peculiar triple system with a white dwarf and a Jupiter-mass companion has also been observed in a globular cluster.[12,13]

1.1. *Science with pulsars in globular clusters*

The scientific achievements made possible by this unique population of pulsars together with the possibility of observing a large number of pulsars in the same telescope beam have made globular clusters a high priority target in the past decades.

The internal composition of neutron stars is determined by the equation-of-state that can be probed by measuring their masses. This can be achieved through pulsar timing by measuring the so-called post-Keplerian parameters, which quantify relativistic orbital effects.[14] One of these parameters is the relativistic precession of the periastron that is relatively easily accessible in highly eccentric systems, and can be used to place constraints on the total mass of the systeem assuming

general relativity. Thanks to this method, some neutron stars with the potential of breaking the current mass limit have been identified.[15,16] The importance of determining neutron star masses is not limited to the value of the maximum mass, also the minimum mass and the distribution of masses can be used to test various formation and recycling scenarios.[17]

Another avenue of research that can be pursued in globular clusters regards the maximum rotation speed. Currently the record of 1.395 ms is held by J1748-2446ad in Terzan 5[1] but even faster pulsars might be present in clusters and set more constraints on the equation of state.

Studies of eclipsing pulsars like 'black widows' and 'redbacks' are essential to study the possible evolution scenarios of MSPs and to constrain the properties of the companions.[18,19]

If we change focus from specific pulsars to the entire population of pulsars in a single cluster, the science perspective broadens to include the properties of the globular clusters themselves. The gravitational effects of the globular clusters on the pulsars are accessible through the derivatives of the rotational period.[20] With a significant number of pulsars, this can give us access to the structural parameters of the clusters and explore the possibility of the presence of an intermediate mass black hole in the center.[21–23]

Using the dispersion measures (DM) and estimating the 3-d position of the pulsars inside the cluster, it becomes possible to look for diffuse gas. This method has led to the first detection of ionized gas in a globular cluster.[23,24] If we add the information coming from the rotation measure, it becomes possible to probe also the magnetic fields. This led to the possible discovery of a magnetized outflow from the Galaxy in the direction of the globular cluster 47 Tucanae.[25]

The numerous scientific possibilities suggest that globular clusters pulsars should still be considered extremely profitable targets for fututre research. Simulations show that a significant population of potentially interesting pulsars is still undiscovered in the clusters.[26,27] These could include MSP-black hole systems, which would be invaluable for tests of gravitational theories.[28] However, despite the efforts, the number of new discoveries in the last ten years has been very low. The ones that were discovered were found in archival data using new search techniques.[29–31] This suggests that we had reached the sensitivity limit of the current observing facilities. To uncover the numerous and potentially interesting pulsars new and more sensitive facilities are needed. One such facility is FAST[32] in China that became operative in 2016 and has already discovered 32 pulsars in globular clusters.[33–35] Another new facility that recently came online and has the potential to revolutionize the field is MeerKAT[36] in South Africa.

2. Advantages of the MeerKAT radio telescope

The MeerKAT radio telescope is an interferometer composed of 64 antennas each with a diameter of 13.5 m. The maximum baseline within antennas is 8 km.

Thanks to its location in South Africa at a latitude of $-30°$, it can observe the entire Southern sky. When observing with all antennas it can reach telescope gains four times higher than Parkes, the only other radio telescope capable of observing pulsars in cm-wavelengths below a declination of $-45°$. The gain is also 1.4 times higher than the Green Bank Telescope giving MeerKAT a significant advantage when looking at the central regions of the Galaxy that are observable at high elevations for long hours.

MeerKAT is currently able to observe in UHF-band (544-1088 MHz), L-band (856-1712 MHz) showing remarkably RFI-clear bands. In near future also the S-band (1750-3500 MHz) receivers will be available for observations. A description of the capabilities and potentialities of MeerKAT as a pulsar observatory can be found in Bailes et al. 2020.[37]

Of the MeerKAT Large Science Projects (LSPs) that are currently using MeerKAT for observations, two include pulsars as the main target: MeerTIME[38] and TRAPUM.[39]

2.1. *MeerTIME*

MeerTIME[b] is an LSP based on timing already known pulsars with the high sensitivity of MeerKAT that started collecting data in early 2019. It has four main scientific goals: timing relativistic binary pulsars in order to measure the masses of the systems and test theories of gravity[40]; the Thousand Pulsars Array that monitors a wide variety of pulsars to study their geometries, magnetospheres and interstellar effects[41]; a pulsar timing array that monitors high precision pulsars to contribute to the search for nanohertz gravitational waves [Spiewak et al. submitted]; time pulsars in globular clusters.[42]

The project plans to observe globular cluster pulsars in order to study the eclipses, measure the masses of the pulsars, and study the properties of the globular clusters themselves.

MeerTIME can observe up to four tied array beams using the Pulsar Timing User Supplied Equipment (PTUSE) machines as the main data acquisition system. These beams can either be in "timing" mode where a pulsar is folded in real time using an ephemeris or in "search" mode where the data is saved in a "filterbank" style file and can be folded later or searched for new pulsars or single pulses from previously known ones. For both modes the observations are done with very high time resolution (9 μs), full polarimetric information, and real-time coherent dedispersion.

Observing globular clusters has the advantage that a large number of pulsars fall within the same beam of the telescope and we are therefore capable of observing them simultaneously if the data is recorded in "search" mode. However, the beam of MeerKAT using the full array with a baseline of 8 km would be too small to

[b]http://www.meertime.org

observe all of the pulsars in some globular clusters so in most cases only the central 44 antennas with a maximum baseline of 1 km are used.

2.2. *TRAPUM*

The TRAnsients and PUlsars with MeerKAT (TRAPUM[c]) LSP focuses on searching for new pulsars. It searches for pulsars in unidentified Fermi sources, supernova remnants, pulsar wind nebulae, in the Galactic plane, in nearby galaxies and in globular clusters. The globular cluster working group is focused on searching both in clusters with known pulsars (which allows de-dispersion at the known DM of the cluster) and in clusters with no known pulsars. The project started taking data in April 2020.

TRAPUM uses Filterbanking Beam-former User Supplied Equipment (FBFUSE) and the Accelerated Pulsar Search User Supplied Equipment (APSUSE), a 60 node computing cluster, to synthesize up to ~ 400 beams and record incoherently de-dispersed search-mode data for each one. This allows us to cover a large portion of the sky (up to $\sim 1-4$ arcmin in radius depending on the configuration) while keeping the full sensitivity of MeerKAT. In this way it is possible to cover the entire cluster with one pointing and search for pulsars in the center and in the outskirts of the cluster simultaneously. However, due to the very high data rate, it is not possible to retain full temporal and spectral resolution nor full polarimetric information.

Because of the complementarity of science goals, the globular cluster working groups of MeerTIME and TRAPUM have decided to collaborate sharing observing time and resources. This collaboration has already resulted in two publications.[42,43]

3. New discoveries

The joint collaboration has discovered 36 new pulsars in globular clusters[d]. The discoveries are summarized in Table 1 and 2 and can be split chronologically into two groups: the ones made with the PTUSE machine before TRAPUM became operative and the ones made possible by the APSUSE machine of TRAPUM.

3.1. *MeerTIME discoveries*

The first batch of discoveries made with observations taken by MeerTIME is already published.[42] This publication contains the description and the properties of 8 new millisecond pulsars found in six different globular clusters. Three of them are isolated pulsars while the rest are found in binary systems. The profiles of these pulsars are shown in Figure 1.

NGC 6624K	2.7686	87.46	Isolated

These discoveries include two new eclipsing millisecond pulsars 47 Tuc ac and 47 Tuc ad. Fitting for the orbits of these pulsars suggest that 47 Tuc ac is a ‘black widow’ pulsar while 47 Tuc ad is a ‘red-back’. Both of these discoveries were then

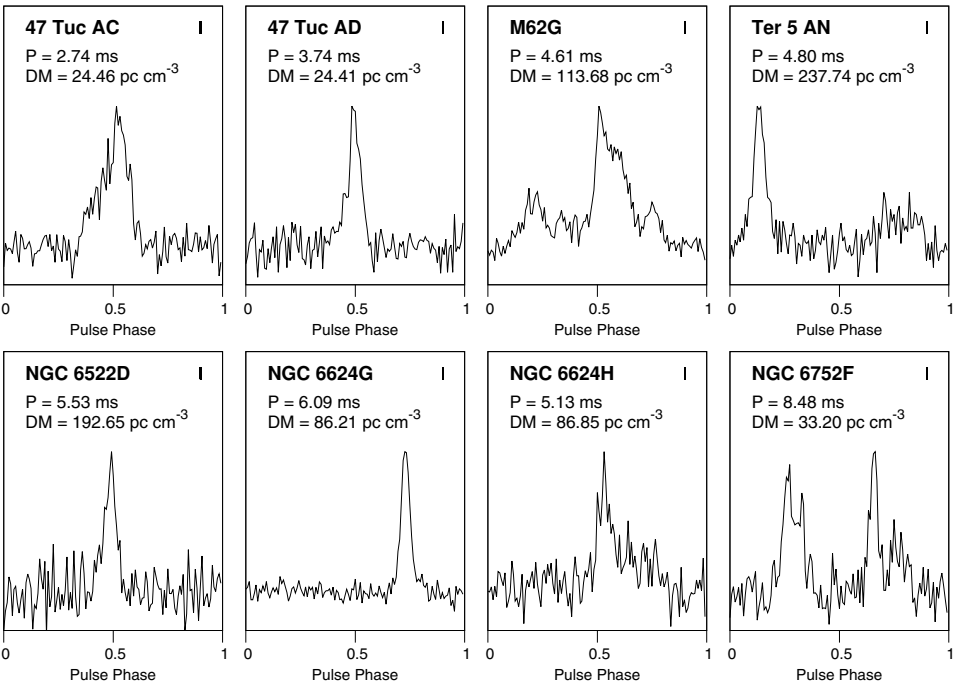

Fig. 1. Profiles of the eight new pulsar discoveries published in Ridolfi et al. 2021.[42]

re-detected in previous Parkes observations but due to scintillation effects and eclipses the detections were too few to allow for deriving phase-connected timing solutions.

Possibly the most interesting pulsar in this set of discoveries is NGC 6624G. This pulsar is found in a binary with orbital period of 1.54 days and eccentricity of 0.38. Because of the very high eccentricity it was possible to use only 11 months of data to measure the rate of advance of periastron $\dot{\omega} = 0.217 \pm 0.004$ deg yr^{-1}. Assuming that this advance is caused entirely by relativistic effects and using formulas derived in General Relativity (GR) it is possible to derive the total mass of the system, $M_{tot} = 2.65 \pm 0.07 \mathrm{M}_{\odot}$. This parameter alone is not enough to measure precisely the mass of the pulsar itself, see Figure 2, but suggests that the neutron star is particularly heavy. Measurements of further post-keplerian parameters will be needed to accurately determine the mass. The companion mass is also particularly heavy suggesting that it was not the original companion that recycled the pulsar but a new companion gained in an exchange encounter. This is the type of secondary exchange products that we have been looking for.

Another newly discovered pulsar that has the potential of being particularly massive is Ter 5 an. This binary has an eccentricity of 0.0066, two orders of magnitude higher than the average millisecond pulsar binaries found in the Galactic field. It is likely caused by distant stellar encounters in the dense cluster environment. Also

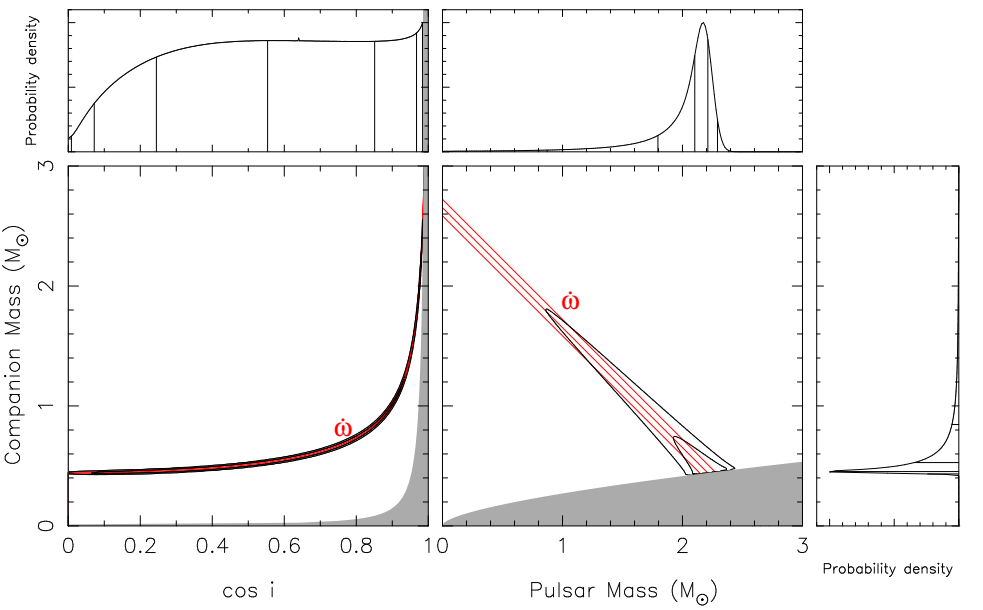

Fig. 2. Mass-inclination and mass-mass diagrams for NGC 6624G. The main square panels depict the $\cos i$-M_c and M_c-M_p planes. The grey areas in the former are excluded by the requirement that the mass of the pulsar is positive, the grey areas in the latter are excluded by the mass function and the requirement that $\sin i \leq 1$. The red lines depict the masses consistent with the measurement of $\dot{\omega}$ and its ± 1-σ uncertainties, under the assumption that this effect is dominated by the GR contribution and that GR is the correct theory of gravity. The contours include 68.3 and 95.4% of a 2-D probability distribution function (pdf) derived from the χ^2 of `TEMPO` fits that assumed all GR effects to be according to the masses and orbital inclination at each point. The side panels show the probability density functions for the $\cos i$ (top left), M_p (top right) and M_c (right) derived by marginalizing the aforementioned 2-D pdfs. we obtain a median for the pulsar mass of 2.1 $M_\odot$, but with a tail of probability that extends to lower masses: there is a 31% probability of $M_p < 2$ $M_\odot$ and a 3.8% probability of $M_p < 1.4$ $M_\odot$. Thus, either the pulsar is very massive, or it has a massive companion; the system was likely formed in an exchange encounter. Credits: Ridolfi et al. 2021.[42]

here, owing to the recovery of the system in data from the Green Banks Telescope and the resulting long baseline, it was possible to measure an advance of the periastron with a rate of $\dot{\omega} = 0.009 \pm 0.001$ deg yr^{-1}. With the assumption that it fully caused by GR effects, the total mass becomes $M_{tot} = 2.95 \pm 0.52 M_\odot$. The mass-inclination and mass-mass diagrams are shown in Figure 3. The uncertainties in this case are higher allowing for a greater range in pulsar mass.

The other pulsars discovered by MeerTIME are in the process of being published. Of these, one is particularly interesting: NGC 6440H. It is a binary pulsar with a very light companion. Assuming a pulsar mass of 1.4 $M_\odot$, the companion has a minimum mass of 0.0062 $M_\odot$. This very low mass of the companion suggests that it could be brown dwarf or a planet. If the planetary nature of the companion is confirmed, this would be only the second pulsar with such a companion.[12,13]

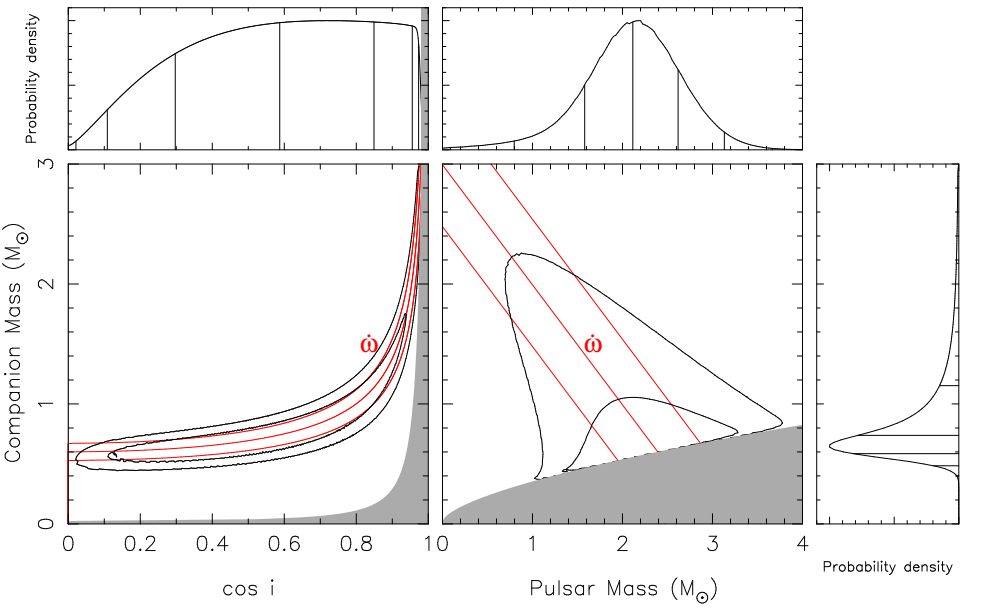

Fig. 3. Same mass-inclination and mass-mass diagrams as in Figure 2 but for Ter 5 an. The estimated median pulsar mass is 2.13 $M_\odot$ and median companion mass is 0.75 $M_\odot$. Credits: Ridolfi et al. 2021.[42]

3.2. *TRAPUM discoveries*

Only a small fraction of the observations of globular clusters with the APSUSE machine with TRAPUM have currently been processed. The large volumes of data produced in these observations require a large processing power to be properly analyzed. Despite this, the new pulsar discoveries are already more than double than those made using the PTUSE machines and only the central 44 antennas. The list is shown in Table 2.

More than half of these discoveries come from just one globular cluster NGC 1851. This is a core-collapsed cluster that was known to contain only one pulsar NGC 1851A. TRAPUM observations in just the central beam have confirmed the presence of 13 new pulsars. This large population makes NGC 1851 the third globular cluster for number of known pulsars together with M28. Once phase connected ephemerides are determined for all these pulsars it will be possible to probe the potential well and test the presence of gas and magnetic fields within the cluster.

Two of these new discoveries, NGC 1851D and NGC 1851E, are binary systems with very high eccentricities. NGC 1851E has an orbital period of around 7 days and an eccentricity of $e = 0.71$. This high value means that in the near future it will be possible to measure the rate of precession of the periastron to high accuracy and therefore the total mass of the system. Early fits to the orbit suggest that, assuming a pulsar mass of 1.4 $M_\odot$, the companion has a minimum mass of 1.5 $M_\odot$.

This suggests that there is a high probability of this being another double neutron star system.

The vast majority of the discoveries are fast spinning MSPs but there are some exceptions: NGC 6624J and NGC 1851I have periods respectively of 20.89 and 32.65 ms, that suggest that they are mildly recycled pulsars. Another exceptions is NGC 6441E, a slow pulsar with a period of 251.15 ms. Particularly interesting is also J1823-3022 with a period of 2497.72 ms. This potentially record breaking pulsar has been found in the outskirts of the globular cluster NGC 6624 and has a DM that is higher than the rest of the pulsars in the cluster. Because of these reasons it is not clear if it is really a member of the cluster or if it is a Galactic disk pulsar positioned along the same line of sight. All of these slow pulsars are in core-collapsed clusters validating the correlation between spin periods and dynamical state of the cluster suggested previously.[2]

These early results from a fraction of the observations suggest that many new discoveries are possible by analyzing the data that has already been captured.

4. Future plans

Early observations have showed that the future of the two projects MeerTIME and TRAPUM can prove revolutionary for the science of globular cluster pulsars.

MeerTIME will focus on timing the already discovered pulsars in order to measure the masses of the most interesting binaries and characterise the eclipses of the ecplising 'black-widows' and 'redbacks'. Furthermore, by improving the timing models of all pulsars it will be possible the study the properties of the clusters like the gas content, magnetic field and the presence of intermediate mass black holes.

TRAPUM, on the other hand, will continue to search for new pulsars broadening the scope in order to include clusters with no previously known pulsars. The searches will involve all of the available bands, going from the UHF band, where the pulsars are brighter but the interstellar medium is more noisy to the L band and the S band where the effects of scattering and the interstellar medium are minimized.

In closing, the last few years have shown an almost unprecedented growth in the number of pulsars in globular clusters going from 150 in 2018 to over 230 in 2021. The largest contributor is the MeerKAT telescope with 36 but a very close second is FAST with 32 new discoveries. These numbers are likely to increase in the following years and with them also the possibility of finding even more exotic systems like a double millisecond pulsar binary or a pulsar-black hole binary.

We investigate gravitational lensing by rotating Simpson-Visser black hole in the strong field limit and find that deflection angle α_D, photon sphere radius x_m and ratio of the flux of the first image to all other images r_{mag} decreases. In contrast, angular position θ_1, angular separation s increases more rapidly with l and their behaviour is similar to that of the Kerr black hole. By considering the supermassive black holes NGC 4649, NGC 1332, Sgr A* and M87* as rotating Simpson-Visser black holes, we found that the latter can be quantitatively distinguished from the Kerr black hole when probed by gravitational lensing effects. The deviation of the lensing observables $\Delta\theta_1$ and Δs by considering the Sgr A* and M87* as rotating Simpson-Visser black holes from Kerr black hole for $0 < l/2M < 0.6$ ($a/2M = 0.45$) are in the range $0.0422 - 0.11658$ μas and $0.031709 - 0.08758$ μas, which are too small to be distinguished by the current Event Horizon Telescope observations, and one has to wait for future observations by new generation EHT that can pin down the exact constraint.

Keywords: Lensing, Simpson-Visser black hole

1. Introduction

The singularity theorems of Hawking and Penrose[1] (see also Ref.[2]) established that the end state of gravitational collapse of a sufficiently massive star ($\sim 3.5M_\odot$) is a gravitational singularity i.e., spacetime ceases to exist and hence marking a breakdown of the laws of physics. Apart from the quantum gravity which is expected to resolve the singularity issue,[3] significant attention has also shifted to regular models which can allow one to understand the black hole interior. Sakharov[4] and Gliner[5] pioneered the idea of regular models that suggests a de Sitter core and the cosmological vacuum obeys the equation of state. Motivated by Sakharov[4] and Gliner,[5] Bardeen[6] proposed the first regular black hole with horizons.[7,8] The Bardeen black hole spacetime asymptotically reduces to Schwarzschild black hole[7] but acts like the de Sitter spacetime near the origin thus eventually settling with a regular center. Later, it was shown in Ref.[9] that Bardeen's model is an exact solution of general relativity coupled to nonlinear electrodynamics thereby an alteration of the

Reissner−Nordström black hole solution.[10] Bardeen's proposal with non-linear electrodynamics as the source has been extended to regular black holes,[11–13] and also on regular rotating black[8,14,15] holes.

Lately, Simpson-Visser propose an interesting spherically symmetric regular black hole spacetime[16–18] where a parameter l is introduced to cause a repulsive force to avoid singularity and is responsible for the regularisation of the metric at $r = 0$. The Simpson-Visser metric which interpolates between the Schwarzschild black hole and the Morris–Thorne traversable wormhole is regular everywhere as the scalar.[16] The Simpson-Visser spacetime received significant attention with a discussion on the energy conditions, causal structure, and innermost stable circular orbit (ISCO),[16] regularity, quasi-local mass, energy conditions and the causal structure of black bounce models,[18] gravitational lensing[19] and shadow formation.[22,23]

Graviatational lensing(GL), a vital and prior prediction of general relativity(GR) primarily in the strong field regime,[24] is considered an important test of GR. Since then, GL proved to be an essential tool for providing insights on the spacetime.[25] In the strong field regime, photon encircles the black hole more than once resulting in a bending angle greater than 2π radians and results in shadow,[26] photon rings[27] and relativistic images.[28–32] GL for various spacetimes has been discussed in detail.[29–39] Virbhadra and Ellis developed a numerical method[33] to study the large deflection of light rays in strong field. Later, Bozza analysed analytically the strong field gravitational lensing for general spherically symmetric and static spacetime.[29–32] Tsukamoto[37] worked on similar lines to study the lensing by spherically symmetric and static spacetime. GL began to be crucial in 1990's which triggered quantitative studies by Kerr black holes[29,40,41] and has since then recieved significant attention[42–49] due to the tremendous advancement of observational facilities.

This paper investigates the strong gravitational lensing by rotating Simpson-Visser black holes[20] and assess the phenomenological differences with the Kerr black holes; in particular, we discuss the effect of deformation parameter l on gravitational lensing observables and time delay between the relativistic images. Further, considering the supermassive black holes as the lens, we obtain the positions, separation, magnification, and time delay in the formation of relativistic images.

We adopt natural units ($8\pi G = c = 1$)

2. Rotating Simpson-Visser black holes

The rotating Simpson-Visser black hole metric apart from mass M and angular momentum a, has an additional parameter l, which in Boyer-Lindquist coordinates reads as[20]

$$ds^2 = -\left(1 - \frac{\sqrt{x^2 + l^2}}{\Sigma}\right) dt^2 + \frac{\Sigma}{\Delta} dx^2 + \Sigma d\theta^2 - \frac{2a \sin^2\theta \sqrt{x^2 + l^2}}{\Sigma} dt d\phi + \frac{\mathbb{A} \sin^2\theta}{\Sigma} d\phi^2, \tag{1}$$

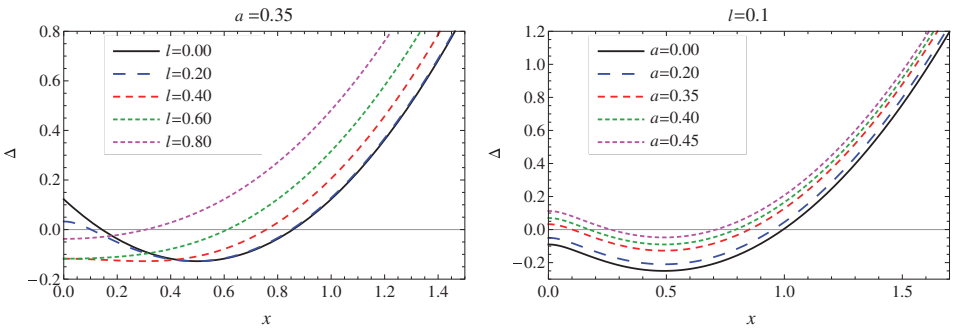

Fig. 1. The horizons (zeroes of Δ) of rotating Simpson-Visser black holes. The case $l = 0$ (Kerr black hole) is shown for comparison. For $l > l_c$ (e.g., for $a = 0.35$, $l_c \approx 0.1429$ and for $a = 0.45$, $l_c \approx 0.282$), the black holes admit only event horizon.

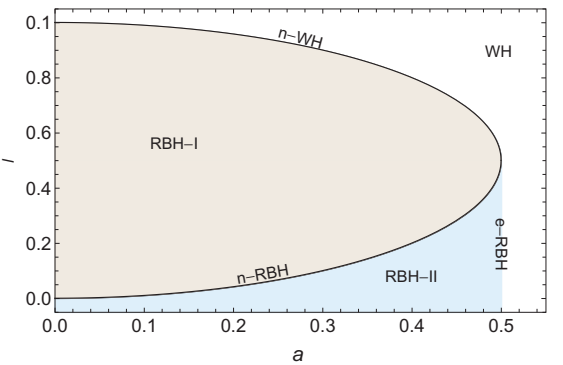

Fig. 2. Parameter space for the rotating Simpson-Visser black hole and the corresponding spacetime structure. For $a = 0.3$ the rotating Simpson-Visser black hole admits both Cauchy and event horizon for $0.0 < l_{cb} < 0.1$ and only event horizon for $0.1 < l_c < 0.9$. For $a = 0.45$, both Cauchy and event horizon exist for $0.0 < l_{cb} < 0.282055$ and only event horizon is present for $0.282055 < l_c < 0.717945$. We measure the quantities a and l in units of Schwarzschild radius $2M$.

where $\Sigma = x^2 + l^2 + a^2\cos^2\theta$, $\Delta = x^2 + l^2 + a^2 - 2\sqrt{x^2 + l^2}$ and $\mathbb{A} = (x^2 + l^2 + a^2)^2 - \Delta a^2 \sin^2\theta$. We measure the quantities r, a, t, and l in units of Schwarzschild radius $2M$[31] and use x instead of radius r.

Moreover, the metric (1) is composed of identical portions around $x = 0$ which is a regular surface of finite size for $l \neq 0$, and the observer can easily cross.[20] Depending on the value of the parameter l, the metric (1) is either a regular black hole or a traversable wormhole.[20]

The points of coordinate singularities, which exist at $\Delta = 0$, are also the horizons of the black hole metric (1) and are located at $x_\pm$ (cf. Fig. 1). The horizons of the metric (1) exist when $|a| < 0.5$ and $l < 0.5 + \sqrt{(0.5)^2 - a^2}$ (cf. Fig. 1). Consequently, following cases are possible for the metric (1)

- For $l < 0.5 - \sqrt{(0.5)^2 - a^2}$, we have two horizons $x_\pm$, corresponding to the radii of outer (event) (x_+) and inner (Cauchy) (x_-) horizons (This corresponds to RBH-II, in Fig. 2).
- For $0.5 - \sqrt{(0.5)^2 - a^2} < l < 0.5 + \sqrt{(0.5)^2 - a^2}$, only event horizon exists. (This corresponds to RBH-I, in Fig. 2).
- For $|a| = 0.5$ and $l < 0.5$, Cauchy and event horizon correspond to extremal black hole (e-RBH) with degenerate horizons, while for $|a| = 0.5$ and $l > 0.5$, there are no horizons and so no black hole.
- The case $|a| > 0.5$ with no horizons, the metric (1) describes a traversable wormhole with a time-like throat, which becomes null for $|a| = 0.5$.[20]

We restrict the values of a and l in the range $|a| < 0.5$ and $0 < l < 0.5 + \sqrt{(0.5)^2 - a^2}$ for at least one horizon to exist and to qualify the spacetime as a black hole. We shall also consider the values $x > 0$ as the solution (1) is symmetric around $x = 0$.

3. Gravitational lensing

The rotating Simpson-Visser black hole in the equatorial plane takes the form

$$\mathrm{d}s^2 = -A(x)dt^2 + B(x)dx^2 + C(x)d\phi^2 - D(x)dt\,d\phi, \tag{2}$$

where

$$A(x) = 1 - \frac{1}{\sqrt{\Sigma}}, \quad B(x) = \frac{\Sigma}{\Delta}, \quad C(x) = \frac{\mathbb{A}}{\Sigma}, \quad D(x) = \frac{2a}{\sqrt{\Sigma}},$$

$\Sigma = x^2 + l^2$ and $\mathbb{A} = (x^2 + l^2 + a^2)^2 - \Delta a^2$. Further, we also assume the source, which is located behind the lens, to be almost aligned along the optical axis such that the images are highly magnified and very prominent.

The projection of four-momentum p^μ along the two commuting Killing vectors $\xi^\mu_{(t)}$ and $\xi^\mu_{(\phi)}$ results in two linearly independent conserved quantities; energy E and axial angular momentum component L.

$$p_t = g_{tt}p^t + g_{t\phi}p^\phi = -E, \qquad p_\phi = g_{t\phi}p^t + g_{\phi\phi}p^\phi = L. \tag{3}$$

Solving the two coupled equations results in the following equations of motion for t and ϕ coordinates[56]

$$\Sigma\frac{dt}{d\tau} = a(L - aE\sin^2\theta) + \frac{x^2 + l^2 + a^2}{\Delta}[E(x^2 + l^2 + a^2) - La] \tag{4}$$

$$\Sigma\frac{d\phi}{d\tau} = \frac{L}{\sin^2\theta} - aE + \frac{a}{\Delta}[E(x^2 + l^2 + a^2) - La], \tag{5}$$

We follow the Hamilton-Jacobi equation and the integral approach pioneered by Carter[57] to obtain the equations of motion in the first-order differential form for

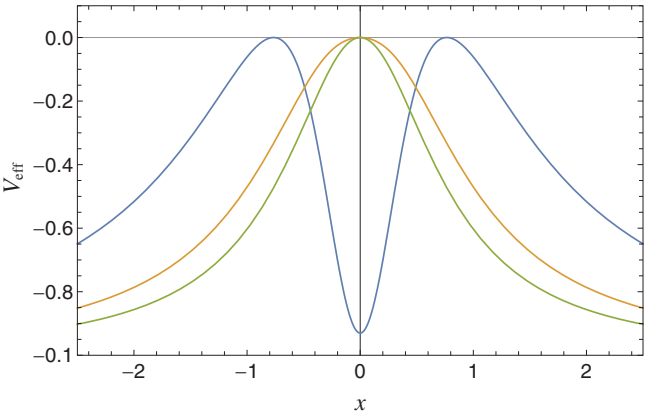

Fig. 3. The effective potential as a function of radial coordinate x. (a) The blue line represents the effective potential for rotating Simpson-Visser black hole black hole with $a = 0.334$ and $l = 0.698$ (b) the orange line represents the wormhole throat with $a = 0.5$ and $l = 0.7$ (c) the green line represents the traversable wormhole with $a = 0.884$ and $l = 0.746$.

the rotating Simpson-Visser black hole spacetime (1), where the equations descend from

$$\frac{\partial S}{\partial \tau} = -\frac{1}{2} g^{\mu\nu} \frac{\partial S}{\partial x^{\mu}} \frac{\partial S}{\partial x^{\nu}}, \tag{6}$$

where S is the action and τ is the affine parameter along the geodesic. Using the conserved quantities p_t and p_ϕ, the Jacobi action S admits a separable solution in the first integral form as follows[57]

$$S = -Et + L\phi + S_x(x) + S_\theta(\theta). \tag{7}$$

Here, $S_x(x)$ and $S_\theta(\theta)$, respectively, are functions only of the x and θ coordinates. On using the four-momentum relations

$$\frac{dS_x}{dx} = p_x = g_{xx} p^x = \frac{\Sigma}{\Delta} \frac{dx}{d\tau}, \tag{8}$$

$$\frac{dS_\theta}{d\theta} = p_\theta = g_{\theta\theta} p^\theta = \Sigma \frac{d\theta}{d\tau}, \tag{9}$$

in Eq. (6), the following system of first-order ordinary differential equations are obtained

$$\Sigma \frac{dx}{d\tau} = \pm \sqrt{\mathcal{R}(x)}\ , \tag{10}$$

$$\Sigma \frac{d\theta}{d\tau} = \pm \sqrt{\Theta(\theta)}\ , \tag{11}$$

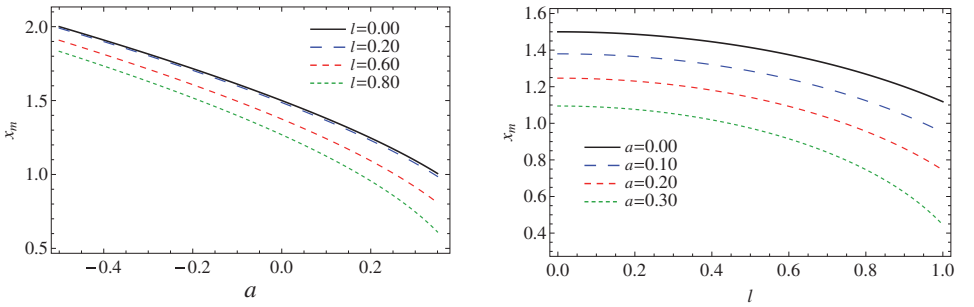

Fig. 4. Plot showing radii of unstable circular photon orbit for rotating Simpson-Visser black hole (dashed curve) in comparison to Kerr black hole (solid curve in the left plot).

where the effective potentials $\mathcal{R}(x)$ and $\Theta(\theta)$ for radial and polar motion are given by

$$\mathcal{R} = [E(x^2 + l^2 + a^2) - La]^2 - \Delta[(L - aE)^2 + \mathcal{K}], \tag{12}$$

$$\Theta = \mathcal{K} - \cos^2\theta\left[a^2E^2 + \frac{L^2}{\sin^2\theta}\right]. \tag{13}$$

$\mathcal{K}$ is a separability constant related to the Carter constant that derives its existence from a Killing tensor. The motion of the photon is symmetric around the equatorial plane in the region $\mathcal{R} \geq 0$ and $\Theta(\theta) \geq 0$. The bound orbits can be identified by the solutions of[56, 58]

$$\mathcal{R}|_{(x=x_m)} = \left.\frac{\partial\mathcal{R}}{\partial x}\right|_{(x=x_m)} = 0, \text{ and } \left.\frac{\partial^2\mathcal{R}}{\partial x^2}\right|_{(x=x_m)} > 0, \tag{14}$$

where x_m is the unstable photon orbit radius. Eq.(10) can be rewritten as

$$\dot{x}^2 + V_{\text{eff}} = 0 \tag{15}$$

where V_{eff} is the effective potential. For simplicity we take $E = 1$ and plot the effective potential in Fig. 3.

The deflection angle of a photon moving on the equatorial plane using the geodesics Eqs. (5) and (10), for rotating Simpson-Visser black hole is given by[32]

$$\alpha_D(x_0) = 2\int_{x_0}^{\infty} \frac{\sqrt{A_0 B}\,(2AL + D)}{\sqrt{4AC + D^2}\sqrt{A_0 C - AC_0 + L\,(AD_0 - A_0 D)}}dx - \pi, \tag{16}$$

where x_0 is the distance of closest approach of the light to the lens, L is the projection of angular momentum and A_0 is defined by $A(x_0)$. Equation (14) gives the radii of photon sphere which can be rewritten as[32]

$$A(x)C'(x) - A'(x)C(x) + L(A'(x)D(x) - A(x)D'(x)) = 0. \tag{17}$$

The radii of unstable photon sphere is depicted in Fig. 4 and is smaller when compared with the Kerr black hole.[32] Further, the deflection angle when expanded in

the SDL takes the form

$$\alpha_D(\theta) = -\bar{a}\log\left(\frac{\theta D_{OL}}{u_m} - 1\right) + \bar{b} + \mathcal{O}\left(u - u_m\right), \tag{18}$$

where u is the impact parameter and u_m is the value of impact parameter at $x_0 = x_m$ and is independent of the parameter l (cf. Table 1). The deflection angle in Eq.(18) is depicted in Fig. 6 wherein it is evident that deflection angle diverges at u_m.

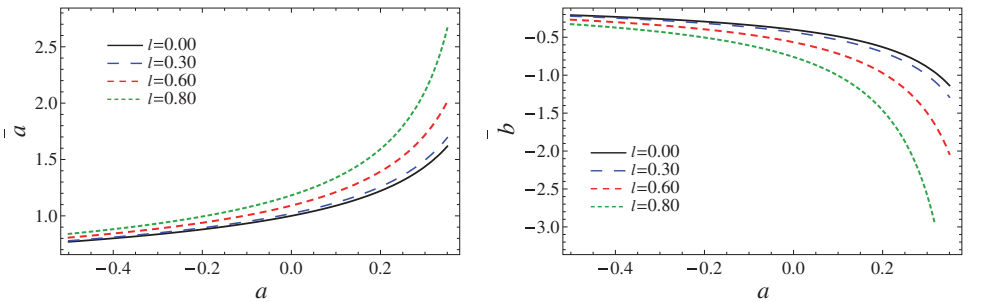

Fig. 5. Plot showing the behaviour of strong lensing coefficients $\bar{a}$ and $\bar{b}$. The solid black curve corresponds to Kerr black hole.

Table 1. Estimates for the strong lensing coefficients $\bar{a}$, $\bar{b}$ and the impact parameter u_m/R_s. We measure the quantities a and l in units of Schwarzschild radius $2M$.

		Lensing Coefficients		
a	l	$\bar{a}$	$\bar{b}$	u_m/R_s
	0.00	1.00000	-0.400230	2.59808
	0.25	1.01419	-0.423912	2.59808
	0.50	1.06066	-0.506783	2.59808
0.00	0.75	1.15470	-0.698106	2.59808
	0.95	1.29219	-1.03047	2.59808
	0.00	1.43692	-0.891314	1.91924
	0.25	1.47594	-0.965136	1.91924
	0.50	1.61535	-1.256170	1.91924
0.30	0.75	1.97301	-2.180740	1.91924
	0.90	2.52527	-4.037170	1.91924
	0.00	2.58352	-2.76735	1.42221
	0.30	2.79948	-3.26402	1.42221
	0.40	3.01084	-3.79273	1.42221

	0.60	4.05135	-6.94521	1.42221

The behaviour of coefficients $\bar{a}$ and $\bar{b}$ is similar to the Kerr black hole ($l = 0$) and spherical Simpson-Visser ($a = 0$) (cf. Fig. 5). The deflection angle for rotating

Simpson-Visser black hole in SDL (cf. Fig. 6) like Kerr black hole, is more than 2π radians and multiple images of the source are formed.

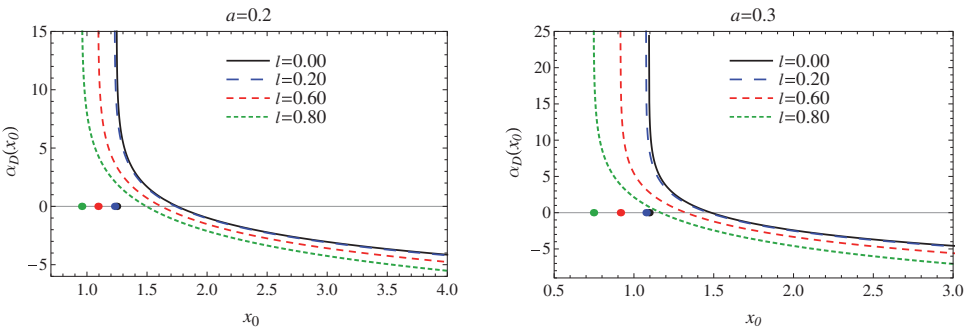

Fig. 6. Plot showing the variation of light deflection angle as a function of minimum distance x_0 for different values of a and l.

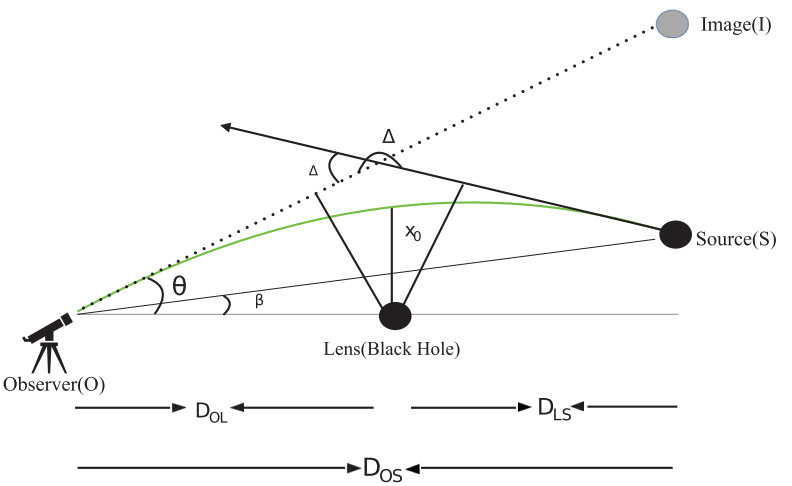

Fig. 7. Schematic diagram depicting the lensing configuration. α_D represent the deflection angle, where as θ and β are the angular positions of the image and source, respectively.

3.1. *Observables*

Next, we consider the lens equation to define a geometrical relationship between the observer, the source and the lens (cf. Fig. 7) as given in,[31,54]

$$\beta = \theta - \frac{D_{LS}}{D_{OL} + D_{LS}} \Delta\alpha_n, \tag{19}$$

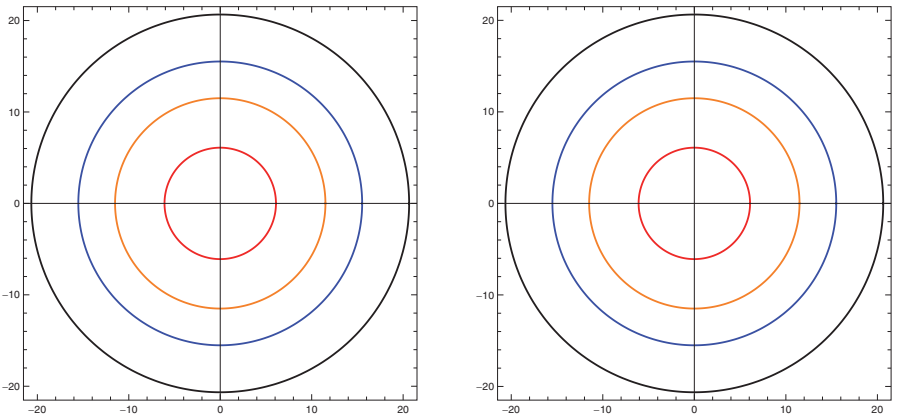

Fig. 8. The polar plot of θ_n^E (for $n = 1$): The angular radius of the outermost Einstein ring. Here, we consider Kerr black hole ($a = 0.25$ and $l = 0$) (left) and rotating Simpson-Visser balck hole ($a = 0.25$ and $l = 0.7$) (right) as supermassive black holes Sgr A* (black), M87* (blue), NGC 4649 (orange) and NGC 1332 (red).

where $\Delta\alpha_n$ is the extra deflection angle with $n \in N$ and $0 < \Delta\alpha_n \ll 1$. It has been acessed in[54] that lens equation discussed in[55] is bit more accurate than Eq.(19) but the latter has an advantage in analysing the observational effects more precisely. We shall estimate the observables for the strong gravitational lensing by rotating Simpson-Visser black hole as in.[31,32,42,52] Using the lens Eq. (19) and Eq. (18), the angular separation between the lens and the $n-$th image is given by[32]

$$\theta_n = \frac{u_m}{D_{OL}}(1 + e_n) + \frac{D_{OL} + D_{LS}}{D_{LS}} \frac{u_m e_n}{\bar{a} D_{OL}} (\beta - {\theta_n}^0), \tag{20}$$

where

$$e_n = \exp\left(\frac{\bar{b}}{\bar{a}} - \frac{2n\pi}{\bar{a}}\right). \tag{21}$$

Here the first term corresponds to value of θ when photon travels $2n\pi$ radians around the black hole and second term is the correction part to $2n\pi$.[31] For $\beta = 0$, a ring-shaped image is produced, known as Einstein rings.[25] Solving Eq. (20) for $\beta = 0$ and $D_{OL} = D_{LS}$, the angular radius of the Einstein rings can be obtained as[31,51]

$$\theta_n^E = \frac{u_m}{D_{OL}} (1 + e_n), \tag{22}$$

where $n = 1$ is the angular radius of the outermost Einstein ring (cf. Fig. 8).[42,52]

The brightness or magnification of the image is preserved in the deflection of the light but the appearance of the solid angle changes, thus magnifying the brightness

of the images. The magnification of n-loop image is given by[31,32]

$$\mu_n = \left|\frac{\beta}{\theta}\frac{\partial\beta}{\partial\theta}\right|^{-1}_{\theta_n^0} = \frac{1}{\beta}\left[\frac{u_m}{D_{OL}}(1+e_n)\left(\frac{D_{OL}+D_{LS}}{D_{LS}}\frac{u_m e_n}{D_{OL}\bar{a}}\right)\right]. \tag{23}$$

Table 2. Estimates for the observable θ_∞ and time delay $\Delta T_{2,1}$ for supermassive black holes at the center of nearby galaxies. These observables are independent of l.

	Sgr A*		M87*		NGC 4649		NGC 1332	
a	$\theta_\infty(\mu$as)	$\Delta T_{2,1}$(min)	$\theta_\infty(\mu$as)	$\Delta T_{2,1}$(hrs)	$\theta_\infty(\mu$as)	$\Delta T_{2,1}$(hrs)	$\theta_\infty(\mu$as)	$\Delta T_{2,1}$(hrs)
0.00	26.3299	11.4968	19.782	289.647	14.6615	210.328	7.76719	113.185
0.30	19.4504	8.4928	14.6133	213.968	10.8307	155.374	5.73777	83.612
0.45	14.4132	6.29295	10.8289	158.543	8.02585	115.127	4.2518	61.9538

The Eq. (23) diverges at $\beta \to 0$, suggesting that the perfect alignment maximises the possibility of the detection of the images. If the first image can be distinguished from the rest packed ones, we can have three characteristic observables[31] as

$$\theta_\infty = \frac{u_m}{D_{OL}}, \tag{24}$$

$$s = \theta_1 - \theta_\infty \approx \theta_\infty \exp\left(\frac{\bar{b}}{\bar{a}} - \frac{2\pi}{\bar{a}}\right), \tag{25}$$

$$r_{\rm mag} = \frac{\mu_1}{\sum_{n=2}^{\infty}\mu_n} \approx \frac{5\pi}{\bar{a}\,\log(10)}, \tag{26}$$

where, θ_∞ and θ_1 are the angular positions of the innermost image and outermost image, respectively and s is the angular separation between them. $r_{\rm mag}$ gives the ratio of the flux of the first image and the all other images. By observationally measuring these observables and inverting the Eqs. (24-26), the lensing coefficients $\bar{a}$, $\bar{b}$, the minimum impact parameter u_m can be obtained.[53]

The time delay, which is another important observable, is defined as the time difference between the formation of relativistic images considering the source with luminosity variations. If the time signal between the first and second image can be distinguished, the time delay $\Delta T_{2,1}$, when images are on the same side of the lens, can be approximated as[50]

$$\begin{aligned}\Delta T_{2,1} &\approx \frac{2\pi}{\bar{a}\sqrt{c_{2m}}}\frac{2x^2\sqrt{B(x)A(x_0)}[C(x)-LD(x)]}{x_0\sqrt{C(x)(D(x)^2+4A(x)C(x))}}\left(1-\frac{1}{\sqrt{A(x_0)}f(z,x_0)}\right)\\ &= 2\pi u_m,\end{aligned} \tag{27}$$

To measure the time delay, it is necessary that the source should be pulsating and the pulses show up in the images with a temporal phase thus making it possible to measure the time difference.

Table 3. Estimates for the lensing observables for supermassive black holes at the center of nearby galaxies for different values of a and l.

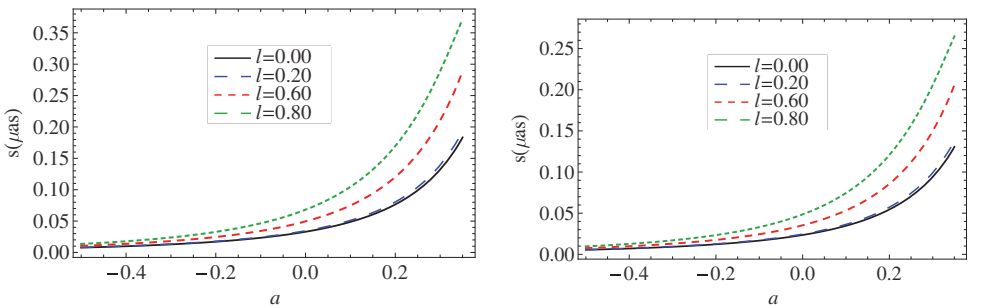

Fig. 9. Plot showing strong lensing observables s for the Sgr A*(left panel) and M87*(right panel) black holes.

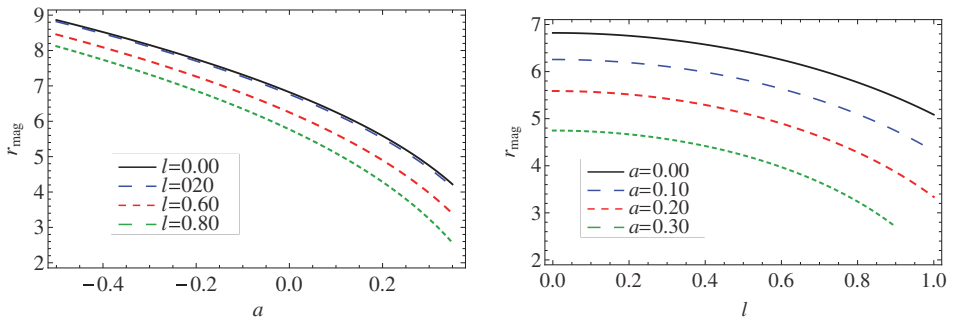

Fig. 10. Plot showing strong lensing observables r_{mag} for different parameters. r_{mag} is independent of the black hole mass or its distance from the observer.

4. Applications to supermassive black holes

Here, we model the supermassive black holes Sgr A*, M87*, NGC4649 and NGC1332 as the rotating Simpson-Visser black holes to estimate and compare the observables in SDL with the GR counterparts, and use mass and distance as in the Ref.[42]. The observables θ_∞ and time delay $\Delta T_{2,1}$ are independent of the parameter l and are shown in Table 2. We observe that θ_1 for Sgr A* and M87* is in the range of 14.84 μas $< \theta_1 <$ 26.36 μas and 11.15 μas $< \theta_1 <$ 19.80 μas, respectively. The observables s and r_{mag} for rotating Simpson-Visser black holes are depicted in Fig. 9 and 10, whereas their values, along with the position of the first image θ_1 are tabulated in Table 3. Further, the angular separation s between the first and inner most image due to the rotating Simpson-Visser black hole for Sgr A* and M87* are in the range of 32.95 $n$as $< s <$ 433.8 $n$as and 24.75 $n$as $< s <$ 413.55 $n$as, respectively (cf. Table 3). Although the rotating Simpson-Visser black holes deviate from the Kerr black hole but the deviation are beyond the threshold of the current EHT observation (cf. Table 4) and should wait for the next generation event horizon telescope (ngEHT). From the brightness difference, we find that Kerr black holes produces less intense images. The angular position and angular separation of the relativistic images are larger for the Sgr A* black hole than the M87*, NGC4649 and NGC1332 black holes. The time delay of the first image from that of the second image $\Delta T_{2,1}$, for Sgr A*, M87*, NGC4649 and NGC1332 respectively, can reach $\sim$ 11.49 min, $\sim$ 289.6 hrs, $\sim$ 210.3 hrs and $\sim$ 113.2 hrs (cf. Table 2).

Table 4. Deviation of the lensing observables of rotating Simpson Visser black holes from Kerr black hole for supermassive black holes at the center of nearby galaxies for $a = 0.3$ and $a = 0.45$. For $a = 0.3$ the rotating Simpson-Visser black hole admits both Cauchy and event horizon for $0.0 < l_{cb} < 0.1$ and only event horizon for $0.1 < l_c < 0.9$. For $a = 0.45$, both Cauchy and event horizon exist for $0.0 < l_{cb} < 0.282055$ and only event horizon is present for $0.282055 < l_c < 0.717945$. Here $\Delta(X) = X_{RSV} - X_{Kerr}$.

5. Conclusions

We have investigated the gravitational lensing of light in strong field limit due to rotating Simpson-Visser black holes which has an additional deviation parameter l besides mass M and spin a. We find that $\bar{a}$ increases whereas $\bar{b}$ and deflection angle α_D decrease with increasing l. On the other hand, u_m depends only on the spin of

the black hole and is independent of the black hole parameter l. The observables θ_∞ and $\Delta T_{2,1}$ do not depend of l. Further, the relative magnification of the first and innermost images is independent of the black hole mass or its distance from the observer. Interestingly, it turns out that the separation between the two relativistic images for Simpson-Visser black holes is greater than that for the Kerr black holes.

Although, the gravitational lensing analysis (cf. Figs. 6, 9 and 10) and horizon structure (cf. Figs. 1 and 2), constrain the rotating Simpson-Visser black holes parameter l but the deviation produced in lensing observables by taking the rotating Simpson-Visser black holes as the supermassive black holes, namely, Sgr A*, M87*, NGC 4649 and NGC 1332, from those for Kerr black hole for $0 < l < 0.6$ ($a = 0.45$) are $\mathcal{O}(\mu\text{as})$ (cf. Table 4). Our results are the generalization of previous discussions, on the Kerr black holes, in a more general setting in the limit $l \to 0$, reduced exactly to *vis-à-vis* the Kerr black hole results.

We discuss a recently proposed geometric method[1] for constructing a nontrivial Killing tensor of rank two in a foliated spacetime of codimension one that lifts trivial Killing tensors from slices to the entire manifold. The existence of nontrivial Killing tensor is closely related to generalized photon surfaces. The method is illustrated on some known cases and used to construct the hitherto unknown Killing tensor for the Nutty dyon in dilaton-axion gravity.

Keywords: Killing tensors, photon surfaces, gravitational lensing, black hole shadows.

1. Introduction

Killing tensors of the second rank express hidden symmetries of spacetime[2,3] providing integrals of motion for geodesics and wave operators in field theories. Some constructive procedures to find them were suggested for spaces with a warped/twisted product structure,[4] spaces admitting a hypersurface orthogonal Killing vector field,[5,6] or special conformal Killing vector fields.[7] Recently, some deformed Kerr metrics attracted attention when trying to find new physics in ultracompact astrophysical objects. Classes of such metrics were listed that admit Killing tensors,[8,9] but for others the separation of variables in geodesic equations is not guaranteed.

The new procedure[1] suggested for foliated spacetime of codimension one is based on lifting the trivial Killing tensors in slices with an arbitrary second fundamental form.[1] This remove some particular assumptions about slices, so, hopefully, we can move further in the study of separability. The method is closely related to formalism of fundamental photon surfaces introduced in.[10] This generalizes one previous observation[11] on the relationship between spacetime separability and spherical photon orbits. It is also worth noting that our method does not require sovling diffenerial equations at all.

As illustrations, we apply this new technique to some conventional metrics of Petrov type D demonstrating that this technique allows to obtain known Killing tensors[12,13] purely algebraically, without solving any differential equations. Then we successfully apply new technique to find Killing tensor for Gal'tsov-Kechkin solution[14,15] in dilaton-axion gravity which belongs to the general Petrov type I. The new method reveals the nature of Killing tensors as arising from isometries of low-dimensional slices of a smooth foliation.

In Sec. 2 we briefly describe the equations for the Killing vectors and Killing tensors of rank two. In Sec. 3 we consider spacetimes with foliation of codimension one and present the equations governing the interplay between symmetries in the bulk and in the slices. Eventually we describe the Killing generating technique. In Sec. 4 we reveal the connection between the Killing tensors and the fundamental photon surfaces. Sec. 5 provides examples with axial symmetry in different models.

2. Conventions

Let M be a Lorentzian manifold of dimension m with scalar product $\langle\,\cdot\,,\,\cdot\,\rangle$ and Levi-Civita connection ∇[a].

Definition 2.1. A vector field $\mathcal{K}: M \to TM$ is called a Killing vector field if[16]

$$\underset{\mathcal{X}\leftrightarrow\mathcal{Y}}{\mathrm{Sym}}\,\{\langle\nabla_{\mathcal{X}}\mathcal{K},\mathcal{Y}\rangle\} = 0, \quad \forall\mathcal{X},\mathcal{Y}\in TM. \tag{1}$$

Definition 2.2. A linear self-adjoint mapping $K(\,\cdot\,): TM \to TM$ is called a Killing mapping if

$$\underset{\mathcal{X}\leftrightarrow\mathcal{Y}\leftrightarrow\mathcal{Z}}{\mathrm{Sym}}\,\{\langle\nabla_{\mathcal{X}}K(\mathcal{Z}),\mathcal{Y}\rangle\} = 0, \quad \forall\mathcal{X},\mathcal{Y},\mathcal{Z}\in TM, \tag{2}$$

where the linear mapping $\nabla_{\mathcal{X}}K(\,\cdot\,): TM \to TM$ is defined as follows

$$\nabla_{\mathcal{X}}K(\mathcal{Y}) \equiv \nabla_{\mathcal{X}}(K(\mathcal{Y})) - K(\nabla_{\mathcal{X}}\mathcal{Y}), \quad \forall\mathcal{X},\mathcal{Y}\in TM. \tag{3}$$

One can introduce a Killing tensor as a symmetric form $K(\mathcal{X},\mathcal{Y}) = \langle K(\mathcal{X}),\mathcal{Y}\rangle$, which is associated with the conservation law quadratic in momenta. Let $\mathcal{K}_\alpha$ be a set of n Killing vector fields. Then, one can define the following trivial Killing mapping

$$K(\mathcal{X}) = \alpha\mathcal{X} + \sum_{\alpha,\beta=1}^{n} \gamma^{\alpha\beta}\,\langle\mathcal{X},\mathcal{K}_\alpha\rangle\,\mathcal{K}_\beta, \quad \gamma^{\alpha\beta} = \gamma^{\beta\alpha}, \tag{4}$$

where α and $\gamma^{\alpha\beta}$ is the set of $n(n+1)/2+1$ independent constants in M. Note that the trivial Killing mapping does not give new conservation laws. However, one can show the existence of manifolds with nontrivial Killing tensors, which are not associated with the manifold isometries directly.

3. Generation of a non-trivial Killing tensor

Consider a timelike/spacelike *foliation* of the manifold M by a smooth family of hypersurfaces S_Ω parameterized by $\Omega\in\mathbb{R}$ (slices) with the lapse function φ, and

[a]Here we also use the notation $\underset{\mathcal{X}\leftrightarrow\mathcal{Y}}{\mathrm{Sym}}\,\{B(\mathcal{X},\mathcal{Y})\} \equiv B(\mathcal{X},\mathcal{Y}) + B(\mathcal{Y},\mathcal{X})$.

vector field ξ normal to slices ($\langle\xi,\xi\rangle \equiv \epsilon = \pm 1$). Then, the second fundamental form ${}^{\Omega}\sigma(\,\cdot\,,\,\cdot\,) : TS\times TS \to \mathbb{R}$ and the mean curvature of slices S_Ω are defined as follows

$$ {}^{\Omega}\sigma(X,Y) \equiv \epsilon\,\langle \nabla_X Y, \xi\rangle\,, \quad \forall X,Y \in TS, \qquad H \equiv \mathrm{Tr}({}^{\Omega}\sigma)/(m-1). \tag{5} $$

In particular, one can decompose the Killing vector field into the sum $\mathcal{K} = \mathcal{K}_\Omega + k_N\xi$, with the normal $k_N\xi$ and tangent $\mathcal{K}_\Omega \in TS_\Omega$ components. In the general case, the projection $\mathcal{K}_\Omega$ is not a Killing vector in the slices of foliation.[1,10] An exception is the case of totally umbilic or totally geodesic slice, where the projection of any Killing field is a conformal or ordinary Killing vector field respectively. Such slices arise if the field generating the foliation is a (conformal) Killing field and/or the spacetime has the structure of a warped/twisted product.[16] Therefore, the generation of the Killing vectors in M from Killing vectors $\mathcal{K}_\Omega$ with a nontrivial normal component k_N is possible in the case of the totally geodesic slices only. As we will see further, the case of Killing tensors is more intricate.

Similarly, the Killing mapping can be split to normal and tangent components $K(\,\cdot\,) = K_\Omega^{(\,\cdot\,)} + k_N^{(\,\cdot\,)}\xi$, where $k_N^{(\,\cdot\,)}\xi$ is a normal component and $K_\Omega^{(\,\cdot\,)} \in TS_\Omega$ is a tangent component. In the case of totally geodesic slices, one can lift the Killing tensor from the slice to the whole manifold and obtain a nontrivial normal component $k_N^{(\,\cdot\,)}$. This particular case of totally geodesic slices was considered, for example, in the Ref.[5]. Moreover, if we consider the conformal Killing tensors, a similar technique can be applied in the warped spacetimes,[4] where the foliation slices are totally umbilic.[16] In this paper, we consider the Killing tensor lift technique for arbitrary slices (not totally geodesic submanifolds). In this case, the second fundamental form ${}^{\Omega}\sigma$ is not trivial, and Killing equations imply $k_N^X = 0$, $K_\Omega^\xi = 0$. Then, the family of Killing mappings $K_\Omega : TS_\Omega \to TS_\Omega$ can be lifted from the slices to the Killing mapping $K(\,\cdot\,) = K_\Omega^{(\,\cdot\,)} + k_N^{(\,\cdot\,)}\xi$ in the manifold M with nontrivial normal components, if the following equations hold[1,10]

$$ k_N^X = 0, \quad K_\Omega^\xi = 0, \quad \xi(k_N^\xi) = 0, \quad X(k_N^\xi) = 2k_N^\xi \nabla_X \ln\varphi - 2\nabla_{K_\Omega^X}\ln\varphi, \tag{6a} $$

$$ \underset{X\leftrightarrow Y}{\mathrm{Sym}} \left\{ \frac{1}{2}\cdot\left\langle \nabla_\xi K_\Omega^X, Y\right\rangle + \epsilon\cdot {}^{\Omega}\sigma(X,K_\Omega^Y) - \epsilon k_N^\xi \cdot {}^{\Omega}\sigma(X,Y)\right\} = 0. \tag{6b} $$

Suppose that the manifold M has a collection $n \le m-2$ of linearly independent Killing vector fields $\mathcal{K}_\alpha$ tangent to the slices S_Ω of the foliation $\mathcal{F}_\Omega$. Then, such vectors $\mathcal{K}_\alpha$ are also Killing vectors in the slices S_Ω, and a trivial Killing mapping of the form (4) is always defined. Substituting this mapping into equations (6a), (6b) we obtain

$$ X(k_N^\xi) = 2(k_N^\xi - \alpha)\nabla_X \ln\varphi, \quad \xi(k_N^\xi) = 0, \quad X(\alpha) = 0, \quad X(\gamma^{\alpha\beta}) = 0, \tag{7a} $$

$$ 2\epsilon(k_N^\xi - \alpha)\cdot {}^{\Omega}\sigma(X,Y) = \xi(\alpha)\,\langle X,Y\rangle + \sum_{\alpha,\beta=1}^{n} \xi(\gamma^{\alpha\beta})\,\langle X,\mathcal{K}_\alpha\rangle\,\langle \mathcal{K}_\beta, Y\rangle\,, \tag{7b} $$

for any $X, Y \in TS_\Omega$. There is always a trivial solution for these equations

$$k_N^\xi = \alpha, \quad \xi(\alpha) = 0, \quad \xi(\gamma^{\alpha\beta}) = 0, \tag{8}$$

corresponding to the trivial Killing tensor in M. However, in some cases it can also have nontrivial solutions, which corresponds to the nontrivial Killing tensor and new conservation laws. Let us additionally assume that the Gramian matrix $\mathcal{G}_{\alpha\beta} = \langle \mathcal{K}_\alpha, \mathcal{K}_\beta \rangle$ is not degenerate ($\mathcal{G} \equiv \det(\mathcal{G}_{\alpha\beta}) \neq 0$). Then, we can introduce a basis $\{\mathcal{K}_\alpha, e_a\}$ in S_Ω in such a way that $e_a \in \{\mathcal{K}_\alpha\}^\perp$ with $a = 1, \ldots, m-n-1$. A non-trivial Killing tensor can be generated using the technique from the following theorem[1]:

Theorem 3.1. *Let the manifold M contains a collection of $n \leq m-2$ Killing vector fields $\mathcal{K}_\alpha$ with a non-degenerate Gramian $\mathcal{G}_{\alpha\beta} = \langle \mathcal{K}_\alpha, \mathcal{K}_\beta \rangle$, tangent to the foliation slices S_Ω (partially umbilic if $n < m-2$) with the second fundamental form*[b]

$${}^\Omega\sigma = \begin{pmatrix} -\frac{1}{2}\epsilon \cdot \xi\mathcal{G}_{\alpha\beta} & 0 \\ 0 & h^\Omega \cdot \langle e_a, e_b \rangle \end{pmatrix} \tag{9}$$

Then, there is a nontrivial Killing tensor on manifold M, if the following steps can be successfully completed:

***Step one**: Check compatibility and integrability conditions (10), (11)*

$$X(h^\Omega \cdot \varphi^3) = 0, \tag{10}$$

$$X\left(\mathcal{G}^{\alpha\beta} - \frac{\epsilon}{2h^\Omega} \cdot \xi\mathcal{G}^{\alpha\beta}\right) = 0. \tag{11}$$

***Step two**: Obtain α from (12) and check the condition (13)*

$$\xi \ln \xi(\alpha) = \xi \ln h^\Omega - 2\epsilon h^\Omega, \tag{12}$$

$$X(\alpha) = 0. \tag{13}$$

***Step three**: Define $\gamma^{\alpha\beta}$ from (14) using the conditions $\xi\nu^{\alpha\beta} = 0$, $X\gamma^{\alpha\beta} = 0$.*

$$\gamma^{\alpha\beta} = \epsilon\frac{\xi(\alpha)}{2h^\Omega} \cdot \mathcal{G}^{\alpha\beta} - \nu^{\alpha\beta}, \tag{14}$$

***Step four**: Using the functions found in the previous steps, construct a Killing map and the corresponding Killing tensor:*

$$K(\mathcal{X}) = \alpha\mathcal{X} + \sum_{\alpha,\beta=1}^{n} \gamma^{\alpha\beta} \langle \mathcal{X}, \mathcal{K}_\alpha \rangle \mathcal{K}_\beta + \frac{\xi(\alpha)}{2h^\Omega} \langle \mathcal{X}, \xi \rangle \xi. \tag{15}$$

[b]The form of the left upper block is a consequence of the tangent Killing vectors, and this does not impose a new condition. The non-diagonal zero elements is a new condition, which is satisfied in many applications. The right lower block is a condition of partially umbilical surfaces, which imposes constraints if $\dim\{e_a\} > 1$.

4. Connection with photon submanifolds

Consider the case of a manifold with two Killing vectors spanning a timelike surface ($\mathcal{G} < 0$). Let us define a Killing vector field ρ^α with index $\alpha = 1, 2$ numbering Killing vectors of the basis $\{\mathcal{K}_\alpha\}$, which is supposed to have constant components $\rho^\alpha = (\rho, 1)$. The quantity ρ can be called the generalized impact parameter (see[10] for details). However, one can choose arbitrary parametrization of ρ^α up to the norm.

Proposition 4.1. *The fundamental photon surface is a partially umbilic surface with a second fundamental form of the form (9), with the following connection between h^Ω and $\mathcal{G}_{\alpha\beta}$[10]*

$$\rho^\alpha \mathcal{M}_{\alpha\beta}\rho^\beta = 0, \qquad \mathcal{M}_{\alpha\beta} \equiv \frac{1}{2h^\Omega}\cdot\xi\mathcal{G}_{\alpha\beta} - \mathcal{G}_{\alpha\beta} - \frac{1}{2h^\Omega}\cdot\xi\ln\mathcal{G}\cdot\mathcal{G}_{\alpha\beta}. \tag{16}$$

If the surface under consideration is totally umbilic $\mathcal{M}_{\alpha\beta} = 0$, it is obviously a fundamental photon surfaces for any ρ. Since totally umbilic surfaces usually exist in spherically symmetric solutions (both static and non-static) or non-rotating solutions with NUT-charge,[17] and they have been considered in detail in a number of works,[18,19] we will focus on the case $\mathcal{M}_{\alpha\beta} \neq 0$.

Consider the foliation generating a nontrivial Killing tensor in accordance with Theorem 3.1, and ask the question whether its slice S_Ω is a fundamental photon surface. First of all, we need to solve the quadratic equation (16) for ρ and check the condition $\rho^\alpha\mathcal{G}_{\alpha\beta}\rho^\beta \geq 0$. It has nontrivial solution if the eigenvalues of the matrix $\mathcal{M}_{\alpha\beta}$ have different signs, that is $\mathcal{M} \equiv \det(\mathcal{M}_{\alpha\beta}) < 0$. Then the solution for ρ reads as

$$\rho = \frac{-\mathcal{M}_{12} \pm \sqrt{-\mathcal{M}}}{\mathcal{M}_{11}}. \tag{17}$$

Condition $\rho^\alpha\mathcal{G}_{\alpha\beta}\rho^\beta \geq 0$ is satisfied if the following inequality holds

$$\pm 2(\mathcal{G}_{12}\mathcal{M}_{11} - \mathcal{G}_{11}\mathcal{M}_{12})\sqrt{-\mathcal{M}} - 2\mathcal{G}_{11}\cdot\mathcal{M} + \mathcal{M}_{11}\cdot\mathcal{G}\cdot\mathrm{Tr}(\mathcal{M}) \geq 0, \tag{18}$$

where $\mathrm{Tr}(\mathcal{M}) = \mathcal{M}_{\alpha\beta}\mathcal{G}^{\alpha\beta} = -2-(2h^\Omega)^{-1}\cdot\xi\ln\mathcal{G}$. Equation (18) defines the so-called photon region,[20,21] which arises as a flow of fundamental photon surfaces.[10] However, it has not been proven that the expression (17) for ρ is constant in every slice. But the integrability condition (11) guarantees that it is true in fact.[1] Therefore, we have the following theorem.

Theorem 4.1. *Let S_Ω be a non totally umbilic foliation slice with compact spatial section satisfying all conditions of the theorem 3.1 for $dim\{\mathcal{K}_\alpha\} = 2$. Then maximal subdomain $U_{PS} \subseteq S_\Omega$ such that the inequality (18) holds for all $p \in U_{PS}$ is a fundamental photon surface*[c].

[c] In the case of not compact spatial section, the slice is not a fundamental photon surface by definition.[10] However, the theorem can be generalized for such not compact surfaces.

In particular, the region $U_{PR} \subseteq M$, such that the inequality (18) holds for any point $p \in U_{PR}$, is a photon region. This theorem generalizes the connection between the existence of Killing tensors of this type and photon surfaces or spherical null geodesics, which was noted in Refs.[11,19,22]. Unfortunately, in the opposite direction, the theorem is not fair, since the existence of fundamental photon surfaces does not guarantee the existence of the Killing tensor. As a counterexample, one can suggest Zipoy-Voorhees metric[23] where the fundamental photon surfaces exists[24] but there is no nontrivial Killing tensor.[25] Nevertheless, the existence of fundamental photon surfaces can serve as a sign that the Killing tensor can be presented in the corresponding metric, and it is advisable to check the conditions of consistency and integrability.

5. Axially symmetric spacetimes

Consider a Lorentzian manifold M with the metric tensor

$$ds^2 = -f(dt - \omega d\phi)^2 + \lambda dr^2 + \beta d\theta^2 + \gamma d\phi^2. \tag{19}$$

where all metric components depend on r and θ only and the foliation with timelike slices $r = \Omega$. Generally, this metric possesses two Killing vectors $\mathcal{K}_1 = \partial_t$, $\mathcal{K}_2 = \partial_\varphi$. One can find that the second fundamental form of these slices has the form (9) and other quantities are

$$\xi = \lambda^{-1/2}\partial_r, \quad h^\Omega = -\frac{1}{2}\lambda^{-1/2} \cdot \partial_r \ln\beta, \quad \varphi = \lambda^{1/2}, \quad \mathcal{G}^{\alpha\beta} = \frac{1}{\gamma}\begin{pmatrix} \omega^2 - \gamma f^{-1} & \omega \\ \omega & 1 \end{pmatrix}. \tag{20}$$

In this case, the number of Killing vector is one less than the slices dimension, so the boundary $n \geq m - 2$ saturates and the partially umbilic condition just imposes a relation on h^Ω. The compatibility and integrability conditions (10), (11) take the form

$$\partial_\theta(\lambda \cdot \partial_r \ln\beta) = 0, \qquad \partial_\theta\left(\mathcal{G}^{\alpha\beta} + \frac{1}{\partial_r \ln\beta}\partial_r\mathcal{G}^{\alpha\beta}\right) = 0. \tag{21}$$

The Eq. (12) can be solved as follows

$$\alpha = A_\theta \cdot \beta + B_\theta, \tag{22}$$

where the arbitrary functions A_θ, B_θ depend on θ only, obeying the condition $\partial_\theta\alpha = 0$. As the result, we have one more necessary condition for the case in this section: the function β must be of the form

$$\beta(r,\theta) = \beta_1(\theta)\beta_2(r) + \beta_3(\theta), \tag{23}$$

where $\beta_{1,2,3}$ are some functions of the corresponding variables. In particular, the normal component is $k_N^\xi = B_\theta$. Next, we can define the matrix γ:

$$\gamma^{\alpha\beta} = -\beta A_\theta \cdot \mathcal{G}^{\alpha\beta} - \nu^{\alpha\beta}. \tag{24}$$

The integrability condition guarantees that $\gamma^{\alpha\beta}$ always satisfies the equations (7) for some $\nu^{\alpha\beta}$ depending only on θ. On the other hand, we have to find a $\nu^{\alpha\beta}$ that makes the equation $\partial_r \gamma^{\alpha\beta} = 0$ true. Therefore, we can omit the θ-dependent part in $\gamma^{\alpha\beta}$ to some constant matrix instead of looking for $\nu^{\alpha\beta}$. Combining everything together, we get the final Killing tensor in the holonomic basis

$$K^{\mu\nu} = \alpha g^{\mu\nu} + \sum_{\alpha,\beta=t,\phi} \gamma^{\alpha\beta} \mathcal{K}^{\mu}_{\alpha} \mathcal{K}^{\nu}_{\beta} - \beta A_\theta \lambda^{-1} \delta^{\mu}_{r} \delta^{\nu}_{r}. \tag{25}$$

The compatibility and integrability conditions, as well as the condition on the function β, are invariant under the multiplicative transformations of the form

$$\lambda \to \lambda' = u(r)\lambda, \quad \beta \to \beta' = v(\theta)\beta. \tag{26}$$

If β possesses the aforementioned form (23), one can simplify the integrability condition by the substitution $\mathcal{G}^{\alpha\beta} = \tilde{\mathcal{G}}^{\alpha\beta} \cdot \beta_1/\beta$. Then, the integrability condition is $\partial_\theta \partial_r \tilde{\mathcal{G}}^{\alpha\beta} = 0$, which is solved by $\tilde{\mathcal{G}}^{\alpha\beta} = \tilde{\mathcal{G}}^{\alpha\beta}_r(r) + \tilde{\mathcal{G}}^{\alpha\beta}_\theta(\theta)$. This generalizes the result of Ref.[26], where the similar condition was obtained from the separability of the Hamilton-Jacobi equation. In our case, we have also included the $\beta_1(\theta)$ term. Furthermore, the compatibility condition and the function form (23) leads to the form of $\lambda = \lambda_r(r)\beta/\beta_1$, where λ_r is an arbitrary function of r.

5.1. *Kerr metric*

As a simple illustration, consider Kerr solution in the Boyer-Lindquist coordinates:

$$ds^2 = -\frac{\Delta - a^2 \sin^2\theta}{\Sigma}(dt - \omega d\phi)^2 + \Sigma\left(\frac{dr^2}{\Delta} + d\theta^2 + \frac{\Delta \sin^2\theta}{\Delta - a^2\sin^2\theta} d\phi^2\right), \tag{27}$$

$$\Sigma = r^2 + a^2\cos^2\theta, \qquad \omega = \frac{-2Mar\sin^2\theta}{\Delta - a^2\sin^2\theta}, \tag{28a}$$

$$\Delta = r(r-2M) + a^2. \tag{28b}$$

In the Kerr metric, $\beta = r^2 + a^2\cos^2\theta$, $\lambda = \beta/\Delta$, satisfy the compatibility condition. One can explicitly verify that $\mathcal{G}^{\alpha\beta}$ satisfies the integrability equation. In this case $\alpha = r^2$, $A_\theta = 1$ and $k^{\xi}_{N} = B_\theta = -a^2\cos^2\theta$ (here we have fixed the multiplicative integration constant, which appears due to the linearity of Killing equations). The part of $\gamma^{\alpha\beta}$ independent on θ reads

$$\gamma^{\alpha\beta} = \Delta^{-1} \begin{pmatrix} (a^2+r^2)^2 & a(a^2+r^2) \\ a(a^2+r^2) & a^2 \end{pmatrix}. \tag{29}$$

Finally, we get α and $\gamma^{\alpha\beta}$, which correspond to the well-known nontrivial Killing tensor for Kerr solution

$$\begin{aligned} K^{\mu\nu} &= r^2 g^{\mu\nu} + \Delta^{-1} S^\mu S^\nu - \Delta \delta^{\mu}_{r} \delta^{\nu}_{r}, \\ S^\mu &= s\delta^{\mu}_{t} + a\delta^{\mu}_{\varphi}, \qquad s = r^2 + a^2. \end{aligned} \tag{30}$$

5.2. *Plebanski-Demianski solution*

This is a less trivial example of the type D solution of Einstein-Maxwell equations with the cosmological constant, which contains also an acceleration parameter. The metric line element ds^2 is more conveniently presented in the conformally related frame using the Boyer-Lindquist coordinates:

$$\Omega^2 ds^2 = \Sigma\left(\frac{dr^2}{\Delta_r}+\frac{d\theta^2}{\Delta_\theta}\right)+\frac{1}{\Sigma}\left((\Sigma+a\chi)^2\Delta_\theta\sin^2\theta-\Delta_r\chi^2\right)d\phi^2 \tag{31}$$

$$+\frac{2}{\Sigma}\left(\Delta_r\chi-a(\Sigma+a\chi)\Delta_\theta\sin^2\theta\right)dtd\phi-\frac{1}{\Sigma}\left(\Delta_r-a^2\Delta_\theta\sin^2\theta\right)dt^2, \tag{32}$$

where we have defined the functions

$$\Delta_\theta = 1-a_1\cos\theta-a_2\cos^2\theta, \quad \Delta_r = b_0+b_1r+b_2r^2+b_3r^3+b_4r^4, \tag{33}$$

$$\Omega = 1-\lambda(N+a\cos\theta)r, \quad \Sigma = r^2+(N+a\cos\theta)^2, \quad \chi = a\sin^2\theta-2N(\cos\theta+C), \tag{34}$$

with the following constant coefficients in Δ_θ and Δ_r:

$$a_1 = 2aM\lambda-4aN\left(\lambda^2(k+\beta)+\frac{\Lambda}{3}\right), \quad a_2 = -a^2\left(\lambda^2(k+\beta)+\frac{\Lambda}{3}\right), \quad b_0 = k+\beta, \tag{35}$$

$$b_1 = -2M, \quad b_2 = \frac{k}{a^2-N^2}+4MN\lambda-(a^2+3N^2)\left(\lambda^2(k+\beta)+\frac{\Lambda}{3}\right), \tag{36}$$

$$b_3 = -2\lambda\left(\frac{kN}{a^2-N^2}-(a^2-N^2)\left(M\lambda-N\left(\lambda^2(k+\beta)+\frac{\Lambda}{3}\right)\right)\right), \tag{37}$$

$$b_4 = -\left(\lambda^2k+\frac{\Lambda}{3}\right), \tag{38}$$

$$k = \frac{1+2MN\lambda-3N^2\left(\lambda^2\beta+\frac{\Lambda}{3}\right)}{1+3\lambda^2N^2(a^2-N^2)}(a^2-N^2), \quad \lambda = \frac{\alpha}{\omega}, \quad \omega = \sqrt{a^2+N^2}\,. \tag{39}$$

Generally, the coordinates t and r range over the whole $\mathbb{R}$, while θ and ϕ are the standard coordinates on the unit two-sphere. Seven independent parameters $M, N, a, \alpha, \beta, \Lambda, C$ can be physically interpreted as mass, NUT parameter (magnetic mass), rotation parameter, acceleration parameter, $\beta = e^2+g^2$ comprises the electric e and magnetic g charges, Λ is the cosmological constant, and the constant C defines the location of the Misner string.

The first step is to check the compatibility and integrability conditions (10), (11). The first one holds if $\alpha \cdot a = 0$, i.e. either the acceleration α or the rotation a are zero. Indeed, as shown in Ref.[12], the general PD solution with acceleration possesses a conformal Killing tensor, but not the usual one. In the case $a = 0$, the second condition does not hold. So, further we will consider the solution with zero acceleration $\alpha = 0$, which corresponds to the dyonic Kerr-Newman-NUT-AdS solution.

In the **second step** we pick up the r-dependent part from $\beta = \Sigma/\Delta_\theta$ for α

$$\beta = \frac{\Sigma}{\Delta_\theta} \quad \Rightarrow \quad \alpha = r^2, \quad A_\theta = \Delta_\theta. \tag{40}$$

Similarly, as the **third step**, the r-dependent part for $\gamma^{\alpha\beta}$ is defined as

$$\gamma^{\alpha\beta} = \Delta_r^{-1} \begin{pmatrix} s^2 & as \\ as & a^2 \end{pmatrix}, \quad s = \Sigma + a\chi = r^2 + a^2 - 2aCN + N^2. \tag{41}$$

In the last **fourth step**, we obtain the nontrivial Killing tensor for the Kerr-Newman-NUT-AdS metric:

$$K^{\mu\nu} = r^2 g^{\mu\nu} + \Delta_r^{-1} S^\mu S^\nu - \Delta_r \delta^\mu_r \delta^\nu_r, \quad S^\mu = s\delta^\mu_t + a\delta^\mu_\varphi. \tag{42}$$

6. Gal'tsov-Kechkin (GK) solution

In 1994 one of the present authors in collaboration with O. Kechkin derived the general stationary charged black hole solution within the Einstein-Maxwell- dilaton-axion (EMDA) gravity, which is the $\mathcal{N} = 4, D = 4$ supergravity consistently truncated to the theory with one vector field.[14] This solution was seven-parametric, containing mass M, electric and magnetic charges Q, P, rotation parameter a, NUT N and asymptotic values of the dilaton and axion (irrelevant for the metric) as independent parameters. Less general (without NUT) solution was derived by A. Sen[27] in the context of the dimensionally reduced effective action of the heterotic string, and now it is commonly referred as Kerr-Sen metric. Non-rotating solutions with NUT were independently obtained by Kallosh et al.[28] and Johnson and Myers.[29] Now the Kerr-Sen metric is often considered as a deformed Kerr solution in modeling deviations from the standard picture of black holes.

The GK solution[14] was shown[15] to belong to type Petrov I, contrary to Kerr-Newman-NUT solution in the Einstein-Maxwell gravity. The same was shown for Kerr-Sen solution without NUT.[30] Though the Kerr-Sen metric is not type D, the Hamilton-Jacoby equation was shown to be separable for it,[31,32] though the Killing tensor was not found explicitly (for further discussion see[9]). But for the solution with NUT, it was claimed that no second rank Killing tensor exists.[33] So here we use the new technique to resolve this controversy.

The line element of the GK solution can be written in the form (27) where the functions Δ, ω, Σ are redefined as follows

$$\begin{aligned}
&\Delta = (r - r_-)(r - 2M) + a^2 - (N - N_-)^2, \\
&\Sigma = r(r - r_-) + (a\cos\theta + N)^2 - N_-^2, \\
&\omega = \frac{-2w}{\Delta - a^2 \sin^2\theta}, \quad w = N\Delta\cos\theta + a\sin^2\theta\,(M(r - r_-) + N(N - N_-))\,.
\end{aligned}$$

The full solution also contains Maxwell, dilaton ϕ and axion κ fields (whose form can be found in[14]), and represents a family with seven parameters: mass M,

NUT charge N, rotation parameter a, electric and magnetic charges Q and P, and asymptotic complex axidilaton charge $z_\infty = \kappa_\infty + i\mathrm{e}^{-2\phi_\infty}$, irrelevant for the metric. The following abbreviations are used:

$$r_- = \frac{M|\mathcal{Q}|^2}{|\mathcal{M}|^2}, \quad N_- = \frac{N|\mathcal{Q}|^2}{2|\mathcal{M}|^2}, \quad \mathcal{M} = M + iN, \quad \mathcal{Q} = Q - iP, \quad \mathcal{D} = -\frac{\mathcal{Q}^{*2}}{2\mathcal{M}}. \tag{43}$$

The metric is presented in the Kerr-like form, but the metric functions are essentially different. The solution reduces to Kerr-NUT for $Q = P = 0$.

Now we apply our procedure to construct the Killing tensor. It can be easily verified that the consistency (10) and the integrability (11) conditions are satisfied. The uplift turns out to be as simple as in the vacuum Kerr example, leading to the result

$$\begin{aligned} &K^{\mu\nu} = r(r - r_-)g^{\mu\nu} + \Delta^{-1}S^\mu S^\nu - \Delta\delta^\mu_r\delta^\nu_r, \\ &S^\mu = s\delta^\mu_t + a\delta^\mu_\varphi, \qquad s = r(r - r_-) + a^2 + N^2 - N_-^2. \end{aligned} \tag{44}$$

This expression is new and is applicable both to the Kerr-Sen solution $N = N_- = 0$, and for the full GK solution.

7. Conclusions

In this article, we reviewed new geometric method of generating Killing tensor in spacetimes with codimension one foliation.[1] Using our general lift equations one can try to rise a trivial Killing tensor defined in the slices into a nontrivial Killing tensor in the bulk. For this, the foliation must satisfy some consistency and integrability conditions, which we have presented explicitly. Furthermore, we have completely solved the lifting equations in terms of the functions α, $\gamma^{\alpha\beta}$ and formulated the theorem (3.1) for generation of the non-trivial Killing tensor.

Finding a foliation compatible with integrability and consistency conditions can be a challenging task. The existence of such a foliation means that the slices represent fundamental photon surfaces provided the corresponding inequalities hold. This generalizes the result of Ref.[19] to the case of general stationary spaces. Conversely, the existence of fundamental photon surfaces, though does not guarantee the existence of the Killing tensor, but may serve as an indication that such tensor may exist. Therefore, it is recommended to check the consistency and integrability conditions for fundamental photon surfaces, if these are known. This property makes the search for fundamental photon surfaces important also for studying the integrability of geodesic motion. It is tempting to conjecture that the existence of fundamental photon surfaces implies the existence of Killing tensor if the slice is equipotential or spherical.[34]

Using this technique, we were able to derive Killing tensor for EMDA dyon with NUT (GK solution[14]), which is also valid for Kerr-Sen solution as a particular case.

Decoding black hole metrics from the interferometric pattern of relativistic images

V. Bozza

The image of a source around a black hole is replicated an infinite number of times by photons performing an arbitrary number of turns around the black hole. Such relativistic images generate a characteristic staircase structure in the complex visibility measured in interferometric observations. For a quasi-static source, we present analytical formulae describing the visibility function in the strong deflection limit of gravitational lensing. These formulae are then used to extract the properties of the metric from features in the visibility.

Keywords: Black hole, gravitational lensing, interferometry

1. Introduction

The sensational observation of the image of the supermassive black hole at the center of M87* by the EHT collaboration has opened the era of the investigation of black holes at high resolution.[1] Black holes typically appear as a dark spot surrounded by a light ring created by the radiation emitted by the accreting matter revolving around the black holes thanks to the strong gravitational fields.[2,3] This is possible because an unstable circular orbit for photons exists at a specific radius, depending on the black hole parameters and the inclination of the photon trajectory with respect to the equatorial plane. For this reason, any compact sources around the black hole generate two infinite sequences of images asymptotically approaching the light ring.[4–7]

Higher order images of the accretion disk should generate concentric light rings asymptotically approaching the shadow border.[8] Such structure would be detectable in very long baseline interferometry, since the complex visibility should have a staircase structure, with each step generated by an image at specific order.[9]

We propose to describe the complex visibility generated by a compact source using the tools of gravitational lensing in the strong deflection limit. With an analytical description at hand, it is then possible to track the dependence of the observables on the black hole metric and disentangle the metric parameters from the source characteristics.[10]

2. Relativistic images of a compact source

Consider a source at distance r_S from a black hole at angle ϕ_S from the optical axis (i.e. the line joining the observer to the black hole). The direct image will be formed by weakly deflected light rays and will be the largest one, thus dominating the lower angular frequencies in the visibility. Relativistic images are formed by light rays performing n turns around the black hole before reaching the observer.[4] The angular separation of these images from the black hole in the observer sky can be described in the strong deflection limit by a simple exponential formula[11]

$$\theta_{n,\pm} = \theta_m(1 + \epsilon_{n,\pm}), \tag{1}$$

where θ_m is the angular radius of the shadow,

$$\epsilon_{n,\pm} = \eta_O \eta_S e^{\frac{b \pm \phi_S - 2n\pi}{a}}, \tag{2}$$

$$\eta_O = 1 - \frac{r_m}{r_O} \qquad \eta_S = 1 - \frac{r_m}{r_S}, \tag{3}$$

r_O is the observer's distance and r_m is the radius of the unstable circular orbit for photons.

The quantities r_m, u_m, a and b are all functions of the specific black hole metric and can be calculated by standard algorithms.[11] Therefore, in principle, the observation of higher order images can be used to constrain the metric of the black hole. The tangential extension of higher order images $\Delta\vartheta_I$ is the same as the tangential extension of the source $\Delta\vartheta_S$ in the hypothesis of spherical symmetry. The radial extension is obtained by differentiation of Eq. (1)

$$\Delta\theta_{n,\pm} = \Delta\theta_0 \; \epsilon_{n,\pm} \tag{4}$$

$$\Delta\theta_0 = \frac{\theta_m}{a}\Delta\phi_S + \theta_m \frac{r_m}{r_S^2}\left(\frac{1}{\eta_S} + \frac{g_1(\eta_S)}{a}\right)\Delta r_S. \tag{5}$$

Higher order n are exponentially thinner with n. The coefficient $\Delta\theta_0$ does not depend on n, instead.

3. Complex visibility of a compact source

Interferometric observations measure the amplitude of the complex visibility, which is calculated by a Fourier transform of the image pattern.[9] If we assume a static source with a Gaussian profile, the images will be aligned along one axis in the observer sky (say the x-axis). The complex visibility expressed in the angular frequencies (u, v) conjugate to the angular coordinates (x, y) will be

$$V(u,v) = N(v) \sum_{p=\pm 1} \sum_{n=1}^{+\infty} \epsilon_{n,p} \; e^{-2\pi^2 \Delta\theta_{n,p}^2 u^2} e^{-2\pi\imath p\theta_{n,p} u}, \tag{6}$$

$$N(v) = 2\pi I_0 \theta_m \Delta\theta_0 \Delta\vartheta_S e^{-2\pi^2 \theta_m^2 \Delta\vartheta_S^2 v^2}. \tag{7}$$

The shape of the visibility in the v direction $N(v)$ does not depend on n and is the same for all contributions. In the u direction, each image contributes with a Gaussian function whose size scales with $1/\Delta\theta_n$ and thus increases exponentially with n. As the contribution of order n decays, the order $n+1$ dominates, generating the staircase structure already suggested in Ref. 9. Fig. 1 shows this structure for various source positions ϕ_S.

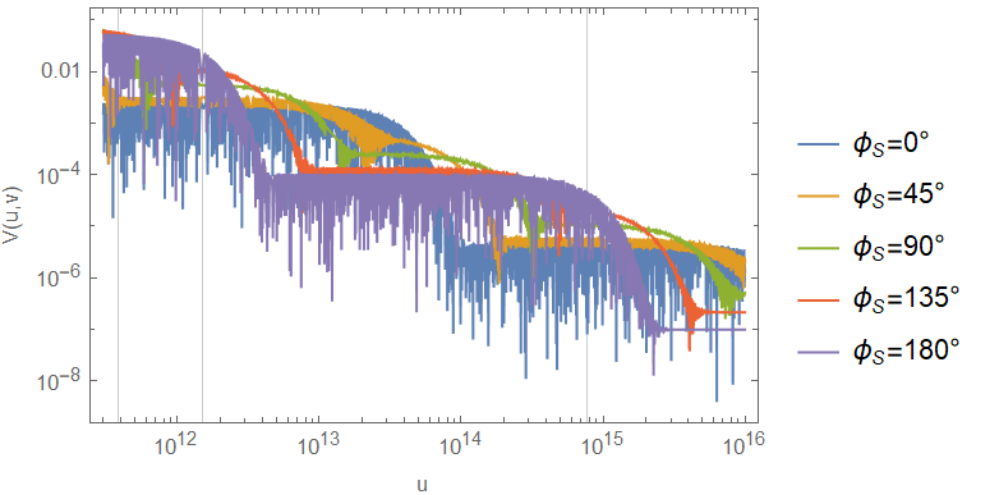

Fig. 1. Visibility function in Schwarzschild space-time for various source azimutal angles. The three vertical lines correspond to Moon baseline, Lagrangian point L2 baseline and Jupiter semi-major axis respectively at the wavelength $\lambda = 1$mm.

The direct image only contributes to low angular frequencies and rapidly decays, leaving space to higher order images at high angular frequencies. Such contributions are analytically expressed by Eq. (6), which can be used to relate the main characteristics such as amplitude, size and periodicity of each contribution to the characteristics of the black hole metric.[10]

Simple algebra allows to invert such expressions so as to write down the gravitational lensing parameters as functions of the observables.[10] The coefficient a is given by the ratio of the amplitude $h_{n,+}$ of contributions by images of consecutive orders

$$a = \frac{2\pi}{\ln\left(h_{n,+}/h_{n+1,+}\right)}. \tag{8}$$

The source angular position is obtained by comparing the amplitude of contributions by positive and negative parity images

$$\phi_S = \frac{a}{2}\ln\left(h_{n,+}/h_{n,-}\right). \tag{9}$$

The angular radius of the shadow and the coefficient b are derived from the frequencies $\nu_{n,\pm}$ of the periodicities in the visibility at scales when two contributions interfere

$$\theta_m = \frac{1}{4}\left\{e^{\frac{2\pi}{a}}\left[\nu_{n,-} + e^{-\frac{2\phi_S}{a}}\left(\nu_{n,-} - \nu_{n,+}\right)\right] - \nu_{n,+}\right\}\left(\coth\frac{\pi}{a} - 1\right), \tag{10}$$

$$\eta_O \eta_S e^{\frac{b-2n\pi}{a}} = \frac{2(\nu_{n,+} - \nu_{n,-})}{\nu_{n,-}\left(e^{\frac{\phi_S}{a}} + e^{-\frac{\phi_S}{a}}\right) - \nu_{n,+}\left(e^{\frac{\phi_S - 2\pi}{a}} + e^{-\frac{\phi_S}{a}}\right)}. \tag{11}$$

These analytical formulae allow to constrain the coefficients of gravitational lensing in the strong deflection limit, which are functions of the black hole metric. It could be possible, therefore, to distinguish between different metrics through the observation of the visibility of a compact source.[10]

4. Discussion and conclusions

As pointed before, the baselines needed for the resolution of higher order images are of the order of millions km.[9] The great scientific expectations on such observations are pushing forward projects for very long baseline interferometry in space, which could be available in the next decades.[12,13]

The physical setup analyzed in this study is very basic: a single static compact source at some distance from a spherically symmetric black hole. In this framework, the complex visibility generated by the infinite sequence of higher order images is simple enough to be described in a fully analytical form. The properties of the metric can be extracted in a clean and source-independent way, something that is quite difficult for non-compact sources or with the whole accretion flow.[14]

However, in order to apply this idealized case to real astrophysical situations, we need a powerful source dominating over the accretion flow with its higher order images. In the mm band this may happen with a very powerful flare in the accretion flow due to some local change in the magnetic fields.[15] In the Near Infrared, we may consider bright stars orbiting the black hole as compact sources.[16] Secondly, in order to have all images aligned on the same axis, we need perfect spherical symmetry and a quasi-static source. In fact, higher order images are formed by photons taking longer paths as they revolve around the black hole. Therefore, such images would follow an orbiting source with some delay.[17] This limits the applicability of this framework to sources far enough to neglect their orbital motion.

In spite of these limitations, this fully analytical calculation stands as a reference limiting case for more complicated calculations and opens the investigation to more complete physical setups.

Symplectic evolution of an observed light bundle

N. Uzun

Univ Lyon, Ens de Lyon, Univ Lyon1, CNRS, Centre de Recherche Astrophysique de Lyon Lyon, UMR5574, F69007, France
E-mail: nezihe.uzun@ens-lyon.fr
http://www.univ-lyon1.fr

Each and every observational information we obtain from the sky regarding the brightnesses, distances or image distortions resides on the deviation of a null geodesic bundle. In this talk, we present the symplectic evolution of this bundle on a reduced phase space. The resulting formalism is analogous to the one in paraxial Newtonian optics. It allows one to identify any spacetime as an optical device and distinguish its thin lens, pure magnifier and rotator components. We will discuss the fact that the distance reciprocity in relativity results from the symplectic evolution of this null bundle. Other potential applications like wavization and its importance for both electromagnetic and gravitational waves will also be summarized.

Keywords: General relativity, geodesic deviation, optics, symplectic

1. Introduction

When we make an observation on the sky, we deduce the brightness, distance and image distortion information about astrophysical objects via a bundle of null rays. This geodesic bundle connects the emitter and the observer that are located at two distant regions of a spacetime. Nevertheless, they receive reciprocal information about each other.

For example, an observer located at point O on Earth, obtains the distance to a galaxy cluster located at point G, by making use of the observed solid angle at point O, and the estimated cross–sectional area on the sky at point G. This gives the angular diameter distance, D_A. Such a distance estimation is mostly relevant for standard rulers in cosmology as, for example, baryon acoustic oscillations. Likewise, an observer at point G can estimate the distance to a point O in a similar fashion. According to an observer on Earth, on the other hand, this information is contained in the luminosity distance, D_L. Namely, by using the observed flux

$$F_{\text{observed}} = \frac{\text{Source luminosity}}{\text{Surface area}} = \frac{L_{\text{source}}}{4\pi D_U^2}, \tag{1}$$

one can deduce an *uncorrected* luminosity distance, D_U. When the relativistic corrections are included, one obtains a corrected luminosity distance, D_L, via

$$D_L = (1+z)^{-1} D_U, \tag{2}$$

where z is the redshift factor. The relationship between the luminosity distance and the angular diameter distance is given by Etherington's distance reciprocity theorem[1]

$$D_L = (1+z)D_A. \tag{3}$$

The distance reciprocity, eq (3), was originally derived for light propagation within a single spacetime. This means that the initial point of the propagation is an observation point at which the geodesic deviation vector becomes zero. Eventually, it can be shown that the distance reciprocity follows from the symmetries of the Riemann curvature tensor.[1,2]

Previously, we showed that[3] one can extend the proof for more generic scenarios. Namely, for a ray bundle propagating in multiple geometries, one needs to propagate a bundle with arbitrary initial conditions. Such a scenario was used, for example, in Fleury *et al.*[4,5] In those investigations, there exists a 4×4 Wronskian matrix which takes the initial ray bundle variables to the final ones. A similar construction can be found[6–9] where the Wronskian in question is 8–dimensional and it includes more information regarding the light bundle evolution. We demonstrated[3] that the Wronskian matrix of Fleury *et al.* is indeed symplectic and the most general form of the distance reciprocity follows from the symplectic symmetries of this transformation matrix. This was achieved by following a Hamiltonian formalism defined on a 4–dimensional phase space. Note that our approach is analogous to the reduced phase space optics formalism developed for classical paraxial rays.[10,11]

In classical optics, one starts with Fermat's action in order to obtain a Hamiltonian formalism in which rays are the geodesic solutions of the corresponding optical metric of Fermat. Likewise, we implemented the usage of geodesic actions applied to a null bundle. The outcome is an effective geodesic deviation action which was originally derived up to higher orders in Vines' work.[12]

The aim of this talk is to give a brief summary of our previous formalism,[3] along with discussing the importance of implementing such new techniques to gravitational optics. We summarize the aforementioned symplectic phase space approach in Section (2). Some perspectives on the symplectic ray bundle evolution is given in Section (3) and we conclude with Section (4).

2. Symplectic evolution of light bundles on phase space

2.1. *Vines' bi–local geodesic deviation action*

It is known that connecting two geodesics is, in general, non–local. Therefore, if one wants to obtain a geodesic deviation action, one needs to consider a bi–local formalism. Vines[12] achieves this for generic curves by following the definition of Synge's world function[13] $\sigma(x,y)$. This is a bi–local object which depends on two spacetime points x and y. Those two points are connected by a unique geodesic, Σ,

such that

$$\sigma(x,y) = \frac{1}{2}\begin{cases} (\text{proper distance})^2, & \Sigma : \text{spacelike} \\ 0, & \Sigma : \text{null} \\ -(\text{proper time})^2, & \Sigma : \text{timelike.} \end{cases}$$

Now consider a bundle whose outer most null geodesic, $\Upsilon(v)$, has a tangent vector $\vec{k}'$ (See Fig. 1.). The central null geodesic, $\chi(v)$, with a tangent vector $\vec{k}$, can also be parameterized with the same affine parameter v. This is called isosynchronous parameterization. Then those tangent vectors satisfy $\nabla_{\vec{k}'}\vec{k}' = 0$ and $\nabla_{\vec{k}}\vec{k} = 0$ where ∇ denotes the covariant derivative operator defined at a specified point. Moreover, physical sizes of the objects on the sky are estimated by the proper sizes. Therefore, a spacelike world function, being the measure of proper distance between two spacetime points, is the most relevant tool for our construction.

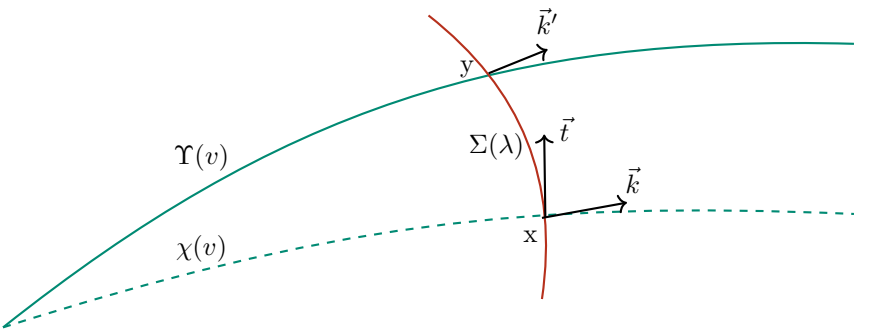

Fig. 1. The central null geodesic $\chi(v)$ is plotted with dashed lines. The red curve represents $\Sigma(\lambda)$ given by Synge's world function that is spacelike. The outermost null geodesic $\Upsilon(v)$ can be uniquely obtained through $\chi(v)$ and $\Sigma(\lambda)$.

Now consider a spacelike geodesic, $\Sigma(\lambda)$, that connects $\Upsilon(v)$ to $\chi(v)$. One can define an exponential map on $\Sigma(\lambda)$ via the derivatives of the world function $\sigma(x,y)$. This results in a bi–local object $\vec{\eta}$, whose variation with respect to the affine parameter that parameterizes the null bundle, is given by[3,12]

$$\dot{\eta}^\alpha = \frac{\mathbb{D}\eta^\alpha}{dv} = \left(k^\beta \nabla_\beta + k'^\mu \nabla_\mu\right)\eta^\alpha. \tag{4}$$

Note that for an arbitrarily large separation one needs to consider the covariant derivatives of $\vec{\eta}$ at two distinct points along the null bundle as in eq. (4). In that case, one can write the action functional of $\Upsilon(v)$, i.e., $S_\Upsilon = \int \frac{1}{2}k'^2 dv$, by making use of the action functional, $S_\chi = \int \frac{1}{2}k^2 dv$, of the central null geodesic, $\chi(v)$, and some additional terms,[3,12] i.e.,

$$S_\Upsilon = S_\chi + \int \frac{1}{2}\left[2\vec{k}\cdot\dot{\vec{\eta}} + \dot{\vec{\eta}}\cdot\dot{\vec{\eta}} - R_{\vec{\eta}\vec{k}\vec{\eta}\vec{k}} + O(\vec{\eta},\dot{\vec{\eta}})^3\right] dv. \tag{5}$$

Here, $R^{\alpha}{}_{\gamma\beta\delta}$ is the Riemann curvature tensor. In order to obtain the second integral, that appears on the r.h.s of eq. (5), one solves eq. (4) for $\vec{k}'$ and substitutes it in $S_{\Upsilon} = \int \frac{1}{2} k'^2 dv$. However, this is not a straightforward calculation as it requires the bi–local object $\dot{\eta}^{\alpha}$ to be Taylor expanded in the coincidence limit. We advice the reader to see the original derivation of Vines[12] for generic scenarios or our previous paper[3] for further details in this context.

On the other hand, for the observations on the sky, what is relevant is a thin bundle of null geodesics, rather than the ones with large separations. Thus, once the local limit of eq. (5) is taken for an infinitesimally thin bundle, one can consider $\vec{\eta}$ as a local geodesic deviation vector. Then, one obtains an effective action

$$S = \int \left(\frac{1}{2} \dot{\vec{\eta}} \cdot \dot{\vec{\eta}} + \frac{1}{2} R_{\vec{\eta}\vec{k}\vec{k}\vec{\eta}} \right) dv, \tag{6}$$

whose extremization results in a first order geodesic deviation equation

$$\ddot{\eta}^{\alpha} = R^{\alpha}{}_{\vec{k}\vec{k}\vec{\eta}}\,. \tag{7}$$

Note that as from eq. (6), and onwards, the overdot represents a local covariant derivative with respect to the central ray $\vec{k}$.

In the next section, we will introduce a local tetrad and an associated screen basis around an observation point. This will allow us to rewrite the action functional (6) in terms of the observable variables in the following sections.

2.2. *Screen basis, cross–sections and solid angles*

Consider an observer with 4–velocity $\vec{u}$. Assume that (s)he observes a thin null bundle with a central geodesic whose tangent vector is given by $k^{\alpha} = \omega\,(u^{\alpha} + r^{\alpha})$. Here, the observed frequency of light is given by $\omega = -\vec{k} \cdot \vec{u}$ and $\vec{r}$ is a spacelike vector and thus $\vec{u} \cdot \vec{r} = 0$. We will also consider a 2–dimensional spacelike screen represented by the Sachs basis,[14,15] s^{α}_{a}, with $\{a, b\} = \{1, 2\}$. Then,

$$\vec{s}_a \cdot \vec{s}_b = \delta_{ab}, \qquad \vec{u} \cdot \vec{s}_a = 0, \qquad \vec{r} \cdot \vec{s}_a = 0, \qquad \nabla_{\vec{k}} \vec{s}_a = 0, \tag{8}$$

are satisfied. This orthogonal screen is the one on which the observables are projected.

For an observational bundle, $\vec{k} \cdot \vec{\eta} = 0$ holds initially as the null bundle converges into a vertex point where the observer is located. Note that this condition is preserved throughout the evolution of the bundle as (i) $\nabla_{\vec{k}} \vec{\eta} = \nabla_{\vec{\eta}} \vec{k}$ holds due to the propagation vector, $\vec{k}$, and its Jacobi field, $\vec{\eta}$, being Lie dragged along each other,[16] (ii) the propagation vector satisfies the null condition, (iii) the first order geodesic deviation equation, (7), is satisfied. Therefore, one can decompose the deviation vector as[3,15]

$$\vec{\eta} = \eta^{k} \vec{k} + \eta^{1} \vec{s}_1 + \eta^{2} \vec{s}_2. \tag{9}$$

Note that we will denote components of $\vec{\eta}$ residing on the orthogonal screen as $\boldsymbol{\eta} := \eta^{1} \vec{s}_1 + \eta^{2} \vec{s}_2$.

Those screen–projected components are useful in identifying observationally relevant objects. For example, the cross–sectional area, $d\mathcal{A}$, of an extended object and an observed solid angle, $d\Theta$, are respectively given by[2]

$$d\mathcal{A} := \left|\eta^1 \wedge \eta^2\right|, \qquad d\Theta := \left|\frac{d\eta^1}{d\ell} \wedge \frac{d\eta^2}{d\ell}\right|. \tag{10}$$

where $|d\ell| = \omega dv$ is the infinitesimal proper length written in terms of the affine parameter, v, of the null bundle and the observed frequency of light, ω. The symbol $\wedge$ represents the exterior product.

In the next section, we will introduce a Hamiltonian formalism associated with the action functional, (6). This Hamiltonian will be defined on a phase space whose coordinates are constructed via the screen–projected deviation vector, $\boldsymbol{\eta}$, and its derivatives, $\dot{\boldsymbol{\eta}}$.

2.3. *A reduced phase space and its Hamiltonian*

In general relativity, the standard way of constructing an optical phase space resides on a $3+1$ decomposition of a spacetime. Specifically, one chooses the phase space coordinates as the ones induced on a 3–dimensional spacelike hypersurface and the phase space momenta are chosen as the induced 3–momenta of a photon. Alternatively, we show that[3] a 4–dimensional phase space can be effectively constructed for a null bundle via treating the screen–projected deviation vector, as phase space Darboux coordinates, q^a, and its derivatives along the bundle as phase space momenta, p_b. Then a phase space vector can be defined as

$$\boldsymbol{\varkappa} = \begin{bmatrix} q^a \\ p_b \end{bmatrix} = \begin{bmatrix} \eta^1 \\ \eta^2 \\ \dot{\eta}_1 \\ \dot{\eta}_2 \end{bmatrix}. \tag{11}$$

Note that, the overdot in eq. (11) now denotes a standard total derivative with respect to the evolution parameter v as we are considering only the dyad components of $\vec{\eta}$.

Let us reconsider the effective geodesic deviation action functional given in eq. (6). By (i) treating the integrant of the action functional as a Lagrangian, (ii) using the symmetries of the Riemann tensor and (iii) rewriting the Lagrangian in terms of the phase space coordinates, one can obtain a reduced Lagrangian. A passage to the Hamiltonian formalism gives us a reduced Hamiltonian

$$H = \frac{1}{2}\delta^{ab}\dot{\eta}_a\dot{\eta}_b - \frac{1}{2}\mathcal{R}_{ab}\,\eta^a\eta^b, \tag{12}$$

where $\mathcal{R}_{ab} := R_{a\vec{k}\vec{k}b}$ is known as the *optical tidal matrix* in cosmology.[15,17]

Then, the corresponding Hamiltonian equations can be written as a matrix equation

$$\dot{\boldsymbol{\varkappa}} = \mathbf{L_H}\,\boldsymbol{\varkappa}, \qquad \text{with} \qquad \mathbf{L_H} = \left[\begin{array}{c|c} \mathbf{0_2} & \delta^{ab} \\ \hline \mathcal{R}_{ab} & \mathbf{0_2} \end{array}\right], \tag{13}$$

where $\mathbf{L_H}$ is the Hamiltonian matrix representation of the Lie operator defined through the reduced Hamiltonian, H, given in eq (12) and $\mathbf{0_2}$ is a 2×2 zero matrix.

Let us now investigate the solutions of the Hamiltonian equations, (13), in the next section.

2.4. *Symplectic evolution and its symmetries*

The Hamiltonian equations, (13), presented in the previous section are linear equations as $\mathbf{L_H} = \mathbf{L_H}(v)$. Then, its solutions are given by a linear transformation of an input phase vector, $\boldsymbol{\varkappa}_0$, defined at v_0, which gives an output phase space vector, $\boldsymbol{\varkappa}$, at some value of v, i.e.,

$$\boldsymbol{\varkappa} = \mathbf{T}\,(v, v_0)\,\boldsymbol{\varkappa}_0. \tag{14}$$

Substituting eq. (14) back into eq. (13) shows that the ray bundle transfer matrix, $\mathbf{T}$, satisfies a similar equation as the phase space vector $\boldsymbol{\varkappa}$, i.e., $\dot{\mathbf{T}} = \mathbf{L_H}\,\mathbf{T}$. Then, its solution is given by taking an ordered exponential (OE) map,

$$\mathbf{T}\,(v, v_0) = \mathrm{OE}\left[\int_{v_0}^{v} \mathbf{L_H} dv\right] \mathbf{T}\,(v_0, v_0)\,, \qquad \text{with} \qquad \mathbf{T}\,(v_0, v_0) = \mathbf{I_4}, \tag{15}$$

and $\mathbf{I_4}$ is a 4×4 identity matrix. In that case, $\mathbf{T}$, is a symplectic matrix which satisfies

$$\mathbf{T}^{\intercal}\,\boldsymbol{\Omega}\,\mathbf{T} = \boldsymbol{\Omega}, \qquad \det \mathbf{T} = 1, \tag{16}$$

as exponential map of Hamiltonian matrices are symplectic matrices. Here, $^{\intercal}$ denotes the transpose operator and $\boldsymbol{\Omega}$ is the well–known *fundamental symplectic matrix* whose components are given by

$$\Omega^{ij} = \left[\begin{array}{c|c} \mathbf{0_2} & \mathbf{I_2} \\ \hline -\mathbf{I_2} & \mathbf{0_2} \end{array}\right]. \tag{17}$$

This allows one to treat the ray bundle evolution in general relativity analogous to a dynamical problem in classical mechanics. A similar approach has indeed been developed in paraxial Newtonian optics much earlier (Cf. references in[10,11]). In that case, this approach is also known as the *ABCD–matrix method* as it is very common to represent a symplectic matrix, $\mathbf{T}$, in a block form

$$\mathbf{T} = \left[\begin{array}{c|c} \mathbf{A} & \mathbf{B} \\ \hline \mathbf{C} & \mathbf{D} \end{array}\right]. \tag{18}$$

In our case, the submatrices in eq. (18) are all 2×2 matrices which satisfy certain symmetry conditions

$$\begin{gathered} \mathbf{A}\mathbf{B}^{\intercal},\ \mathbf{A}^{\intercal}\mathbf{C},\ \mathbf{B}^{\intercal}\mathbf{D} \text{ and } \mathbf{C}\mathbf{D}^{\intercal} \text{ are symmetric,} \\ \mathbf{A}\mathbf{D}^{\intercal} - \mathbf{B}\mathbf{C}^{\intercal} = \mathbf{I_2}, \end{gathered} \tag{19}$$

due to $\mathbf{T}$ being a symplectic matrix, i.e., eq. (16) is satisfied. Then, the Hamiltonian equations, (13), become equivalent to,

$$\begin{aligned} \dot{\mathbf{A}} &= \mathbf{C}, & \mathbf{A}\,(v_0, v_0) &= \mathbf{I_2}, \\ \dot{\mathbf{B}} &= \mathbf{D}, & \mathbf{B}\,(v_0, v_0) &= \mathbf{0_2}, \\ \dot{\mathbf{C}} &= \mathcal{R}\mathbf{A}, & \mathbf{C}\,(v_0, v_0) &= \mathbf{0_2}, \\ \dot{\mathbf{D}} &= \mathcal{R}\mathbf{B}, & \mathbf{D}\,(v_0, v_0) &= \mathbf{I_2}. \end{aligned} \tag{20}$$

Therefore, once the solutions of the equation set above is found, one can find the explicit form of the transfer matrix, $\mathbf{T}$, and the geodesic deviation variables of the null bundle in question. This allows one to estimate certain observables as we discuss in the next section.

3. Some perspectives on the symplectic ray bundle evolution

3.1. *Distance reciprocity*

The relationship of the ray bundle transfer matrix, $\mathbf{T}$, to the observables is not immediately obvious. In order to estimate the distance to an object located at G, for example, one starts with propagating the bundle with the initial phase space vector $\boldsymbol{\varkappa}_o = (\mathbf{0}, \dot{\eta}_o)^\intercal$ at the observation point O (See Fig. 2.). Then, one can calculate the cross–sectional area, $d\mathcal{A}$, at G by (i) making use of the definitions of $d\mathcal{A}$ and the solid angle, $d\Theta$, given in eq. (10), (ii) inputting the information of the measured $d\Theta$ at point O in the initial phase space vector, $\boldsymbol{\varkappa}_o = (\mathbf{0}, \dot{\eta}_o)^\intercal$, and (iii) considering the ray bundle transformation matrix $\mathbf{T}$ that transfers the initial phase space vector to a final one as in eq. (14). In that case, the estimated distance in question is the angular diameter distance given by $D_A = (d\mathcal{A}_G/d\Theta_O)^{1/2}$. Likewise, a similar distance estimation can be done by an observer located at point G. Then, the estimated distance is the luminosity distance given by $D_L = (d\mathcal{A}_O/d\Theta_G)^{1/2}$.

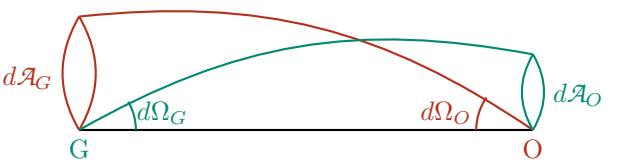

Fig. 2. Observer at O measures a solid angle $d\Omega_O$ and estimates the cross-sectional area of an astrophysical object at G as $d\mathcal{A}_G$. Same thing is applicable for an observer at G as well. Reciprocity of the estimated distances is written as $d\mathcal{A}_O/d\Omega_G = (1+z)^2\, d\mathcal{A}_G/d\Omega_O$.

As the solution of a phase space vector is given by eq. (14) in which $\mathbf{T}$ is represented in a block form (18), one obtains the angular diameter and luminosity distances respectively by making use of only the submatrix $\mathbf{B}$, i.e.,

$$D_A = \omega_O \det\left[\mathbf{B}\,(v_G, v_O)\right]^{1/2}, \qquad D_L = \omega_G \det\left[\mathbf{B}\,(v_O, v_G)\right]^{1/2}. \tag{21}$$

Here, ω_O and ω_G are the frequencies measured at respective points through which a redshift parameter is defined as $1+z=\omega_G/\omega_O$. Note that the frequency terms appear in the process of transforming the proper length, as it appears in the definition of solid angle in eq.(10), to the affine parameter, v, as we discussed in Section (2.2). The abbreviation "det" refers to the determinant of a given matrix.

In order for Etherington's distance reciprocity, eq. (3), to hold one needs to show that $\det\left[\mathbf{B}\left(v_G,v_O\right)\right]=\det\left[\mathbf{B}\left(v_O,v_G\right)\right]$ holds. Indeed, this was previously proven by making use of the symmetries of the Riemann tensor.[15] Note that such a case is applicable for light propagation within a single geometry. For scenarios that include light propagation in multiple spacetimes, one needs to propagate the bundle not only from the initial vertex point but also from arbitrary initial phase space points to other arbitrary ones. In that case, the information about the light bundle transformation is not only contained in the submatrix $\mathbf{B}$ but in all of the submatrices of $\mathbf{T}$. For example, this is applicable for light propagation in Swiss–cheese type models.[4,5]

Previously, we showed that distance reciprocity follows from the symplectic conditions, eq. (19), of the ray bundle transfer matrix for generic scenarios.[3] To be more specific, consider a ray bundle matrix, $\mathbf{T}(v_f,v_i)$, which takes an initial phase space vector, $\boldsymbol{\varkappa}(v_i)$, to a final one, $\boldsymbol{\varkappa}(v_f)$. Such a linear transformation should be equal to its inverse, once the initial and final points are traversed, i.e., $\mathbf{T}(v_i,v_f)=\mathbf{T}^{-1}(v_f,v_i)$. Moreoever, symplectic matrices form a group, thus inverse of a symplectic matrix is also symplectic. This requires $\mathbf{T}^{-1}(v_f,v_i)=\boldsymbol{\Omega}^{-1}\,\mathbf{T}^{\intercal}(v_f,v_i)\boldsymbol{\Omega}$. Then, it is easy to show that the distance reciprocity indeed follows from $\mathbf{T}(v_i,v_f)=\boldsymbol{\Omega}^{-1}\,\mathbf{T}^{\intercal}(v_f,v_i)\boldsymbol{\Omega}$. See our previous work[3] for further details in which we show this result more explicitly.

3.2. *Decomposition of an optical propagation*

One of the earliest predictions of Einstein's general relativity was on the light propagation within our Solar System. Back then, the idea of a spacetime structure was so hard to grasp that the astronomers conceptualized the effect of a massive object on the trajectory of light as "bending". Similarly, the name "gravitational lensing" remained within the community after Eddington performed his famous Solar eclipse experiment. Even more than 100 years after this observation, the researchers in the field use the term gravitational lensing in a loose sense.

On the other hand, in Newtonian optics a lens is defined more rigorously. For the paraxial case, for example, it is identified as a linear transformation that creates a shearing affect on the phase space defining the ray propagation. Though, lenses are not the only type of optical devices and there is a common practice in Newtonian optics in order to identify the components of light propagation. This is achieved by an Iwasawa decomposition[18] where a symplectic ray transformation matrix is decomposed into its submatrices belonging to a nilpotent subgroup, an abelian subgroup and a maximally compact subgroup for 1–dimensional systems.

This allows one to identify the thin lens, the pure magnifier and the fractional Fourier transformer components of an optical propagation problem uniquely. In higher dimensions, such an identification is known as Iwasawa factorization whose components can be obtained via the submatrices of the transformation matrix **T** (Cf.[10] for further details).

Previously, we proposed that any spacetime can be treated as an optical device within our formalism[3] which allows one to identify the lenses, the magnifiers and the rotators of an optical propagation in general relativity in a rigorous manner. In that case, spacetimes can be compared and contrasted in terms of their significance in different types of optical transformations, by making use of the Iwasawa factorization of their symplectic ray bundle transfer matrices.

3.3. *From rays back to waves*

Finding the exact solutions of the Maxwell's equation on a curved background is not an easy task in general relativity. There exists a similar problem in Newtonian optics for light propagation in media with an arbitrary refractive index. Within the paraxial regime of Newtonian optics, there exist certain "wavization" techniques that are adopted from quantum mechanics in order to find approximate solutions of the Maxwell equations.

The analogy between classical optics and quantum mechanics follows from the similarities between the Schrödinger equation of a particle wavefunction and the Maxwell equation of a complex amplitude of a classical wave in the scalar theory.[19,20] The $\hbar \to 0$ limit of quantum mechanics is said to give classical mechanics, and $\lambda \to 0$ limit of wave optics gives ray optics. Moreover, both the classical mechanics and the paraxial ray optics are constructed on symplectic phase spaces. Thus, in the first order limit, a wave picture can be attained back by making use of some phase space techniques that were initially introduced within quantum mechanics. In that case, phase space distribution functions, like Wigner function (or other analogous definitions), and metaplectic operators that are responsible for the spreading of a wave, play the central role in the wavization process.[11]

We proposed[3] that such methods can be adopted from Newtonian optics as we also reduced the problem of light bundle propagation into a symplectic evolution problem in phase space. Note that this is immediately relevant for gravitational lensing studies because when the wavelength of light is not much smaller than the gravitational lensing object, the wave effects on lensing become important. It is known that the wave effects amplify the estimated intensity of a wave in general.[21,22] Also, an earlier result showed that the wave and ray optics do not agree in terms of the position of the image formation for a specific geometry.[23] However, there is not much known in terms of the image formation in wave optics of light.[24] There are limited number of studies that investigate the wave optics and those usually only focus on the lensing problem on static background.[25–27] We propose that symplectic methods can be quite useful in this respect.

Moreover, it is known that gravitational waves also have null propagation vectors similar to light rays. Therefore, geometric optics is relevant for the investigation of gravitational waves at the linear order.[28,29] Also, the interaction of gravitational waves with matter fields is known to be weak. Thus, their coherence is expected to be preserved even over cosmological distances.[30] Then, the interplay between the ray and wave behaviours can be used to study gravitational waves within our formalism. Also note that wave effects on the lensing of the gravitational waves have been investigated in some studies only lately.[24,31–37] However, all of those studies focus on wave effects on specific geometries.

In addition, recently, new ideas are introduced to the literature regarding the wave effects. For example, the spin Hall effect which is normally studied in condensed matter field, is known to bring corrections to the geometrical optics limit in the case of light rays. Oancea *et al.*[38] found an analogous effect for the case of gravitational waves. Similarly, the Aharonov-Bohm effect is known from quantum electromagnetism. Baraldo *et al.*[30] found that there exists an analogous effect for the gravitational waves. Namely, a shift is predicted on the interference pattern of the gravitational waves due to the angular momentum of a lensing object.

Therefore, we propose that once a wavization procedure is applied to our symplectic null bundle propagation, evolution of gravitational waves and their lensing can be studied within more generic scenarios as well.

4. Conclusion

In this talk, we summarized our work[3] which reduces an observational light bundle evolution in general relativity analogous to a classical optical problem in phase space. This requires simultaneous implementation of a null geodesic action to the outermost null curve and the central null curve of an observational light bundle. One then obtains an effective geodesic deviation action which can be written in terms of the screen–projected variables of the null geodesic deviation. This reduces the problem by one order and a 4–dimensional reduced phase space can be obtained by treating the screen–projections of the geodesic deviation vectors as canonical coordinates and their derivatives along the central null ray as canonical momenta. The Hamiltonian equations of this first order problem can be written as a matrix equation whose solutions are obtained via linear symplectic transformations. We shortly discussed (i) a generic proof of the distance reciprocity in general relativity by making use of the symmetries of the symplectic ray bundle transfer matrix, (ii) decomposition of the light bundle propagation into thin lens, pure magnifier and fractional Fourier transformation portions such that any spacetime can be rigorously identified as an optical device, (iii) the relevance of our method to the wave optics for electromagnetic and gravitational waves which have been drawing increasing interest in the literature lately.

We study the shadow cast by rotating black holes surrounded by plasma in the context of the 4D Einstein-Gauss-Bonnet theory of gravity. The metric for these black holes results from applying the Newman-Janis algorithm to a spherically symmetric solution. We obtain the contour of the shadow for a plasma frequency model that allows a separable Hamilton-Jacobi equation. We introduce three observables in order to characterize the position, size, and shape of the shadow.

Keywords: Black hole shadow; Modified gravity; Plasma.

1. Introduction

It is well known that Einstein-Gauss-Bonnet theory in four spacetime dimensions is purely topological and thus equivalent to general relativity. A novel gravity theory was recently proposed[1] by rescaling the coupling constant and taking the limit $D \to 4$ in the D-dimensional Einstein-Gauss-Bonnet theory, with the intention of overcoming this standard result. But this approach, based on some particular solutions, lacks of a complete set of field equations and does not have an intrinsically four-dimensional description in terms of a covariantly conserved rank-2 tensor in four dimensions.[2] A theory with a Gauss-Bonnet term in four dimensions that provide a solution to these problems was then presented,[3,4] which propagates a scalar field in addition to the metric tensor and the full action belongs to the Horndeski class of scalar-tensor theories of gravity. The action, obtained by a regularization procedure in a way that is free from divergences, produces well behaved second-order field equations. This theory, usually dubbed regularized or scalar-tensor 4D Einstein-Gauss-Bonnet gravity (4DEGB), includes a nonvanishing contribution coming from the Gauss-Bonnet term.[3,4]

The number of theoretical studies on black hole shadows[5,6] has sharply increased since the Event Horizon Telescope (EHT)[7,8] collaboration obtained the first reconstructed image of the supermassive black hole M87*, located at the center of the giant elliptical galaxy M87. Many articles have been published on this topic in recent years, here we can mention only a few of them,[9–12] in which more references can be found. The presence of plasma surrounding a black hole affects the characteristics of the shadow,[13–15] because photons with different frequencies follow distinct

trajectories, resulting in chromatic effects. In this work, we consider the shadow due to rotating black holes[16,17] in the scalar-tensor 4DEGB gravity, within a plasma environment. We define three observables to describe how the presence of plasma affects the size, the deformation and the position of the shadow. We analyze in detail the case of a Shapiro plasma, with the shadow seen by an equatorial observer. We use units such that $G = c = \hbar = 1$.

2. Black holes in 4D Einstein-Gauss-Bonnet gravity

The scalar-tensor 4DEGB action reads[3,4]

$$S = \int_{\mathcal{M}} d^4x\sqrt{-g}\Big[R + \gamma\Big(4G^{\mu\nu}\nabla_\mu\phi\nabla_\nu\phi - \phi\mathcal{G} + 4\Box\phi(\nabla\phi)^2 + 2(\nabla\phi)^4\Big)\Big] + S_m. \quad (1)$$

The theory is free of divergences and belongs to the Horndeski class, with functions $G_2 = 8\gamma X^2$, $G_3 = 8\gamma X$, $G_4 = 1 + 4\gamma X$, and $G_5 = 4\gamma \ln X$, where $X = -(1/2)\nabla_\mu\phi\nabla^\mu\phi$. The field equations are obtained[3,4] by varying this action with respect to the metric

$$G_{\mu\nu} = \gamma\mathcal{H}_{\mu\nu} + T_{\mu\nu}, \quad (2)$$

where $\mathcal{H}$ is a complicated second order function in the derivatives of the scalar field ϕ; there is another equation that is found[3,4] by varying with respect to the scalar field ϕ. The expressions of these equations are not relevant for our purposes.

The 4DEGB field equations in vacuum admit the spherically symmetric and asymptotically flat solution[1,4] with the metric given by

$$ds^2 = -\left(1 - \frac{2m(r)}{r}\right)dt^2 + \left(1 - \frac{2m(r)}{r}\right)^{-1}dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2), \quad (3)$$

where

$$m(r) = \frac{r^3}{64\pi\gamma}\left(\sqrt{1 + \frac{128\pi\gamma M}{r^3}} - 1\right). \quad (4)$$

The parameter γ of the theory has units of mass squared. We only consider $\gamma > 0$, since the square root becomes imaginary for a finite value of r if $\gamma < 0$. The limit $\gamma \to 0$ corresponds to the Schwarzschild geometry. The black hole mass is M, since we have $m(r) \to M$ as $r \to \infty$.

A rotating solution was subsequently found by applying a modified version of the Newman-Janis algorithm,[16,17] having in the Boyer-Lindquist coordinates the form

$$ds^2 = -\frac{\rho^2\Delta}{\Sigma}dt^2 + \frac{\Sigma\sin^2\theta}{\rho^2}\left[d\varphi - \frac{2am(r)r}{\Sigma}dt\right]^2 + \frac{\rho^2}{\Delta}dr^2 + \rho^2 d\theta^2, \quad (5)$$

where $a = J/M$ is the rotation parameter and

$$\begin{aligned}\rho^2 &= r^2 + a^2\cos^2\theta,\\ \Delta &= r^2 - 2m(r)r + a^2,\\ \Sigma &= (r^2 + a^2)^2 - a^2\Delta\sin^2\theta.\end{aligned} \quad (6)$$

The limit $\gamma \to 0$ recovers the Kerr black hole. The radius r_h of the event horizon corresponds to the largest real and positive solution of the equation $\Delta = 0$. It can be seen numerically that the condition $\gamma/M^2 < 0.00129$ is necessary for the existence of the event horizon, otherwise there is a naked singularity.

3. Photon geodesics in a plasma environment

The motion of photons in a pressureless, nonmagnetized plasma is governed by the Hamiltonian[18]

$$\mathcal{H} = \frac{1}{2}\left(g^{\mu\nu}(x)p_\mu p_\nu + \omega_p(x)^2\right), \tag{7}$$

with $g^{\mu\nu}$ the inverse of the metric tensor, x^μ the spacetime coordinates, p^μ the conjugate momenta, and ω_p the plasma electron frequency

$$\omega_p^2 = \frac{4\pi e^2}{m_e} N, \tag{8}$$

where e and m_e are the electron charge and mass respectively, and N the electron number density. We assume that the plasma frequency is stationary and axisymmetric, so it does not depend on the Boyer-Lindquist coordinates t and φ. As it happens for the Kerr geometry,[13] the inequality $\omega_0^2 \geq -g_{tt}\omega_p^2$ is a necessary and sufficient condition for a light ray with frequency ω_0 (measured by an observer at infinity) to exist at a given point of the spacetime.

3.1. *Hamilton-Jacobi equation*

We can write down the Hamilton-Jacobi (HJ) equation for photons, which reads

$$\mathcal{H}\left(x, \frac{\partial S}{\partial x}\right) = 0 \tag{9}$$

and we introduce the ansatz

$$S = -\omega_0 t + p_\varphi \varphi + S_r(r) + S_\theta(\theta). \tag{10}$$

By substituting it in the HJ equation, we arrive at

$$\begin{aligned}\Delta(S_r')^2 - \frac{1}{\Delta}\left[(r^2+a^2)^2\omega_0^2 + 4am(r)r\omega_0 p_\varphi + a^2 p_\varphi^2\right] \\ +(S_\theta')^2 + a^2\omega_0^2\sin^2\theta + \frac{p_\varphi^2}{\sin^2\theta} + \rho^2\omega_p^2 = 0,\end{aligned} \tag{11}$$

where the prime denotes the derivative with respect to the corresponding coordinate. The HJ equation is separable if and only if the plasma frequency takes the form[13]

$$\omega_p^2 = \frac{f_r(r) + f_\theta(\theta)}{\rho^2}, \tag{12}$$

with $f_r(r)$ and $f_\theta(\theta)$ arbitrary functions of the coordinates r and θ, respectively. The spacetime is axisymmetric, stationary, and asymptotically flat, therefore the

quantities $p_t = -\omega_0$ and p_φ are conserved along the geodesics of photons; $E = \omega_0$ is the photon energy and p_φ is the z component of the angular momentum. Since ω_p only depends on the coordinates r and θ, the quantities E and p_φ are still conserved in the presence of plasma. A third constant of motion for photons is $\mathcal{H} = 0$. By substituting ω_p into the Hamilton-Jacobi equation, we can separate it as

$$(S'_\theta)^2 + \left(a\omega_0 \sin\theta - \frac{p_\varphi}{\sin\theta}\right)^2 + f_\theta = -\Delta(S'_r)^2 + \frac{1}{\Delta}\left[\omega_0(r^2+a^2) - ap_\varphi\right]^2 - f_r. \quad (13)$$

Since the left hand side is a function only of θ and the right hand side a function only of r, they should both be equal to a constant $\mathcal{K}$. For convenience, we use instead the Carter constant,[19] defined by $\mathcal{Q} = \mathcal{K} - (p_\varphi - a\omega_0)^2$, as the fourth constant of motion. From the Hamilton equations, using that $\dot{x}^\mu = p^\mu = g^{\mu\nu}p_\nu$ (the dot denotes the derivative with respect to the curve parameter λ) and $p_\nu = \partial S/\partial x^\nu$, the equations of motion read

$$\rho^2 \dot{t} = \frac{r^2+a^2}{\Delta}P(r) - a(a\omega_0 \sin^2\theta - p_\varphi), \quad (14)$$

$$\rho^2 \dot{\varphi} = \frac{a}{\Delta}P(r) - a\omega_0 + \frac{p_\varphi}{\sin^2\theta}, \quad (15)$$

$$\rho^2 \dot{r} = \pm\sqrt{R(r)}, \quad (16)$$

$$\rho^2 \dot{\theta} = \pm\sqrt{\Theta(\theta)}, \quad (17)$$

where

$$R(r) = P(r)^2 - \Delta[\mathcal{Q} + (p_\varphi - a\omega_0)^2 + f_r], \quad (18)$$

$$\Theta(\theta) = \mathcal{Q} + \cos^2\theta\left(a^2\omega_0^2 - \frac{p_\varphi^2}{\sin^2\theta}\right) - f_\theta, \quad (19)$$

$$P(r) = \omega_0(r^2+a^2) - ap_\varphi. \quad (20)$$

These first-order equations determine the movement of the photons in the presence of plasma.

3.2. *Spherical photon orbits*

The orbits of photons with constant r should fulfill the two conditions given by $R(r) = R'(r) = 0$; such solutions are unstable, satisfying $R''(r) > 0$. From the equation $R(r) = 0$ we find that

$$\mathcal{Q} + (p_\varphi - a\omega_0)^2 + f_r = \frac{(\omega_0(r^2+a^2) - ap_\varphi)^2}{\Delta}. \quad (21)$$

Then, substituting into $R'(r) = 0$, we obtain

$$R' = 4\omega_0 r(\omega_0(r^2+a^2) - ap_\varphi) - \frac{\Delta'}{\Delta}(\omega_0(r^2+a^2) - ap_\varphi)^2 - \Delta f'_r = 0, \quad (22)$$

which is a quadratic equation for p_φ, with the solution

$$p_\varphi = \frac{\omega_0}{a}\left[r^2 + a^2 - \frac{2r\Delta}{\Delta'}\left(1 \pm \sqrt{1 - \frac{\Delta' f'_r}{4\omega_0^2 r^2}}\right)\right]. \quad (23)$$

Then, after some algebra, we can obtain $\mathcal{Q}$ in terms of r, which reads

$$\mathcal{Q} = -\frac{\omega_0^2 r^4}{a^2} + \frac{4\omega_0^2 r^2 \Delta}{a^2 \Delta'}\left[r - \frac{2}{\Delta'}\left(\Delta - a^2\right)\right]\left(1 \pm \sqrt{1 - \frac{\Delta' f_r'}{4\omega_0^2 r^2}}\right) + \frac{\Delta f_r'}{\Delta' a^2}\left(\Delta - a^2\right) - f_r. \tag{24}$$

We have found the critical values of p_φ and $\mathcal{Q}$ associated with the spherical orbits of photons. Any trajectory should have $\Theta \geq 0$, then

$$\mathcal{Q} + \cos^2\theta\left(a^2\omega_0^2 - \frac{p_\varphi^2}{\sin^2\theta}\right) - f_\theta(\theta) \geq 0. \tag{25}$$

This equation defines the photon region: spherical orbits exist at values of r and θ for which this inequality is satisfied.

3.3. *Shadow*

For a distant observer, the shadow is determined by the set of photon directions that never reach infinity and instead cross the event horizon. The boundary consists of those rays that asymptotically approach the spherical photon orbits of the spacetime, so they have the same conserved quantities. In order to relate the directions in the sky with the constants of motion, we take an observer at rest in the asymptotically flat region (large r_o) with an inclinaton angle θ_o from the spin axis of the black hole, and we construct the orthonormal tetrad as usual[9]:

$$\mathbf{e}_{\hat{t}} = \partial_t, \qquad \mathbf{e}_{\hat{r}} = \partial_r, \qquad \mathbf{e}_{\hat{\theta}} = \frac{1}{r_\mathrm{o}}\partial_\theta, \qquad \mathbf{e}_{\hat{\varphi}} = \frac{1}{r_\mathrm{o}\sin\theta_\mathrm{o}}\partial_\varphi, \tag{26}$$

so that the components of the four-momentum in this frame read

$$p^{\hat{t}} = \omega_0, \qquad p^{\hat{r}} = p^r, \qquad p^{\hat{\theta}} = r_\mathrm{o} p^\theta, \qquad p^{\hat{\varphi}} = r_\mathrm{o}\sin\theta_\mathrm{o} p^\varphi = \frac{p_\varphi}{r_\mathrm{o}\sin\theta_\mathrm{o}}. \tag{27}$$

For the plasma model, we assume that

$$\lim_{r\to\infty} \omega_p(r,\theta) = 0, \tag{28}$$

which is equivalent to

$$\lim_{r\to\infty} \frac{f_r(r)}{r^2} = 0, \tag{29}$$

so photons propagate in vacuum far away from the black hole. We adopt the celestial coordinates for an observer at infinity[5]

$$\alpha = -r_\mathrm{o}\frac{p^{\hat{\varphi}}}{p^{\hat{t}}}\bigg|_{r_\mathrm{o}\to\infty}, \tag{30}$$

$$\beta = -r_\mathrm{o}\frac{p^{\hat{\theta}}}{p^{\hat{t}}}\bigg|_{r_\mathrm{o}\to\infty}; \tag{31}$$

replacing p^θ in terms of the conserved quantities, they read

$$\alpha = -\frac{p_\varphi}{\omega_0 \sin\theta_\mathrm{o}}, \tag{32}$$

$$\beta = \pm\frac{1}{\omega_0}\sqrt{\mathcal{Q} + \cos^2\theta_\mathrm{o}\left(a^2\omega_0^2 - \frac{p_\varphi^2}{\sin^2\theta_\mathrm{o}}\right) - f_\theta(\theta_\mathrm{o})}. \tag{33}$$

The contour of the black hole shadow is described by the parametric curve $(\alpha(r), \beta(r))$.

3.4. *Observables*

We define three observables[10]: the area of the shadow, its oblateness, and the horizontal displacement of its centroid, as follows:

- The area is calculated from
$$A = 2\int \beta\, d\alpha = 2\int_{r_+}^{r_-} \beta(r)|\alpha'(r)|\, dr, \tag{34}$$
with the factor 2 arising from the up-down symmetry of the shadow and taking the plus sign in Eq. (33).
- The oblateness is related to the deformation of the shadow as compared to a circle
$$D = \frac{\Delta\alpha}{\Delta\beta}, \tag{35}$$
where $\Delta\alpha$ and $\Delta\beta$ are the horizontal and vertical extent of the shadow.
- The horizontal coordinate of the centroid is given by
$$\alpha_c = \frac{2}{A}\int \alpha\beta\, d\alpha = \frac{2}{A}\int_{r_+}^{r_-} \alpha(r)\beta(r)|\alpha'(r)|\, dr, \tag{36}$$
with the same factor 2 as in the definition of the area.

These observables allow a characterization of the shadow by only three numbers.

4. Example: Shapiro plasma

We consider, in order to provide an example, the well known model of plasma consisting of dust that is at rest at infinity, introduced by Shapiro.[20] In the Kerr spacetime, the mass density and the squared plasma frequency go as $r^{-3/2}$, and they are independent of θ to a very good approximation. However, for this plasma distribution the equations cannot be brought into a separable form; therefore, we take the frequency to have an additional θ dependency[13] by adopting $f_r(r) = \omega_c^2\sqrt{M^3 r}$ and $f_\theta(\theta) = 0$, resulting in a plasma electron frequency

$$\omega_p^2 = \omega_c^2 \frac{\sqrt{M^3 r}}{r^2 + a^2\cos^2\theta}, \tag{37}$$

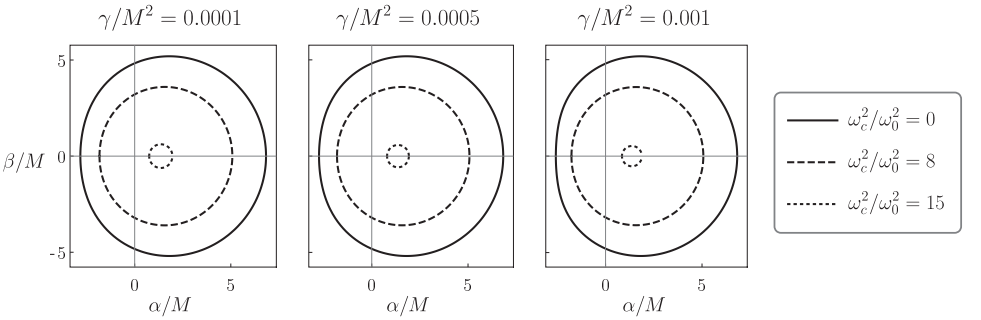

Fig. 1. Shadow of a $4D$ Einstein-Gauss-Bonnet black hole with spin $a/M = 0.9$ surrounded by a Shapiro-type plasma distribution with $f_r(r) = \omega_c^2\sqrt{M^3 r}$, for an equatorial observer.

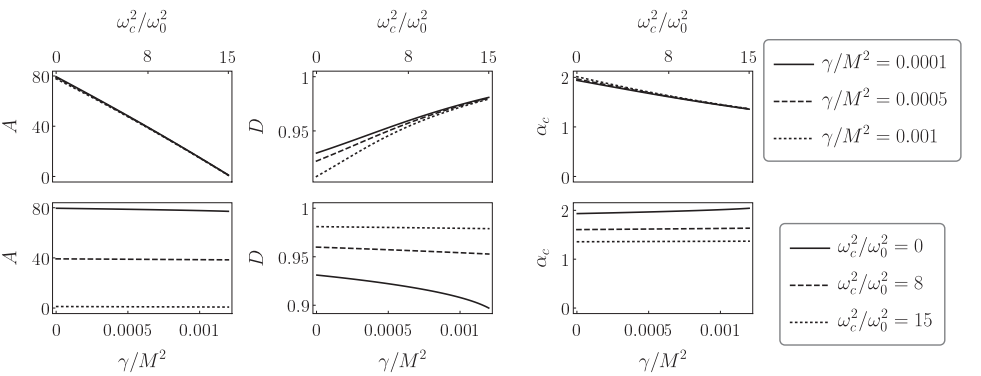

Fig. 2. The area (A), the oblateness (D), and the centroid (α_c) of the shadow. Top: the observables as functions of the frequency ratio ω_c/ω_0, for three values of the EGB parameter γM^2. Bottom: the observables as functions of γM^2, for three values of the frequency ratio ω_c/ω_0.

where ω_c is a constant that characterizes the fluid. At large distances from the black hole, the metric approaches the Kerr one, i.e. $m(r) \to M$, so we expect that the Shapiro model is still valid; but at small distances the metric may be quite different, so we assume that the plasma density is not significantly affected. The trajectories of photons with frequency ω_0 depend only on the ratio ω_c/ω_0. We present in Figs. 1 and 2 some plots of black hole shadows and the corresponding observables, for an equatorial observer, $a/M = 0.9$, and suitably chosen values of the other parameters. For a given value of the plasma frequency ω_c, we can see that:

- For fixed parameter γ/M^2, the shadow reduces in size, is less deformed, and has a smaller centroid displacement, as the photon frequency ω_0 decreases. In particular, the shadow disappears entirely below a certain photon frequency, due to the appearance of the forbidden region. This forbidden region starts as two caps around the poles and grows towards the equatorial plane as the frequency decreases, leading to a reduction of the shadow size.

- For a fixed photon frequency ω_0, the shadow slightly reduces in size, is less deformed, and the centroid displacement slightly grows, as γ/M^2 increases. The effect of increasing the parameter γ/M^2 is more prominent for high frequency photons, particularly in the case of the oblateness.

The existence of plasma surrounding the black hole results in a smaller and less deformed shadow than in vacuum, which corresponds to $\omega_c = 0$.

5. Final remarks

We have studied how the presence of plasma modifies the shadow corresponding to rotating black holes in the scalar-tensor 4-dimensional Einstein-Gauss-Bonnet theory with respect to the vacuum case. These black holes were obtained in previous works from spherically symmetric solutions by applying the Newman-Janis algorithm. We have neglected the gravitational influence of the plasma itself and any processes of scattering, emission or absorption. We have shown that the Hamilton-Jacobi equation for photons is separable if the plasma frequency obeys the usual separability condition introduced for the Kerr spacetime. Light follows timelike curves in the presence of plasma, resulting in a modification of the photon regions and frequency-dependent forbidden regions, where photons cannot travel. We have obtained the expressions for the celestial coordinates of the shadow contour as viewed by a far away observer, which reduce to the already known for vacuum when the plasma frequency goes to zero or the photon frequency to infinity. In order to characterize the size, the shape, and the position, we have presented three observables: the area, the oblateness, and the centroid of the shadow. With the intention to provide a concrete example, we have taken a variation of the Shapiro plasma distribution, which models dust at rest at infinity surrounding a black hole. We have considered an equatorial observer, for simplicity and also because the effects on the shadow in this case are more prominent. For a fixed the plasma frequency $\omega_c \neq 0$ and given values of the mass M and the parameter γ, the shadow becomes smaller and less deformed as the photon frequency ω_0 decreases, with the appearance of a forbidden region around the black hole as a distinctive feature. This forbidden region begins as two caps around the poles and grows towards the equatorial plane for decreasing ω_0, resulting in a sharp reduction of the shadow size and in its eventual disappearance. The presence of plasma always leads to a smaller and less deformed shadow than in the case of vacuum ($\omega_c = 0$). The work presented here is a particular case of the shadow cast by a class of rotating black holes surrounded by plasma, which results from applying the Newman-Janis algorithm to spherically symmetric spacetimes[15] determined by a mass function $m(r)$ satisfying that $m(r) \to M$ when $r \to \infty$.

We study neutrino flavour oscillations in curved spacetime especially emphasising neutrino lensing in Schwarzschild spacetime, and highlight the role that neutrinos lensing induced by a gravitational source can play in inferring neutrino absolute mass and mass hierarchy. Further, the wave packet approach in neutrino lensing and its modifications compared with the plane wave approach is analysed. Finally, we discuss the decoherence effect in the wave packet approach and its possible use in inferring absolute neutrino mass and neutrino mixing parameters.

Keywords: Neutrino mass hierarchy; gravitational lensing.

1. Neutrino oscillations in flat and curved spacetime

It is now clear from experiments that neutrinos have masses, and that they mix and neutrino flavour eigenstates $|\nu_\alpha\rangle$ are now related to their mass eigenstates $|\nu_i\rangle$ by 3×3 unitary matrix[1–3] U

$$|\nu_\alpha\rangle = \sum_i U^*_{\alpha i} |\nu_i\rangle, \tag{1}$$

where $\alpha = e, \mu, \tau$ and $i = 1, 2, 3$. A neutrino flavour state propagation from source S to detector D, located at $\mathbf{x}_S$ and $\mathbf{x}_D$ respectively, is described by

$$|\nu_\alpha\left(t_D, \mathbf{x}_D\right)\rangle = N \sum_i U^*_{\alpha i} \psi_i\left(x_D, x_S\right) |\nu_i\left(t_S, \mathbf{x}_S\right)\rangle\,, \tag{2}$$

where N is a normalisation factor. $\psi_i\left(x_D, x_S\right)$ is the wavefunction, evolved between the time of production (t_S) and detection (t_D), for i^{th} massive neutrino . Assuming neutrino wave-function as a plane wave, the flavour transition probability from $\nu_\alpha \to \nu_\beta$ at the detection point is given by

$$\mathcal{P}_{\alpha\beta} \equiv \left|\langle\nu_\beta|\nu_\alpha(t_D, \mathbf{x}_D)\rangle\right|^2 = \sum_{i,j} U_{\beta i} U^*_{\beta j} U_{\alpha j} U^*_{\alpha i}\, \exp(-i(\Phi_i - \Phi_j))\,. \tag{3}$$

Now, neutrino mass eigenstates develop different phases Φ_i, which gives rise to neutrino oscillation phenomena.[4] Massive neutrino phase in flat spacetime is given by

$$\Phi_i = E_i(t_D - t_S) - \mathbf{p}_i \cdot (\mathbf{x}_D - \mathbf{x}_S)\,. \tag{4}$$

Assuming that all the mass eigenstates in a flavour eigenstate initially produced have equal momentum or energy.[4,5] This assumption together with $(t_D - t_S) \simeq |\mathbf{x}_D - \mathbf{x}_S|$

for relativistic neutrinos ($E_i \gg m_i$) gives

$$\Delta\Phi_{ij} \equiv \Phi_i - \Phi_j \simeq \frac{\Delta m_{ij}^2}{2E_0} \left|\mathbf{x}_D - \mathbf{x}_S\right|, \tag{5}$$

where $\Delta m_{ij}^2 \equiv m_i^2 - m_j^2$. E_0 is the average energy of the relativistic neutrinos produced at S. Substitution of Eq. (5) in Eq. (3) for two flavours of neutrinos lead to the following oscillation formula:

$$\mathcal{P}_{e\mu} = \sin^2 2\alpha \, \sin^2 \left(\frac{\Delta m_{12}^2 \, L}{4E_0}\right) \tag{6}$$

where $L = |\mathbf{x}_D - \mathbf{x}_S|$ and the angle α parameterize elements of matrix U. We see a constant universal shift in the squared masses, i.e. $m_i^2 \to m_i^2 + C$, leaves the expression of $\mathcal{P}_{\alpha\beta}$ unchanged, therefore, $\mathcal{P}_{\alpha\beta}$ depends on the difference of squared masses and not on the absolute masses. In a curved spacetime, the phase in Eq. (4) can be replaced by its covariant form[6]

$$\Phi_i = \int_S^D p_\mu^{(i)} \, dx^\mu \,, \tag{7}$$

where $p_\mu^{(i)}$ is the canonical conjugate momentum to the coordinate x^μ for the i^{th} neutrino mass eigenstate. As in a general curved spacetime, more than one different geodesics starting from the same spacetime point can intersect later, therefore, accounting for all neutrino paths (m) a neutrino flavour state is now given by

$$\left|\nu_\alpha \left(t_D, \mathbf{x}_D\right)\right\rangle = \sum_i U_{\alpha i}^* \sum_m N \psi_i^m \left(x_D, x_S\right) \left|\nu_i \left(t_S, \mathbf{x}_S\right)\right\rangle . \tag{8}$$

Now, normalisation (N), in general, can depend on the path m.

2. Neutrino lensing in Schwarzschild spacetime

We now examine neutrino oscillations in Schwarzschild spacetime specifically emphasizing on the neutrino lensing. The line element in Schwarzschild metric is given by

$$ds^2 = B\left(r\right) dt^2 - \frac{1}{B\left(r\right)} dr^2 - r^2 \left(d\theta^2 + \sin^2\theta d\phi^2\right), \tag{9}$$

where $B\left(r\right) = 1 - \frac{R_s}{r}$, and R_s is Schwarzschild radius. With no lose of generality, we will take $\theta = \pi/2$. Further, it is assumed that the neutrinos are produced as a plane wave.

In the weak gravity limit, there are two paths denoted by impact parameters b_1 and b_2 that neutrino may take to reach at the detector location O. Neutrino flavor transtion probability from α flavour (produced at the source) to β flavour (detected at the detector location) is, then, given by[7]

$$\begin{aligned}\mathcal{P}_{\alpha\beta}^{\text{lens}} = |N|^2 \Bigg(& 2 \sum_i |U_{\beta i}|^2 |U_{\alpha i}|^2 (1 + \cos(\Delta b^2 B_{ii})) + \sum_{i,j\neq i} U_{\beta i} U_{\beta j}^* U_{\alpha j} U_{\alpha i}^* \\ & \times \big(\exp(-i\Delta m_{ij}^2 A_{11}) + \exp(-i\Delta m_{ij}^2 A_{22}) + 2\cos\left(\Delta b^2 B_{ij}\right) \\ & \times \exp\left(-i\Delta m_{ij}^2 A_{12}\right) \big) \Bigg), \end{aligned} \tag{10}$$

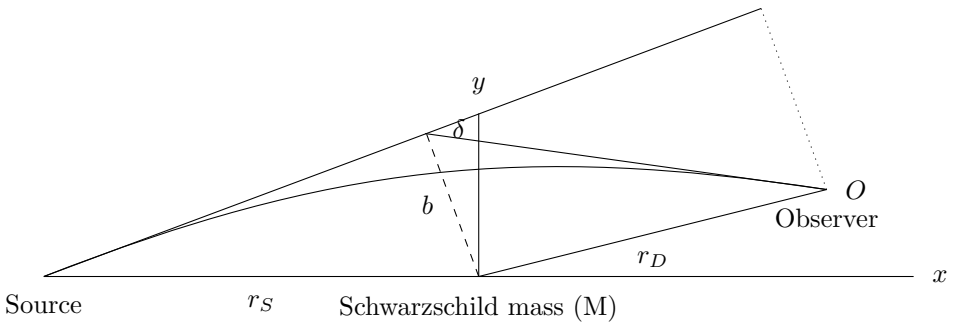

Fig. 1. Diagrammatic representation of weak lensing of neutrinos. Neutrinos are created at the source (S) and get lensed by a Schwarzschild mass (M) and detected at location (O).

with

$$|N|^2 = \left(2 + 2\sum_i |U_{\alpha i}|^2 \cos(\Delta b^2 B_{ii})\right)^{-1} \tag{11}$$

where $\Delta b^2_{12} \equiv \Delta b^2$. It is noted that many similar versions of Eq. (10) are available in literature,[9–11] however, with some subtle differences. Though, the role of normalisation (Eq. (11)) has been neglected in literature[9,11] which is crucial in understanding the neutrino oscillation interference effects.

The change in oscillation phase calculated along neutrino massive trajectory for path (m) is given by

$$\Phi_j^{massive} \simeq \frac{m_j^2}{E_0}(r_S + r_D)\left(1 - \frac{b_m^2}{2r_S r_D} + \frac{2GM}{r_S + r_D}\right), \tag{12}$$

where b_m is the impact parameter and related with deflection angle (δ) as $\delta = -2R_s/b + O\left(R_s m_j^2/bE_0^2\right)$.[8] However, the phase change if calculated along null trajectory for path (m) gives[9]

$$\Phi_j^{null} \simeq \frac{m_j^2}{2E_0}(r_S + r_D)\left(1 - \frac{b_m^2}{2r_S r_D} + \frac{2GM}{r_S + r_D}\right), \tag{13}$$

which is half of $\Phi_j^{massive}$. Despite of this difference in oscillation phase, the bulk of literature employs null ray approximations to calculate the change in the neutrino phase. So, to keep in tune with the bulk of the existing literature on neutrino oscillation, we will employ null ray approximation to study weak lensing. Nevertheless, the results of lensing remain qualitatively consistent if one uses massive trajectories instead of null trajectories. The other quantities in Eq. (10) are related to the phase difference $\Delta\Phi_{ij}^{mn}$ as[7]

$$\Delta\Phi_{ij}^{mn} = \Phi_i^m - \Phi_j^n = \Delta m_{ij}^2\, A_{mn} + \Delta b_{mn}^2\, B_{ij}\,, \tag{14}$$

where

$$A_{mn} = \frac{(r_S + r_D)}{2E_0}\left(1 + \frac{2GM}{r_S + r_D} - \frac{\sum b_{mn}^2}{4r_S r_D}\right),$$

$$B_{ij} = -\frac{\sum m_{ij}^2}{8E_0}\left(\frac{1}{r_S} + \frac{1}{r_D}\right). \tag{15}$$

Here, $\sum b_{mn}^2 = b_m^2 + b_n^2$ and $\sum m_{ij}^2 = m_i^2 + m_j^2$. We note that unless mixing angle $\alpha = \pi/4$ (in the two flavour case) (1) normalization Eq. (11) is not invariant under $m_i \leftrightarrow m_j$ due to $|U_{\alpha i}|^2$ and (2) the neutrino phase Eq. (13) is not invariant under a universal shift $m_i^2 + C$ due to B_{ij} term, unless $\Delta b_{mn}^2 \equiv b_m^2 - b_n^2$ vanishes. Hence, transition probability will be sensitive to both aforementioned points. Fig. 2 shows flavour transition probability for the lensed neutrino, which are lensed by the Sun and detected on the Earth. The Earth trajectory is taken to be circular in the plots. From Fig. 2 one can see the difference in transition probability as the value of mass m_1 changes. Also, the change in mass ordering gives quite a significant difference in transition probabilities and oscillation frequency. We observe that neutrino oscillation frequency increases as we increase the value of m_1. Therefore, one can utilise neutrino lensing to infer neutrino mass. One such way to extract information about absolute mass is to find the flipping point (ϕ_D^e), i.e., where all flavour changing probabilities become the same. The flipping angle in the two flavour case is given by[7]

$$\sum m^2 = \frac{16n\pi E_0 r_S r_D}{Z\Delta b^2} + \frac{16E_0 r_S r_D}{Z\Delta b^2}\cot^{-1}\left(\tan\left(\frac{\Delta m^2 Z\Delta b^2}{16E_0 r_S r_D}\right)\right.$$
$$\left.\times\, G\left(r_S, r_D, \phi_D^e, \alpha, \Delta m^2, R_s\right)\right), \tag{16}$$

$$G_{\pm}\left(r_S, r_D, \phi_D^e, \alpha, \Delta m^2, R_s\right)$$
$$\equiv \frac{2\cos 2\alpha\cos^2\alpha - \sin^2 2\alpha\cos\zeta \pm \sqrt{\sin^4 2\alpha\cos^2\zeta + \sin^2 2\alpha\cos^2 2\alpha}}{2\cos 2\alpha\cos^2\alpha + \sin^2 2\alpha\cos\zeta \mp \sqrt{\sin^4 2\alpha\cos^2\zeta + \sin^2 2\alpha\cos^2 2\alpha}}, \tag{17}$$

where $\zeta \equiv \Delta m^2\left(r_S + r_D + R_s - (r_S + r_D)\sum b^2/4r_S r_D\right)/2E_0$, $Z = r_S + r_D$. In the flipping equation (16), all the measurable quantities are on the right-hand side of the equation, and the term related to absolute mass is on the left-hand side.

3. Neutrino decoherence in gravitational lensing

In a realistic setup neutrinos are produced and detected as a wave packet. So writing detector and neutrino source states in momentum space by using non coordinate tetrad basis,[12] we arrive at the amplitude of flavour transition probability in the

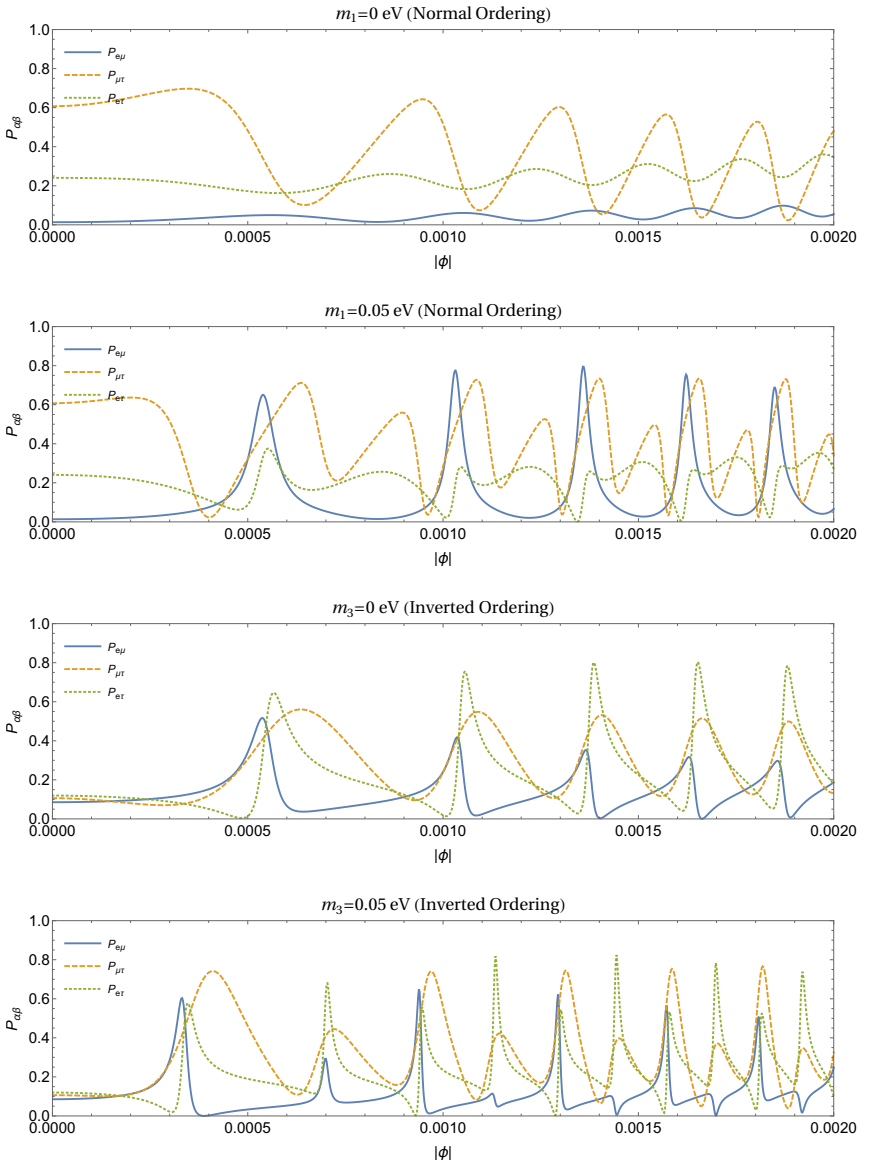

Fig. 2. Probability of $\nu_\alpha \to \nu_\beta$ conversion, for different α and β, as function of azimuthal angle ϕ in three flavour case. We take $R_s = 3$ km, $r_D = 10^8$ km, $r_S = 10^5 r_D$ and $E_0 = 10$ MeV. Neutrino mass squared differences (Δm^2_{ij}), mixing angle and the Dirac CP phase values are taken from (NuFIT 4.1 (2019)) global fit.[3]

wave packet picture and is given by[4, 13, 14]

$$\mathcal{A}^m_{\alpha\beta} \equiv \langle \nu_\beta(\vec{x}_D)|\nu_\alpha(t,\vec{x})\rangle = \sum_i U_{\beta i} U^*_{\alpha i} \int \frac{d^3p}{(2\pi)^3} f^{D*}_{i,\vec{x}}\left(\vec{p},\vec{p}^{\,D}_i\right) f^S_{i,\vec{x}}\left(\vec{p},\vec{p}^{\,S}_i\right) e^{-i\Phi^m_i} \,. \tag{18}$$

The probability of transition $\nu_\alpha \to \nu_\beta$, then, can be computed from the amplitude using[7,14]

$$P_{\alpha\beta} = \frac{\left|\sum_m \mathcal{A}^m_{\alpha\beta}\right|^2}{\sum_\beta \left|\sum_m \mathcal{A}^m_{\alpha\beta}\right|^2} \,. \tag{19}$$

Here, we assume the detection process is time-independent[4] to arrive at the Eq. (18). Further, taking $f^{S,D}_{i,\vec{x}}\left(\vec{p},\vec{p}^{\,S,D}_i\right)$ as Guassian which has a sharp peak around $\vec{p}^{\,S}_i$. We, then, substitute Φ^m_i with its series expansion at $\vec{p}=\vec{p}^{\,S}_i$ in Eq. (18)

$$\Phi^m_i(\vec{p}) = \Phi^m_i(\vec{p}^{\,S}_i) \,+\, \vec{X}^m_i \cdot (\vec{p}-\vec{p}^{\,S}_i) \,+\, \mathcal{O}(p^2)\,, \tag{20}$$

where $\vec{X}^m_i = \partial_{\vec{p}}\Phi^m_i(\vec{p}=\vec{p}^{\,S}_i)$. Furthermore, for simplification, we take $\vec{p}^{\,D,S}_i = \vec{p}^{\,D,S}$ and $\sigma_{i\,D,S} = \sigma_{D,S}$, to arrive at following transition amplitude[14] $\mathcal{A}^m_{\alpha\beta}$ and transition probability[14] $P_{\alpha\beta}$

$$\mathcal{A}^m_{\alpha\beta} = 2\sqrt{2}\left(\frac{\sigma_D\sigma_S}{\sigma_D^2+\sigma_S^2}\right)^{3/2} \sum_i U_{\beta i}U^*_{\alpha i}\, e^{-i\left(\Phi^m_i - \frac{\sigma_S^2}{\sigma_D^2+\sigma_S^2}\vec{X}^m_i\cdot\left(\vec{p}^{\,D}-\vec{p}^{\,S}\right)\right)} \times e^{-\frac{\sigma_D^2\sigma_S^2|\vec{X}^m_i|^2+\left(\vec{p}^{\,D}-\vec{p}^{\,S}\right)^2}{2\left(\sigma_D^2+\sigma_S^2\right)}}\,, \tag{21}$$

$$P_{\alpha\beta} = \frac{\sum\limits_{i,j} U^*_{\beta i}U_{\alpha i}U_{\beta j}U^*_{\alpha j}\sum\limits_{m,n} e^{-i\Phi^{mn}_{ij}}\, e^{-D^{mn}_{ij}}}{\sum\limits_i U_{\alpha i}U^*_{\alpha i}\sum\limits_{m,n} e^{-i\Phi^{mn}_{ii}}\, e^{-D^{mn}_{ii}}}\,, \tag{22}$$

where

$$\Phi^{mn}_{ij} \equiv \left(\Phi^m_i - \Phi^n_j\right) - \frac{\bar{\sigma}^2}{\sigma_D^2}\left(\vec{p}^{\,D}-\vec{p}^{\,S}\right)\cdot\left(\vec{X}^m_i - \vec{X}^n_j\right)\,, \tag{23}$$

$$D^{mn}_{ij} = \mathbf{X}^{mn}_{ij} - \mathbf{X}^{\hat{m}\hat{n}}_{\hat{i}\hat{i}}\,, \tag{24}$$

$$\mathbf{X}^{mn}_{ij} \equiv \frac{1}{2}\bar{\sigma}^2\left(|\vec{X}^m_i|^2 + |\vec{X}^n_j|^2\right)\,, \tag{25}$$

where $\bar{\sigma}^2 = \sigma_D^2\sigma_S^2/(\sigma_D^2+\sigma_S^2)$. From Eq. (22), we define D^{mn}_{ij} to be decoherence factor. In D^{mn}_{ij} (Eq. (24)), the term $\mathbf{X}^{\hat{m}\hat{n}}_{\hat{i}\hat{i}}$ is choosen be the the smallest among $\mathbf{X}^{mn}_{ij}$, such that D^{mn}_{ij} are, by construction, greater than or equal to zero. We note that as D^{mn}_{ij} get large, probabilities approach to values which only depend on neutrino mixing matrix elements, i.e., $P_{\alpha\beta} \to U^*_{\beta 1}U_{\beta 1} = |U_{\beta 1}|^2$. We, also, note that the oscillation phase obtained in Eq. (23) is modified from the one obtained assuming neutrinos as plane waves. Now, oscillation phase also depends on the source and the detector wave profile. The difference between plane wave phase and modified phase become negligible if the neutrino wave packets at production and detection follow $\vec{p}^{\,D} \simeq \vec{p}^{\,S}$ condition. Now considering the Schwarzschild neutrino lensing, taking $b_2 < b_1$ and $m_1 < m_2 < m_3$, one finds the term D^{mn}_{ij}, which approaches last to zero,

is given by D_{12}^{11}. Hence, the coordinate distance at which the transition probability gets suppressed by at least a factor of e^{-1} is given by following condition[14]

$$(r_D + r_S)\left(1 - \frac{b_1^2}{2r_S r_D} + \frac{R_S}{r_D + r_S}\right) \geq 2\sqrt{\frac{2}{B(r_S)}}\frac{E_0^2}{\bar{\sigma}\sqrt{m_2^4 - m_1^4}}\,. \tag{26}$$

Eq. (26) can readily be used to estimate decoherence length, i.e., the distance to which the coherent oscillations last. For the radial outward propagation in the flat and Schwarzschild spacetime, respectively, with the same dilution in probability e^{-1} and written in physical length, is given by

$$L_p^F = r_D - r_S \geq 2\sqrt{2}\frac{E_0^2}{\bar{\sigma}\sqrt{m_2^4 - m_1^4}}, \tag{27}$$

and

$$L_p^S - R_s \ln\frac{r_D}{r_S} \geq 2\sqrt{\frac{2}{B(r_S)}}\frac{E_0^2}{\bar{\sigma}\sqrt{m_2^4 - m_1^4}}\,. \tag{28}$$

From Eq. (27) and Eq. (28) we observe for the same physical distance $L_p^F = L_p^S$ between the source and the detector, neutrino decoher more in the flat spacetime, whereas due to R_s term neutrino decoher less in the Schwarzschild spacetime. This is true even for the non radial and the lensing case. Also, from Eq. (26), Eq. (27) and Eq. (28), we see that rate of dilution depend not only on Δm^2, but also on $\sum m^2$ term. Hence, length at which oscillations cease to exist due to suppression of all terms in transition probability can be used to infer absolute neutrino masses. To make above point clear we take two neutrino flavour case and plot change in transition probability taking $y_D = 0$ and varying only x_D, also now we have $x_D = r_D$. Fig. 4 shows maximum and minimum probability as a function of r_D near dechorence region, we see for $m_1 = 0$ eV decoherence occurs, i.e. $P_{e\mu} \to \sin^2\alpha = 1/2$, later compares to the $m_1 = 0.1$ eV case. We also note from Fig. 3, that decoherence is consistent with $D_{12}^{11} \geq 2$. Right panel of Fig. 3 compute correlations between $\bar{\sigma}$ and r_D for $D_{12}^{11} = 1$. The estimation is done for two different values of the lightest neutrino mass m_1 keeping $m_2^2 - m_1^2 = 10^{-3}eV^2$ fixed.

4. Summary

By studying neutrino lensing in Schwarzschild background, we explicated that neutrino lensing is sensitive to neutrino mass ordering and absolute neutrino masses, contrary to the vacuum neutrino flavour oscillations in flat spacetime. In curved spacetime, neutrinos can take more than one path to arrive at the detector; this gives rise to path difference in the neutrino phase, giving a novel contribution in oscillation probabilities that depends on absolute neutrinos mass. We presented a method for inferring individual neutrino mass from flipping angles/points, i.e. locations in the space where all the neutrino flavours have equal probabilities of being detected by the detector. Using the Sun-Earth model, we explicitly demonstrate

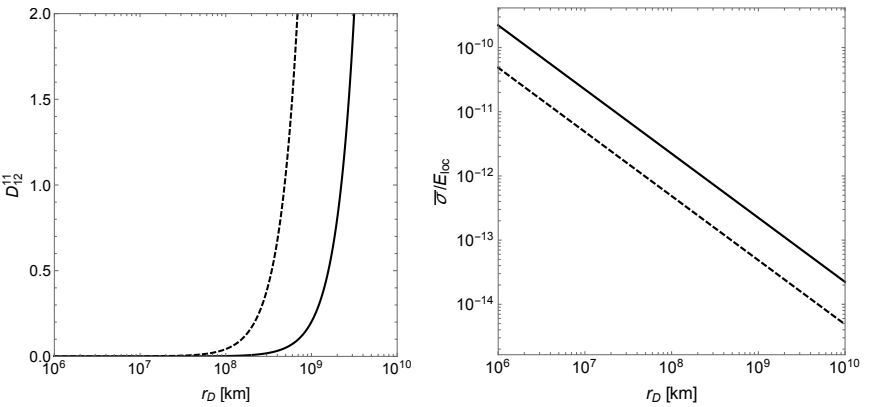

Fig. 3. Left panel: the damping factor D_{12}^{11} as function of r_D for $\bar{\sigma}/E_{\rm loc} = 10^{-13}$. Right panel: contours corresponding to $D_{12}^{11} = 1$. In both the panels, the solid (dashed) line corresponds to $m_1 = 0$ ($m_1 = 0.1$) eV. The other parameters are $r_S = 10^5 r_D$, $R_S = 3$ km, $m_2^2 - m_1^2 = 10^{-3}\,\text{eV}^2$ and $E_{\rm loc} = 10$ MeV.

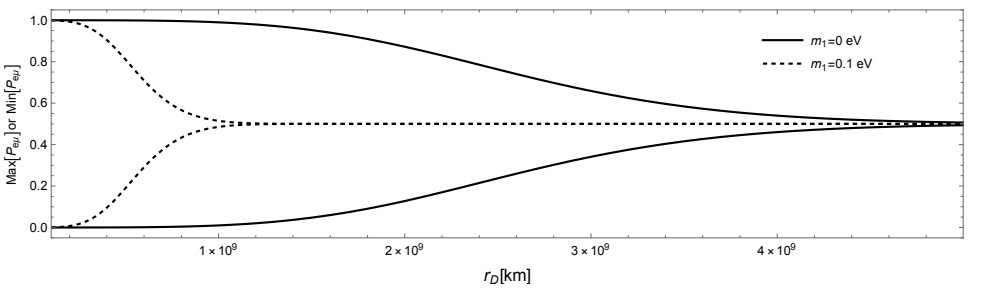

Fig. 4. Maximum and minimum transition probability envelop as a function of r_D for two flavour case. The solid (dashed) line corresponds to $m_1 = 0$ ($m_1 = 0.1$) eV. The mixing angle is $\alpha = \pi/4$ and all the other parameters are as given in the caption of Fig. 3.

oscillation sensitivity on individual neutrino masses in neutrino lensing. Neutrino oscillation frequency increases as we increase the value of m_1. Further, using the Gaussian wavepacket profile for the neutrino and the detector, we find wave packet profile modifies the neutrino phase. Now, the oscillation phase depends on the source and detector wave packet profile $\sigma_{D,S}$ and $\vec{p}^{D,S}$, and reduces to the plane wave neutrino phase when mean momentum $\vec{p}^{D,S}$ of the source and detector are same. The wave packet approach also introduces a new length scale, i.e. decoherence length, after which neutrino oscillations cease to exist. The decoherence length depends not only on Δm^2 but also on $\sum m^2$. Also, in a weak gravity limit, neutrino travels more in the Schwarzschild spacetime as compare to the flat spacetime before decoupling due to decoherence. Further, we highlight that neutrino flavour transition probability settles to the fundamental values of neutrino mixing matrix elements after decoherence. Therefore, the sensitivity of flavour oscillations probabilities and neu-

trino decoherence on $\sum m^2$ can reveal absolute neutrino mass and their ordering. Hence, neutrino lensing can be one of the viable methods for inferring individual neutrino mass. Conversely, one can also use decoherence length and neutrino mass to infer values of neutrino mixing parameters.

Photon regions in stationary axisymmetric spacetimes and umbilic conditions

K. V. Kobialko* and D. V. Gal'tsov†

Faculty of Physics, Moscow State University, 119899, Moscow, Russia

E-mail: kobyalkokv@yandex.ru

†*E-mail: galtsov@phys.msu.ru*

We present the fundamentals of the recently proposed geometric description[1] of *photon regions* in terms of foliation into *fundamental photon hypersurfaces*, which satisfies the umbilic condition for the subbundle of the tangent bundle defined by the generalized impact parameter.

Keywords: Photon regions, photon surfaces, gravitational lensing, black hole shadows.

1. Introduction

Formation of shadows and relativistic images of stationary black holes is closely related to *photon regions*,[2,3] which are defined as compact domains where photons can travel endlessly without escaping to infinity or disappearing at the event horizon. Indeed, the boundary of the gravitational shadow corresponds to the set of light rays that inspiral asymptotically onto the part of the spherical surfaces in photon regions on which closed spherical photon orbits are located.[4–6]

Spherical surfaces in the photon region are just as important for determining the shadow of a stationary black hole as the *photon surfaces*[7,8] in the static case[a]. Recall that an important property of the photon surfaces is established by the theorem asserting that these are timelike *totally umbilic* hypersurfaces S in spacetime. This means that their second fundamental form II[11] is proportional to the induced metric:

$$\mathrm{II}(X,Y) = \mathrm{H}\,\langle X,Y\rangle\,, \quad \forall X,Y \in TS. \tag{1}$$

This property can serve as a constructive definition for analyzing photon surfaces instead of solving geodesic equations. It is especially useful in the cases when the geodesic equations are non-separable, and their analytic solution can not be found.[12–17]

However, in rotating spacetime such as Kerr, spherical surfaces in the photon region do not fully satisfy the umbilic condition and have a boundary. Such surfaces usually form a family, parameterized by the value of the azimuthal impact parameter $\rho = L/E$, where L, E are the integrals of motion corresponding to the timelike and azimuthal Killing vector fields.[18,19] To describe these surfaces and the photon

[a]For recent review of strong *gravitational lensing* and shadows see.[6,9,10]

region geometrically, we introduce the concept of *partially umbilic* submanifolds that weaken the condition (1). Namely, it is possible to impose the condition (1) not on *all* vectors from the tangent space TS, but only on some subset of TS specified by the azimuthal impact parameter. In addition, we must specify the boundary conditions for the submanifolds so that the photon does not escape through them. Together, this leads to the definition of *fundamental photon submanifolds*[1,20] - as generalization of *fundamental photon orbits*.[17] The slices consisting of the fundamental photon surfaces form generalized photon regions.

In this article, we give a concise presentation of the main concepts of the geometric approach to fundamental photon submanifolds and regions. Section 2 describes the partition of the tangent space of the manifold into sectors specified by the azimuthal impact parameter of the geodesics $\rho = L/E$. Then, in the section 3, we introduce the notion of partially umbilic submanifolds on the ρ-constrained sector of the tangent space and define the *fundamental photon submanifolds*. The Section 4 contains the geometric definition of the photon region.

2. Geodesic classes

Let M be a m dimensional Lorentzian manifold[11] with scalar product $\langle \cdot , \cdot \rangle$, Levi-Civita connection ∇, a tangent bundle TM and supposed to possess two commuting Killing vector fields $\mathcal{K}_\alpha$ ($\alpha = t, \varphi$) defining a stationary axisymmetric spacetime such that $\mathcal{G} = \det(\mathcal{G}_{\alpha\beta}) < 0$, where $\mathcal{G}_{\alpha\beta} = \langle \mathcal{K}_\alpha, \mathcal{K}_\beta \rangle$.

Let us define a Killing vector field $\hat{\rho} \in \{\mathcal{K}_\alpha\}$[20] with index numbering Killing vectors fields of the frame $\{\mathcal{K}_\alpha\}$

$$\hat{\rho} = \rho^\alpha \mathcal{K}_\alpha, \quad \rho^\alpha = (\rho, 1), \tag{2}$$

which is determined by arbitrary constant parameter ρ. In addition, we will introduce a vector field $\hat{\tau}$ in $\{\mathcal{K}_\alpha\}$ orthogonal to $\hat{\rho}$:

$$\tau^\alpha = \mathcal{G}^{\alpha\lambda}\epsilon_{\lambda\beta}\rho^\beta, \qquad \langle \hat{\tau}, \hat{\tau} \rangle = -\langle \hat{\rho}, \hat{\rho} \rangle, \qquad \langle \hat{\tau}, \hat{\rho} \rangle = 0, \tag{3}$$

where $\epsilon_{\lambda\beta}$ is the two-dimensional Levi-Civita tensor.

Then there is frame $\{\hat{\tau}, e_a\} \cong \hat{\rho}^\perp$, such that $\{e_a\}$ ($a = 1, m-2$) is a frame in euclidean orthogonal complement $\{\mathcal{K}_\alpha\}^\perp$[b].

Let γ be some geodesic on M, and $\dot{\gamma}$ denotes the tangent vector field to γ. Then there is the following general relationship between geodesics γ and orthogonal complement $\hat{\rho}^\perp$.

Proposition 2.1. *At every point $p \in M$ there is a one-to-one correspondence*[c] *between geodesics γ (with nonzero energy $E \equiv -\langle \mathcal{K}_t, \dot{\gamma} \rangle \neq 0$) with impact parameter $\rho = -\langle \mathcal{K}_\varphi, \dot{\gamma} \rangle / \langle \mathcal{K}_t, \dot{\gamma} \rangle$ and tangent vector fields $\mathcal{X} \in \hat{\rho}^\perp$ with $\langle \mathcal{K}_t, \mathcal{X} \rangle \neq 0$.*

[b] Orthogonal complement $^\perp$ defined in.[11] If $\langle \hat{\rho}, \hat{\rho} \rangle = 0$, then $\hat{\tau}$ and $\hat{\rho}$ are simply proportional and the orthogonal complement $\hat{\rho}^\perp$ will contain only one null vector $\hat{\rho}$ and spacelike e_a.

[c] Accurate to the geodesics reparametrization.

Proof. If geodesic γ has ρ as an impact parameter, then $\rho = -\langle \mathcal{K}_\varphi, \dot\gamma\rangle / \langle \mathcal{K}_t, \dot\gamma\rangle$ and multiplying by $\langle \mathcal{K}_t, \dot\gamma\rangle \neq 0$ we get $0 = \langle \rho\mathcal{K}_t + \mathcal{K}_\varphi, \dot\gamma\rangle = \langle \hat\rho, \dot\gamma\rangle$ and therefore $\dot\gamma \in \hat\rho^\perp$. If $\langle \hat\rho, \mathcal{X}\rangle = 0$ and $\langle \mathcal{K}_t, \mathcal{X}\rangle \neq 0$, then at any point $p \in M$ the any vector $\mathcal{X}|_p$ is a tangent vector to some geodesic γ, which always exists and unique at least in some vicinity of $p \in M$ as solution of ODE with initial conditions $\gamma(0) = p$ and $\dot\gamma(0) = \mathcal{X}|_p$. The geodesic γ has ρ as an impact parameter insofar as $0 = \langle \hat\rho, \dot\gamma(0)\rangle = \langle \rho\mathcal{K}_t + \mathcal{K}_\varphi, \dot\gamma(0)\rangle$ and we get $\rho = -\langle \mathcal{K}_\varphi, \dot\gamma(0)\rangle / \langle \mathcal{K}_t, \dot\gamma(0)\rangle$. □

It is clear that in the general case the Killing vector field $\hat\rho$ can be timelike on the some part of the manifold M. In this case, its orthogonal complement $\hat\rho^\perp$ will not have the Lorentzian signature everywhere, and therefore not all manifolds will be available for null geodesics with a given impact parameter ρ. So, our goal is to find the suitable region $\mathcal{C} \subset M$ in the original manifold M such that $\langle \hat\rho, \hat\rho\rangle|_{\mathcal{C}} \geq 0$.

Proposition 2.2. *If $\nabla_{\hat\rho}\hat\rho \neq 0$ for all null $\hat\rho$, the smooth function $\langle \hat\rho, \hat\rho\rangle$ defines m dimensional manifold with boundary*

$$\mathcal{C} \subset M : \langle \hat\rho, \hat\rho\rangle|_{\mathcal{C}} \geq 0, \tag{4}$$

with interior $\mathcal{O} : \langle \hat\rho, \hat\rho\rangle|_{\mathcal{O}} > 0$ and $m-1$ dimensional boundary $\partial\mathcal{C} : \langle \hat\rho, \hat\rho\rangle|_{\partial\mathcal{C}} = 0$ with outward normal

$$\mathcal{N} = \nabla_{\hat\rho}\hat\rho, \quad \langle \mathcal{N}, \hat\rho\rangle = 0. \tag{5}$$

Proof. Let $\mathcal{X} \in TM$ be an arbitrary vector field in M, then using Killing equation we get

$$\langle \nabla \langle \hat\rho, \hat\rho\rangle, \mathcal{X}\rangle \equiv \nabla_{\mathcal{X}} \langle \hat\rho, \hat\rho\rangle = 2\langle \nabla_X \hat\rho, \hat\rho\rangle = -2\langle \nabla_{\hat\rho}\hat\rho, \mathcal{X}\rangle, \tag{6}$$

$$\Updownarrow$$

$$\nabla \langle \hat\rho, \hat\rho\rangle = -2\nabla_{\hat\rho}\hat\rho. \tag{7}$$

Thus $\nabla \langle \hat\rho, \hat\rho\rangle|_{\partial\mathcal{C}} \neq 0$ and the boundary $\partial\mathcal{C}$ is a hypersurface in M with the normal field $\mathcal{N}$ proportional to $\nabla_{\hat\rho}\hat\rho$. Choosing an outward normal, i.e. directed so that the function $\langle \hat\rho, \hat\rho\rangle$ decreases along the $\mathcal{N}$ we get first condition in (5). Applying Killing equation again we get second condition in (5) since

$$\langle \mathcal{N}, \hat\rho\rangle = \langle \nabla_{\hat\rho}\hat\rho, \hat\rho\rangle = -\langle \nabla_{\hat\rho}\hat\rho, \hat\rho\rangle = 0. \tag{8}$$

□

Definition 2.1. A connected manifold $\mathcal{C}$ will be called causal region. The manifold $\mathcal{O}$ will be called accessible region.[1]

From the point of view of geodesics, and, in particular, the fundamental photon orbits, the region $\mathcal{C}$ represents an accessible region for the null geodesics motion in some effective potential.[17,21] Physical meaning of the causal region $\mathcal{C}$ is that any point can be theoretically observable for any observer in the same region. This causal region may contain spatial infinity (if any) and then will be observable for

an asymptotic observer. In some cases, several causal regions may exist, while null geodesics with a given ρ cannot connect one to another. The boundary $\partial\mathcal{C}$ of the causal region is defined as the branch of the solution of the equation $\langle\hat{\rho},\hat{\rho}\rangle = 0$ and is the set of turning points of null geodesics.

3. Photon submanifold

Let M and S be Lorentzian manifolds, of dimension m and n respectively, and $S \to M$ an isometric embedding[11] defining S as a submanifold[d] in M. We adopt here the following convention for the second fundamental form II of the submanifold[11]:

$$\nabla_Y X = \mathcal{D}_Y X + \mathrm{II}(X,Y), \quad X,Y \in TS, \tag{9}$$

where $\mathcal{D}_X Y \in TS$, $\mathrm{II}(X,Y) \in TS^{\perp}$ and ∇ and $\mathcal{D}$ are the Levi-Civita connections on M and S respectively.

Definition 3.1. We will call a submanifold S invariant, if the Killing vector fields $\mathcal{K}_\alpha$ and $[\mathcal{K}_\alpha,\mathcal{K}_\beta]$ in M are tangent vector fields to S.

For invariant submanifolds the Killing vectors of M will be also the Killing vectors on the submanifold S[20] and well defined restrictions $\hat{\rho}^{\perp}$ and $\mathcal{C}$ on TS and S respectively. We now define a weakened version of the standard umbilic condition (1) requiring it to be satisfied only for some subbundle $V \subset TS$ in the tangent bundle TS.

Definition 3.2. A submanifold S will be called totally V umbilic if[1]

$$\mathrm{II}(X,Y) = \mathrm{H}|_V \langle X,Y\rangle, \quad \forall X,Y \in V. \tag{10}$$

In particular, every totally umbilic submanifold is trivially totally V umbilic for any V. We also note that in the general case $\mathrm{H}|_V$ appearing in this formula is only part of the mean curvature[11] i.e the trace of II on the subbundle V. For invariant totally V umbilic submanifolds, an important theorem on the behavior of null geodesics holds, generalizing the classical result.[7,11]

Proposition 3.1. *Any null geodesic γ with impact parameter ρ in an invariant Lorentzian submanifold $S \subset \mathcal{O}$ is a null geodesic in M if and only if S is totally $\hat{\rho}^{\perp}$ umbilic submanifold.*

Proof. Let S be a totally $\hat{\rho}^{\perp}$ umbilic invariant Lorentzian submanifold and γ be an arbitrary affinely parameterized null geodesic with impact parameter ρ in S i.e. $\mathcal{D}_{\dot\gamma}\dot\gamma = 0$ and $\dot\gamma \in \hat{\rho}^{\perp} \subset TS$. Then by the Gauss decomposition (9)

$$\nabla_{\dot\gamma}\dot\gamma = \mathcal{D}_{\dot\gamma}\dot\gamma + \mathrm{II}(\dot\gamma,\dot\gamma) = \mathrm{H}|_{\hat{\rho}^{\perp}} \langle\dot\gamma,\dot\gamma\rangle = 0, \tag{11}$$

consequently γ is a null geodesic in M.

[d] A hypersurface if $n = m-1$

Conversely, let every null geodesic γ with impact parameter ρ in S be a null geodesic in M, then from the Gauss decomposition (9)

$$\mathrm{II}(\dot\gamma,\dot\gamma)=0, \tag{12}$$

for any null $\dot\gamma\in\hat\rho^\perp\subset TS$. Since we limited ourselves to the accessible region $\mathcal{O}$ we can choose an orthonormal Lorentzian frame $\{\hat\tau/||\hat\tau||,e_a\}\cong\hat\rho^\perp\subset TS$ $(a=1,n-2)$. Then the equality (12) for null vectors $\dot\gamma=\hat\tau/||\hat\tau||\pm e_a$ in the new frame takes the form

$$\mathrm{II}(\hat\tau/||\hat\tau||,\hat\tau/||\hat\tau||)+\mathrm{II}(e_a,e_a)=0,\quad \mathrm{II}(\hat\tau/||\hat\tau||,e_a)=0. \tag{13}$$

And for null vectors $\dot\gamma=\hat\tau/||\hat\tau||\pm(e_a\pm e_b)/\sqrt{2}$

$$\mathrm{II}(e_a,e_b)=0. \tag{14}$$

□

Physical meaning of the Proposition 3.1 is that the null geodesics with a given impact parameter ρ initially touching the spatial section of the invariant totally $\hat\rho^\perp$ umbilic submanifold remain on it for an arbitrarily long time, unless of course they leave it across the boundary. This is a well-known property of a photon sphere and its generalization - a photon surface.[7] Thus, we obtain a generalization of the classical definition of the photon surfaces to the case of a class of geodesics with a fixed impact parameter.

It is useful to obtain an equation for the second fundamental form of the totally $\hat\rho^\perp$ umbilic submanifold in the original basis $\{\mathcal{K}_\alpha,e_a\}$.

Proposition 3.2. *For the invariant $\hat\rho^\perp$ umbilic submanifold, the second fundamental form* II *in the basis $\{\mathcal{K}_\alpha,e_a\}$ has the form*

$$\mathrm{II}=\begin{pmatrix} -\frac{1}{2}\nabla^\perp\mathcal{G}_{\alpha\beta} & -\sum_{A=1}^{m-n}\epsilon_A\left\langle\nabla_{\xi_A}\mathcal{K}_\alpha,e_b\right\rangle\xi_A \\ -\sum_{A=1}^{m-n}\epsilon_A\left\langle\nabla_{\xi_A}\mathcal{K}_\beta,e_a\right\rangle\xi_A & \mathrm{H}|_{\hat\rho^\perp}\left\langle e_a,e_b\right\rangle \end{pmatrix}, \tag{15}$$

where $\mathrm{H}|_{\hat\rho^\perp}$ and $\mathcal{G}_{\alpha\beta}$ satisfy the master equation[20]

$$\rho^\alpha\mathcal{M}_{\alpha\beta}\rho^\beta=0,\quad \mathcal{M}_{\alpha\beta}=\frac{1}{2}\nabla^\perp\left(\mathcal{G}^{-1}\mathcal{G}_{\alpha\beta}\right)-\mathrm{H}|_{\hat\rho^\perp}\left(\mathcal{G}^{-1}\mathcal{G}_{\alpha\beta}\right), \tag{16}$$

$$\mathcal{G}^{\alpha\lambda}\epsilon_{\lambda\beta}\rho^\beta\mathrm{II}(\mathcal{K}_\alpha,e_a)=0, \tag{17}$$

and the derivative along the unit normals $\xi_A\in TS^\perp$ $(A=1,m-n)$ of the submanifold S is defined as

$$\nabla^\perp(\,\cdot\,)=\sum_{A=1}^{m-n}\epsilon_A\nabla_{\xi_A}(\,\cdot\,)\xi_A,\quad \epsilon_A\equiv\left\langle\xi_A,\xi_A\right\rangle. \tag{18}$$

Proof. From the Killing equation for $X\in\{e_a\}$ we find

$$\mathrm{II}(X,\mathcal{K}_\alpha)=\pi^\perp(\nabla_X\mathcal{K}_\alpha)=\sum_{A=1}^{m-n}\epsilon_A\left\langle\nabla_X\mathcal{K}_\alpha,\xi_A\right\rangle\xi_A=-\sum_{A=1}^{m-n}\epsilon_A\left\langle\nabla_{\xi_A}\mathcal{K}_\alpha,X\right\rangle\xi_A. \tag{19}$$

Using the Killing equation again we get

$$\langle \nabla_{\mathcal{K}_\alpha} \mathcal{K}_\beta, \xi_A \rangle = - \langle \nabla_{\xi_A} \mathcal{K}_\beta, \mathcal{K}_\alpha \rangle = -\nabla_{\xi_A} \langle \mathcal{K}_\alpha, \mathcal{K}_\beta \rangle - \langle \xi_A, \nabla_{\mathcal{K}_\beta} \mathcal{K}_a \rangle . \tag{20}$$

Then, using the involutivity condition $[\mathcal{K}_\alpha, \mathcal{K}_\beta] \in TS$ we finally find

$$\mathrm{II}(\mathcal{K}_\alpha, \mathcal{K}_\beta) = \sum_{A=1}^{m-n} \epsilon_A \langle \nabla_{\mathcal{K}_\alpha} \mathcal{K}_\beta, \xi_A \rangle \xi_A = -\frac{1}{2} \sum_{A=1}^{m-n} \epsilon_A \nabla_{\xi_A} \langle \mathcal{K}_\alpha, \mathcal{K}_\beta \rangle \xi_A. \tag{21}$$

and

$$\mathrm{II}(\hat{\tau}, \hat{\tau}) = -\frac{1}{2} \tau^\alpha \tau^\beta \nabla^\perp \mathcal{G}_{\alpha\beta} = -\rho^\alpha \rho^\beta \left(\frac{1}{2} \nabla^\perp \mathcal{G}_{\alpha\beta} + \mathcal{G}^{\lambda\gamma} \epsilon_{\lambda\alpha} \nabla^\perp \epsilon_{\gamma\beta} \right) \tag{22}$$

$$= \frac{1}{2} \rho^\alpha \rho^\beta \left(-\nabla^\perp \mathcal{G}_{\alpha\beta} + \mathcal{G}_{\alpha\beta} \nabla^\perp \ln \mathcal{G} \right). \tag{23}$$

Substituting this expression into the equation (10), we get (16). □

Alternatively, the master equation can be rewritten as expression for the mean curvature

$$\mathrm{H}|_{\hat{\rho}^\perp} = \frac{1}{2} \nabla^\perp \ln \left(\mathcal{G}^{-1} \langle \hat{\rho}, \hat{\rho} \rangle \right). \tag{24}$$

If the submanifold under consideration is totally umbilic we'll get $\mathcal{M}_{\alpha\beta} = 0$.

The notion of an invariant $\hat{\rho}^\perp$ umbilic submanifold is however too general (as is the notion of an umbilic surface by itself[22]) and is not yet defined at the boundary of the causal region $\partial\mathcal{C}$. Generally speaking, these submanifolds are geodesically not complete (in the sense that null geodesics can leave them across the boundary) or have a non-compact spatial section (geodesics can go into the asymptotic region). Moreover, for each ρ there can be an infinite number of them, just as there are an infinite number of umbilic surfaces, but only one photon sphere in the static Schwarzschild[23] solution. Therefore, it is necessary to introduce a more specific definition of fundamental photon submanifolds.[1,20]

Definition 3.3. A fundamental photon submanifold $S \subset \mathcal{C}$ is an invariant Lorentzian submanifold with compact spatial section such that:

(a) The boundary ∂S (if any) lie in $\partial\mathcal{C}$.

(b) The second fundamental form II has the form (15) and satisfies the master equation/inequality

$$\mathcal{M}(\hat{\rho}, \hat{\rho}) = 0, \quad \langle \hat{\rho}, \hat{\rho} \rangle \geq 0. \tag{25}$$

In the case $n = m - 1$, the fundamental photon submanifold is a timelike fundamental photon hypersurface (FPH).

Proposition 3.3. *Every null geodesic γ with an impact parameter ρ at least once touching an arbitrary fundamental photon submanifold S lies in it completely i.e. $\gamma \subset S$.*

Proof. Obviously condition (b) in Definition 3.3, by virtue of Proposition 3.1, prevents null geodesics from leaving the fundamental photon submanifold at all interior points $(S/\partial S) \cap \mathcal{O}$.

Conditions (a-b) for boundary points ∂S and interior points $S \cap \partial\mathcal{C}$ prevents the possibility of null geodesics to leave fundamental photon submanifolds through them. Indeed, $\partial\mathcal{C}$ is the set of turning points for null geodesics in M that cannot move in the direction of the normal $\mathcal{N}|_{\partial S}$, while condition $\mathrm{II}(\hat{\rho},\hat{\rho})|_{\partial S} = 0$ following from (25) not only prevents geodesics from moving in the normal directions ξ_A but also ensures that the normal $\mathcal{N}_{\partial S}$ to ∂S in S coincides with the normal $\mathcal{N}|_{\partial S}$ to the $\partial\mathcal{C}$ in M.

$$\mathcal{N}|_{\partial S} = \nabla_{\hat{\rho}}\hat{\rho}|_{\partial S} = \{\mathcal{D}_{\hat{\rho}}\hat{\rho} + \mathrm{II}(\hat{\rho},\hat{\rho})\}\,|_{\partial S} = \mathcal{D}_{\hat{\rho}}\hat{\rho}|_{\partial S} = \mathcal{N}_{\partial S}. \tag{26}$$

□

From this statement, it is clear that the so-defined fundamental photon submanifolds have trapping properties even at the boundary and contain

(a) non-periodic trapped photon orbits,

(b) periodic fundamental photon orbits.[17]

In stationary and axisymmetric geometry, there exists a vector field

$$\hat{\omega} = \omega^{\alpha}\mathcal{K}_{\alpha}, \quad \omega^{\alpha} = (1,\omega), \tag{27}$$

orthogonal to the all spatial slices Σ of manifold M[e]. In such slices, one can define fundamental photon submanifolds in terms of *principal curvatures*.

Proposition 3.4. *The principal curvatures λ of the spatial section S' of the invariant totally $\hat{\rho}^{\perp}$ umbilic submanifold S satisfy the master equation*

$$\lambda_a - \lambda_{\varphi} = \nabla^{\perp}\ln(||\hat{\rho}||/||\hat{\omega}||), \tag{28}$$

with

$$\lambda_{\varphi} = -\frac{1}{2}\nabla^{\perp}\ln\mathcal{G}_{\varphi\varphi}, \quad \lambda_a = \mathrm{H}|_{\hat{\rho}^{\perp}}. \tag{29}$$

Proof. From the general theory for the second fundamental form II' of the spatial section $S' \subset \Sigma$ of the invariant totally $\hat{\rho}^{\perp}$ umbilic submanifold S we find that

$$\mathrm{II}'(X,Y) = \mathrm{II}(X,Y) = \mathrm{H}|_{\hat{\rho}^{\perp}}\langle X,Y\rangle, \quad \mathrm{II}'(\mathcal{K}_{\varphi},\mathcal{K}_{\varphi}) = \mathrm{II}(\mathcal{K}_{\varphi},\mathcal{K}_{\varphi}) = -\frac{1}{2}\nabla^{\perp}\mathcal{G}_{\varphi\varphi},$$

$$\mathrm{II}'(\mathcal{K}_{\varphi},X) = \mathrm{II}(\mathcal{K}_{\varphi},X) = -\sum_{A=1}^{m-n}\epsilon_A\langle\nabla_{\xi_A}\mathcal{K}_{\varphi},X\rangle\,\xi_A, \quad X \in \{e_a\}.$$

In what follows, we will assume that $\mathrm{II}(\mathcal{K}_{\varphi},X) = 0$.[1] Due to the shape of the second fundamental form of the spatial slices Σ and the expression for mixed components, we find $\mathrm{II}(\hat{\omega},X) = 0$, and therefore from $\mathrm{II}(\mathcal{K}_{\varphi},X) = 0$ follows $\mathrm{II}(\mathcal{K}_t,X) = 0$ and

[e]The norm $||\hat{\omega}||$ of vector field $\hat{\omega}$ is called the lapse function.

the second umbilic condition (17) is fulfilled identically. Further, from the master equation (24) and expressions for the determinant $\mathcal{G}$

$$\begin{aligned}\mathcal{G} &= \langle \mathcal{K}_t, \mathcal{K}_t \rangle \langle \mathcal{K}_\varphi, \mathcal{K}_\varphi \rangle - \langle \mathcal{K}_t, \mathcal{K}_\varphi \rangle^2 \\ &= (\langle \hat{\omega}, \hat{\omega} \rangle - 2\omega \langle \mathcal{K}_t, \mathcal{K}_\varphi \rangle - \omega^2 \langle \mathcal{K}_\varphi, \mathcal{K}_\varphi \rangle) \langle \mathcal{K}_\varphi, \mathcal{K}_\varphi \rangle - \omega^2 \langle \mathcal{K}_\varphi, \mathcal{K}_\varphi \rangle^2 \\ &= \langle \hat{\omega}, \hat{\omega} \rangle \langle \mathcal{K}_\varphi, \mathcal{K}_\varphi \rangle . \end{aligned} \tag{30}$$

we get (28). □

4. Photon region

We now define the concept of a fundamental photon region and a fundamental photon function – a generalization of the classical three-dimensional photon region in the Kerr metric.[2,3,24]

Definition 4.1. The fundamental photon function PF will be called the mapping[1]

$$PF : \rho \to \bigcup S \tag{31}$$

which associates with each ρ one or the union of several fundamental photon submanifolds with the same ρ.

The function PF can be continuous, defining some connected smooth submanifold in the extended manifold $\{M, \rho\}$. At the same time, several continuous functions PF can exist in which different FPHs correspond to one ρ. In particular, for a given ρ, photon and antiphoton FPHs ((un)stable photon surface[25]) can occur simultaneously, indicating the instability of the solution.[8]

Definition 4.2. The fundamental photon region is the complete image of the function PF

$$PR = \bigcup_{\rho} PF. \tag{32}$$

A fundamental photon region is a standard region in the space M in which there are fundamental photon orbits and, in particular, the classical photon region in the Kerr metric. However, the mapping PF can several times cover the image of PR or part of it when the parameter ρ is continuously changed. For example, in the case of a static space, PR is covered at least two times, i.e. PF is a two-sheeted function.

The photon region can also be described using an algebraic equation.[20] To do this, rewrite the equations and the inequality (25) as

$$\mathcal{M}_{tt}\rho^2 + 2\mathcal{M}_{t\varphi}\rho + \mathcal{M}_{\varphi\varphi} = 0, \tag{33}$$

$$\mathcal{G}_{tt}\rho^2 + 2\mathcal{G}_{t\varphi}\rho + \mathcal{G}_{\varphi\varphi} \geq 0. \tag{34}$$

Then, excluding ρ, we find

$$2(-\mathcal{M}_{t\varphi} \pm \sqrt{\mathcal{M}_{t\varphi}^2 - \mathcal{M}_{tt}\mathcal{M}_{\varphi\varphi}})(\mathcal{G}_{t\varphi} - \mathcal{G}_{tt}\mathcal{M}_{t\varphi}/\mathcal{M}_{tt})/\mathcal{M}_{tt} + (\mathcal{G}_{\varphi\varphi} - \mathcal{G}_{tt}\mathcal{M}_{\varphi\varphi}/\mathcal{M}_{tt}) \geq 0, \tag{35}$$

or

$$\pm 2(\mathcal{G}_{t\varphi}\mathcal{M}_{tt} - \mathcal{G}_{tt}\mathcal{M}_{t\varphi})\sqrt{-\mathcal{M}} - 2\mathcal{G}_{tt} \cdot \mathcal{M} + \mathcal{M}_{tt} \cdot \mathcal{G} \cdot \mathrm{Tr}(\mathcal{M}) > 0. \tag{36}$$

These inequality describe a generalized photon region.

5. Conclusion

In this article, we briefly presented a purely geometric approach to defining characteristic surfaces and regions filled with closed photon orbits, based on some generalization of umbilic hypersurfaces. The main new concept is a *partially* umbilic surface, which has umbilic properties with respect to a correctly defined subbundle of the tangent bundle. This approach does not address the integration of geodesic equations, and thus is applicable to spacestimes with a non-integrable geodesic structure.

We tried to give a more clear and concise idea of the main geometric notions presented in,[1] supplementing them with a number of new useful expressions and relations, which, in particular, turned out to be useful for analyzing their connection with Killing tensor fields.[20] We hope that this formalism will pave the way for obtaining new topological constraints, Penrose-type inequalities (and other estimates),[26–28] uniqueness theorems,[23,29–33] similar to ones known for photon spheres and transversally trapping surfaces.[34,35]

Gravitational lensing by charged accelerating black holes

Torben C. Frost

ZARM, University of Bremen, 28359 Bremen, Germany and Institute for Theoretical Physics, Leibniz University Hannover, 30167 Hannover, Germany
E-mail: torben.frost@zarm.uni-bremen.de

Current astrophysical observations show that on large scale the Universe is electrically neutral. However, locally this may be quite different. Black holes enveloped by a plasma in the presence of a strong magnetic field may have acquired a significant electric charge. We can also expect that some of these charged black holes are moving. Consequently to describe them we need spacetime metrics describing moving black holes. In general relativity such a solution is given by the charged C-de Sitter-metric. In this article we will assume that it can be used to describe moving charged black holes. We will investigate how to observe the electric charge using gravitational lensing. First we will use elliptic integrals and functions to solve the geodesic equations. Then we will derive lens equation, travel time and redshift. We will discuss the impact of the electric charge on these observables and potential limitations for its observation.

Keywords: Black Holes; Gravitational Lensing

1. Introduction

X-ray and gravitational wave observations indicate that stellar mass black holes are widely distributed in our galaxy.[1,2] In addition, the motion of gas and stars[3,4] around galactic centres as well as the recent observation of the shadow of the compact object in the centre of the galaxy M87[5] indicate that in the centre of most galaxies we can find at least one supermassive black hole (SMBH). While the resolution of these observations are not yet precise enough to exclude all alternative theories of gravity or different types of compact objects all observational features indicate that these compact objects can be described either by the Schwarzschild metric or the Kerr metric.

Concurrent astrophysical observations show that our Universe is electrically neutral. This indicates that all astrophysical objects, among them black holes, do not carry a significant electric charge. However, if a black hole is surrounded by a plasma with sufficiently large magnetic fields, the black hole may acquire a significant electric charge.[6] In general relativity charged black holes that are at rest and do not carry a spin are described by the Reissner-Nordström metric, or, if we want to take the cosmological expansion into account, by the Reissner-Nordström-de Sitter metric. In the case that we consider real astrophysical environments it is very unlikely that black holes are at rest. Instead it is more realistic to assume that they constantly undergo accelerated motion. Consequently we need spacetimes describing accelerating black holes to describe them accurately. In the framework of general relativity a family of such solutions is described by the charged C-de Sitter metric.[7]

The metric is an exact solution to Einstein's electrovacuum field equations with cosmological constant. It generalises the Reissner-Nordström-de Sitter metric by introducing the acceleration parameter α in addition to the mass parameter m, the electric charge e and the cosmological constant Λ. The charged C-de Sitter metric is axisymmetric and static and describes a charged accelerating black hole with cosmological constant. The acceleration of the black hole results from conical singularities on the axes, which are commonly interpreted as a string pulling the black hole and a strut pushing the black hole. These conical singularities make the spacetime on a first view appear unphysical. However, it may still serve as an approximation for black holes undergoing accelerated motion. Gravitational lensing in the C-metric only attracted attention relatively recently. Grenzebach, Perlick and Lämmerzahl[8,9] investigated the shadow of accelerating black holes in the whole Plebański-Demiański family with acceleration.[10] Sharif and Iftikhar[11] calculated the deflection angle for light rays in the equatorial plane for accelerating Kerr-NUT black holes. The method they used explicitly assumes that the light rays are located in the equatorial plane of the spacetime. However, Alrais Alawadi, Batic and Nowakowski[12] and subsequently Frost and Perlick[13] demonstrated that the C-metric possesses a photon cone $\vartheta_{\mathrm{ph}} \neq \pi/2$ and therefore the method of Sharif and Iftikhar cannot be directly applied. Alrais Alawadi, Batic and Nowakowski[12] calculated the deflection angle on the photon cone. Only a short time later Frost and Perlick[13] investigated gravitational lensing in the C-metric. In their work Frost and Perlick[13] used the canonical form of the elliptic integrals and Jacobi's elliptic functions to solve the geodesic equations. Then, following the apporach of Grenzebach, Perlick and Lämmerzahl,[8] they fixed an observer in the region of outer communication and introduced an orthonormal tetrad to relate latitude and longitude on the observer's celestial sphere to the constants of motion of the light rays. Using the conventions in Bohn et al.[14] they formulated a lens equation, they derived the redshift and the travel time of individual light rays on the celestial sphere of the observer. In this article we will extend their approach to the charged C-de Sitter metric. For this purpose the remainder of this article is structured as follows. As not all readers may be familiar with the charged C-de Sitter metric we will provide a short overview of its physical properties in Section 2. In Section 3 we will demonstrate how to solve the equations of motion. In Section 4 we will first introduce the orthonormal tetrad and show how to parameterise the light rays using the angles on the observer's celestial sphere. Then we will introduce the lens map, formulate the lens equation, and calculate the redshift and the travel time of light rays. In Section 5 we will shortly summarise our results and conclusions. Throughout the whole article we will use geometric units with $c = G = 1$. The metric signature is chosen as $(-,+,+,+)$.

2. The Charged C-de Sitter-Metric

The charged C-de Sitter metric is a solution to Einstein's electrovacuum field equations with cosmological constant. It belongs to the Plebański-Demiański family of

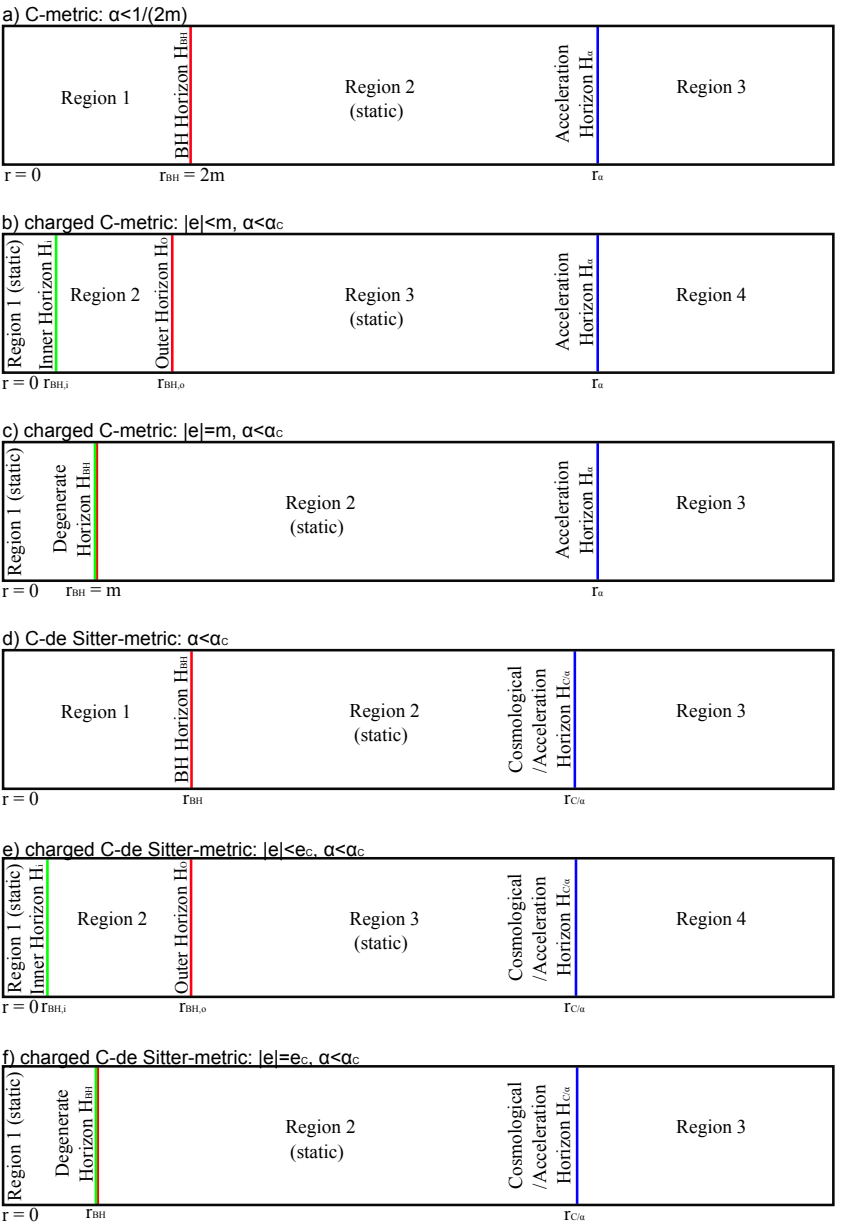

Fig. 1. Position of the curvature singularity at $r = 0$ and the coordinate singularities in a) the C-metric, the charged C-metric with b) $|e| < m$ and c) $|e| = m$, d) the C-de Sitter metric and the charged C-de Sitter metric with e) $|e| < e_{\rm C}$ and f) $|e| = e_{\rm C}$. Note that the angular coordinates are suppressed and other singularities are not shown.

spacetimes of Petrov type D[10] and is axisymmetric and static. The spacetime is characterised by four parameters: the mass parameter m, the electric charge e, the cosmological constant Λ, and the acceleration parameter α. Its line element reads[7]

$$g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu = \frac{1}{\Omega(r,\vartheta)^2}\left(-Q(r)\mathrm{d}t^2 + \frac{\mathrm{d}r^2}{Q(r)} + \frac{r^2\mathrm{d}\vartheta^2}{P(\vartheta)} + r^2\sin^2\vartheta P(\vartheta)\mathrm{d}\varphi^2\right), \quad (1)$$

where

$$Q(r) = (1-\alpha^2r^2)\left(1 - \frac{2m}{r} + \frac{e^2}{r^2}\right) - \frac{\Lambda}{3}r^2, \quad (2)$$

$$P(\vartheta) = 1 - 2\alpha m\cos\vartheta + \alpha^2e^2\cos^2\vartheta, \quad (3)$$

$$\Omega(r,\vartheta) = 1 - \alpha r\cos\vartheta. \quad (4)$$

When we set $\alpha = 0$ the metric reduces to the Reissner-Nordström-de Sitter family of spacetimes including the Schwarzschild metric ($e = 0$, $\Lambda = 0$), the Reissner-Nordström metric ($\Lambda = 0$), and the Schwarzschild-de Sitter metric ($e = 0$). For $e = 0$ and $\Lambda = 0$ the metric reduces to the regular C-metric. For $e = 0$ it reduces to the C-de Sitter metric and for $\Lambda = 0$ it reduces to the charged C-metric. In accordance with observations we choose $0 < m$. Theoretically the electric charge e can take any real value but because the line element (1) only contains its square we restrict it such that we have $0 \leq e \leq e_\mathrm{C}$. Because we live in an expanding Universe we will assume that $0 \leq \Lambda < \Lambda_\mathrm{C}$. α can be restricted from the symmetry of the spacetime. When we replace α by $-\alpha$ and substitute $\vartheta \to \pi - \vartheta$ we see that (1) is invariant and consequently we can restrict the acceleration parameter to $0 < \alpha < \alpha_\mathrm{C}$. Here, e_C, Λ_C and α_C are critical parameters that have to be chosen according to the desired interpretation of the spacetime. In the charged C-de Sitter metric the time coordinate t can assume any real value. In addition we choose the angular coordinates ϑ and φ such that they represent the angular coordinates on the two sphere S^2. The range of the r coordinate is determined by the singularity structure of the spacetime, in particular the singularities arising from $Q(r)$ and $\Omega(r,\vartheta)$. We will discuss these singularities and their implications for the r coordinate in the following. The spacetime admits several singularities. We start by discussing the singularities arising from $Q(r)$. In total $Q(r)$ can lead to up to five singularities in the metric. The equation $Q(r) = 0$ can lead to up to four singularities. In addition the metric has another singularity at $r = 0$. The singularity at $r = 0$ is a curvature singularity. For $e \neq 0$ the curvature singularity is timelike. Because lightlike and timelike geodesics cannot cross the curvature singularity particle motion is limited to $0 < r$. In addition the conformal factor becomes singular when $\Omega(r,\vartheta) = 0$. This singularity corresponds to conformal infinity and limits the radius coordinate r. The singularity starts at $r = 1/\alpha$ on the axis $\vartheta = 0$ and extends to $r = \infty$ for $\pi/2 \leq \vartheta$. The other singularities are only coordinate singularities r_H that can be removed using appropriate coordinate transformations (for the C-metric the procedure is

demonstrated in Ref. 15). In this article we restrict to black hole spacetimes and consequently all coordinate singularities with $0 < r_{\rm H}$ are horizons. In general the horizon struture of each metric depends on the parameters of the spacetime. For each spacetime the critical parameters $e_{\rm C}$, $\Lambda_{\rm C}$ and $\alpha_{\rm C}$ have to be chosen such that all horizons are real and that they lead to physically meaningful black hole spacetimes. The horizon structure of the whole family of charged C-de Sitter metrics is shown in Fig. 1. Panel a) shows the horizon struture of the C-metric. The C-metric has two horizons, a black hole horizon at $r_{\rm BH} = 2m$ and an acceleration horizon at $r_{\rm BH} < r_\alpha = 1/\alpha$. Between the horizons the spacetime is static. In the other two regions the spacetime is non-static. Panels b) and c) show the horizon struture for the charged C-metric. The main difference to the C-metric is that the spacetime now contains an inner and an outer black hole horizon $r_{\rm BH,i} \leq r_{\rm BH,o} < r_\alpha$. When $e = m$ both horizons coincide and form a degenerate horizon at $r_{\rm BH} = m$. The regions $0 < r < r_{\rm BH,i}$ and $r_{\rm BH,o} < r < r_\alpha$ are static. The other two regions are non-static. When we include the cosmological constant Λ (panels d) to f)) the radius coordinates of the horizons change, however, the horizon structure remains unchanged. For a more detailed discussion of the horizon structure in the C-metric we refer the interested reader to Ref. 13. In our case we always choose $e_{\rm C}$ such that $P(\vartheta)$ does not lead to singularities in the metric. Finally, the spacetime has two singularities on the axes at $\sin\vartheta = 0$. As demonstrated in Refs. 7 and 15 these singularities are conical singularites. They are associated with a deficit angle ($\vartheta = 0$) and a surplus angle ($\vartheta = \pi$). The charged C-de Sitter metric is usually interpreted such that it describes a charged accelerating black hole with cosmological constant. In its full analytic extension the spacetime describes two causally separated charged black holes accalerating away from each other. The conical singularity at $\vartheta = 0$ is commonly interpreted as a string pulling the black hole, while the conical singularity at $\vartheta = \pi$ is interpreted as a strut pushing the black hole. As demonstrated in Refs. 7 and 15 one of the conical singularities can always be removed, however, as in our previous work[13] here we will retain both singularities to show the effects of both, the string and the strut on geodesic motion.

3. Equations of Motion

In the charged C-de Sitter metric the equations of motion for light rays are fully separable. In Mino parameterisation[16] they read[8,13]

$$\frac{\mathrm{d}t}{\mathrm{d}\lambda} = \frac{r^2 E}{Q(r)}, \tag{5}$$

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\lambda}\right)^2 = E^2 r^4 - r^2 Q(r) K, \tag{6}$$

$$\left(\frac{\mathrm{d}\vartheta}{\mathrm{d}\lambda}\right)^2 = P(\vartheta) K - \frac{L_z^2}{\sin^2\vartheta}, \tag{7}$$

$$\frac{\mathrm{d}\varphi}{\mathrm{d}\lambda} = \frac{L_z}{\sin^2\vartheta P(\vartheta)}, \tag{8}$$

where the Mino parameter λ is related to the affine parameter s by

$$\frac{\mathrm{d}\lambda}{\mathrm{d}s} = \frac{\Omega(r,\vartheta)^2}{r^2}. \tag{9}$$

Here, the three constants of motion E, L_z and K are the energy, the angular momentum about the z axis and the Carter constant of the light ray, respectively. In this article we choose the energy E such that $\mathrm{d}t/\mathrm{d}\lambda > 0$. In the following we will briefly discuss the equations of motion, the turning points of the r and the ϑ motion and identify the locations of the photon sphere and the photon cone. Then we will turn to solving the equations of motion. We will derive the solutions to the equations of motion for arbitrary initial conditions $(x_i^\mu) = (x^\mu(\lambda_i)) = (t_i, r_i, \vartheta_i, \varphi_i)$ closely following the procedures described in Refs. 13 and 17. Because the main focus of this article will be to apply our results to gravitational lensing we will limit our discussion to lightlike geodesics in the region of outer communication between photon sphere and the cosmological/acceleration horizon.

3.1. *The r Motion*

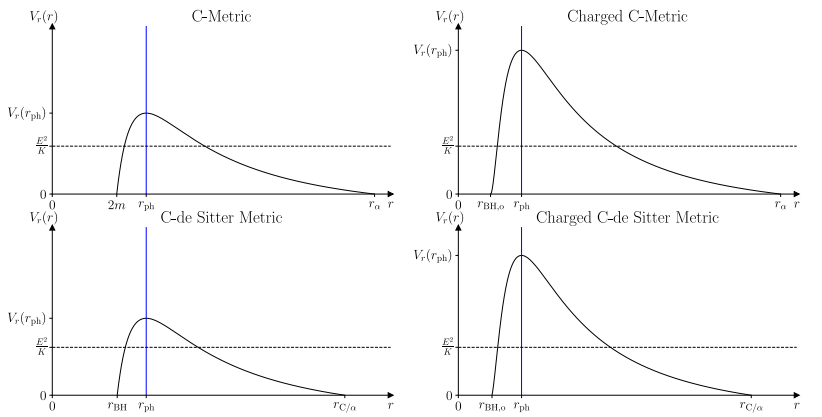

Fig. 2. Potential $V_r(r)$ of the r motion in the C-metric (top left), the charged C-metric (top right), the C-de Sitter metric (bottom left) and the charged C-de Sitter metric (bottom right) for $\Lambda = 1/(200m^2)$, $e = m$, and $\alpha = 1/(10m)$. The axes have the same scale in all four plots.

We begin with discussing the r motion. Following Ref. 13 we first rewrite (6) in terms of the potential $V_r(r)$

$$\frac{1}{r^4 K}\left(\frac{\mathrm{d}r}{\mathrm{d}\lambda}\right)^2 + V_r(r) = \frac{E^2}{K}, \tag{10}$$

where

$$V_r(r) = \left(\frac{1}{r^2} - \alpha^2\right)\left(1 - \frac{2m}{r} + \frac{e^2}{r^2}\right) - \frac{\Lambda}{3}. \tag{11}$$

Fig. 2 shows the potentials for the C-metric (top left), the charged C-metric (top right), the C-de Sitter metric (bottom left) and the charged C-de Sitter metric (bottom right). For all four metrics the potential has a similar structure. The most striking difference occurs close to the (outer) black hole horizon. For $e \neq 0$ the maximum of $V_r(r)$ is much higher than in the uncharged case. In addition for $\Lambda > 0$ $V_r(r)$ approaches zero at a smaller radius coordinate $r_{\mathrm{C}/\alpha} < r_\alpha$. The maximum of the potential at $E^2/K = V_r(r_{\mathrm{ph}})$ marks the radius coordinate of an unstable photon sphere. We can calculate the radius coordinate of the photon sphere by calculating $\mathrm{d}r/\mathrm{d}\lambda = \mathrm{d}^2r/\mathrm{d}\lambda^2 = 0$. Combining both conditions leads to the determining equation

$$r^3 + \frac{1 - \alpha^2 e^2}{m\alpha^2} r^2 - \frac{3}{\alpha^2} r + \frac{2e^2}{m\alpha^2} = 0 \tag{12}$$

for the radius of the photon sphere r_{ph}. It is remarkable that although the spherical symmetry is broken by the acceleration parameter the cosmological constant does not have any effect on the radius coordinate of the photon sphere. The roots of this equation can be analytically obtained using Cardano's method. As long as $e^2 < 1/\alpha^2$ we get three real solutions. Only the largest root lies in the region of outer communication $r_{\mathrm{BH,o}} < r < r_{\mathrm{C}/\alpha}$ and thus marks the position of the photon sphere. When $e = 0$ the polynomial reduces to second order and r_{ph} is given by[12,13]

$$r_{\mathrm{ph}} = \frac{6m}{1 + \sqrt{1 + 12\alpha^2 m^2}}. \tag{13}$$

We can read from Fig. 2 that at r_{ph} $V_r(r_{\mathrm{ph}})$ has always a maximum and thus orbits of geodesics on the photon sphere are unstable. Here, unstable means that if the orbit of a lightlike geodesic on the photon sphere was radially infinitessimally perturbed the light ray would either fall into the black hole or escape to (conformal) infinity. Using the potential we can distinguish three different types of lightlike motion. For $E^2/K > V_r(r_{\mathrm{ph}})$ lightlike geodesics have no turning points. Here we have to distinguish between the cases $K = 0$ (we will see in Section 3.3 that these geodesics are principal null geodesics) and $K > 0$. For $E^2/K > V_r(r_{\mathrm{ph}})$ and $K = 0$ (6) was already solved in Ref. 13. In this case the solution reads:

$$r(\lambda) = \frac{r_i}{1 - i_{r_i} r_i E\,(\lambda - \lambda_i)}, \tag{14}$$

where $i_{r_i} = \operatorname{sgn}\left(\mathrm{d}r/\mathrm{d}\lambda|_{r=r_i}\right)$. In the case $E^2/K > V_r(r_{\mathrm{ph}})$ and $K > 0$ (6) has two real and two complex conjugated roots. We label them such that $r_1 > r_2$ and $r_3 = \bar{r}_4 = R_3 + iR_4$. To solve (6) we now substitute[17,18]

$$r = \frac{r_1\bar{R} - r_2 R + (r_1\bar{R} + r_2 R)\cos\chi_r}{\bar{R} - R + (\bar{R} + R)\cos\chi_r}, \tag{15}$$

where

$$R = \sqrt{(R_3 - r_1)^2 + R_4^2} \quad \text{and} \quad \bar{R} = \sqrt{(R_3 - r_2)^2 + R_4^2}. \tag{16}$$

Then we follow the steps described in Appendix B of Ref. 13 and obtain the solution in terms of Jacobi's elliptic cn function. It reads

$$r(\lambda) = \frac{r_1\bar{R} - r_2 R + (r_1\bar{R} + r_2 R)\mathrm{cn}\left(a_r\left(\lambda - \lambda_i\right) + \lambda_{r_i,k_1}, k_1\right)}{\bar{R} - R + (\bar{R} + R)\mathrm{cn}\left(a_r\left(\lambda - \lambda_i\right) + \lambda_{r_i,k_1}, k_1\right)}, \tag{17}$$

where

$$a_r = i_{r_i}\sqrt{\left(E^2 + \left(\alpha^2 + \frac{\Lambda}{3}\right)K\right)R\bar{R}}, \qquad \lambda_{r_i,k_1} = F_L(\chi_{r_i}, k_1), \tag{18}$$

$$\chi_{r_i} = \arccos\left(\frac{(r_i - r_2)R - (r_i - r_1)\bar{R}}{(r_i - r_2)R + (r_i - r_1)\bar{R}}\right), \; k_1 = \frac{(R + \bar{R})^2 - (r_1 - r_2)^2}{4R\bar{R}}.$$

The condition $E^2/K = V_r(r_{\mathrm{ph}})$ characterises lightlike geodesics asymptotically coming from or going to the photon sphere. In this case (6) has four real roots, two of which are equal. We label them such that $r_1 = r_2 = r_{\mathrm{ph}} > r_3 > r_4$. In this case we substitute

$$r = r_3 + \frac{3a_{3,r}}{12y - a_{2,r}}, \tag{19}$$

where

$$a_{2,r} = 6\left(E^2 + \left(\alpha^2 + \frac{\Lambda}{3}\right)K\right)r_3^2 - 6m\alpha^2 K r_3 - (1 - \alpha^2 e^2)K, \tag{20}$$

$$a_{3,r} = 4\left(E^2 + \left(\alpha^2 + \frac{\Lambda}{3}\right)K\right)r_3^3 - 6m\alpha^2 K r_3^2 - 2(1 - \alpha^2 e^2)K r_3 + 2mK. \tag{21}$$

Then we follow the steps described in Section 3.2.3 in Ref. 13 and obtain as solution for $r(\lambda)$:

$$r(\lambda) = r_3 - \frac{(r_{\mathrm{ph}} - r_3)(r_3 - r_4)}{r_{\mathrm{ph}} - r_3 - (r_{\mathrm{ph}} - r_4)\tanh^2\left(b_r + i_{r_i}\sqrt{\frac{a_{3,r}(r_{\mathrm{ph}} - r_4)}{4(r_{\mathrm{ph}} - r_3)(r_3 - r_4)}}(\lambda_i - \lambda)\right)}, \tag{22}$$

where

$$b_r = \mathrm{artanh}\left(\sqrt{\frac{(r_i - r_4)(r_{\mathrm{ph}} - r_3)}{(r_i - r_3)(r_{\mathrm{ph}} - r_4)}}\right). \tag{23}$$

All remaining lightlike geodesics have $E^2/K < V_r(r_{\mathrm{ph}})$. These geodesics have four real roots and can pass through a turning point. Outside the photon sphere this turning point is always a minimum. For solving (6) we now label the roots such that $r_1 = r_{\mathrm{min}} > r_2 > r_3 > r_4$. Then we substitute[17,18]

$$r = r_2 + \frac{(r_1 - r_2)(r_2 - r_4)}{r_2 - r_4 - (r_1 - r_4)\sin^2\chi_r}. \tag{24}$$

Again we apply the steps described in Appendix B of Ref. 13. This time we obtain the solution to (6) in terms of Jacobi's elliptic sn function

$$r(\lambda) = r_2 + \frac{(r_1 - r_2)(r_2 - r_4)}{r_2 - r_4 - (r_1 - r_4)\mathrm{sn}^2\left(c_r\left(\lambda - \lambda_i\right) + \lambda_{r_i,k_2}, k_2\right)}, \tag{25}$$

where

$$c_r = \frac{i_{r_i}}{2}\sqrt{\left(E^2 + \left(\alpha^2 + \frac{\Lambda}{3}\right)K\right)(r_1 - r_3)(r_2 - r_4)}, \quad \lambda_{r_i,k_2} = F_L(\chi_{r_i}, k_2), \tag{26}$$

$$\chi_{r_i} = \arcsin\left(\sqrt{\frac{(r_i - r_1)(r_2 - r_4)}{(r_i - r_2)(r_1 - r_4)}}\right), k_2 = \frac{(r_2 - r_3)(r_1 - r_4)}{(r_1 - r_3)(r_2 - r_4)}.$$

3.2. *The t Coordinate*

Now we calculate the time coordinate t. The right-hand side of (5) depends only on $r(\lambda)$. Therefore, we first rewrite (5) as a differential of r. For this purpose we divide (5) by the root of (6). Then we integrate over r starting at $t(\lambda_i) = t(r_i) = t_i$. The resulting integral reads

$$t(\lambda) = t_i + \int_{r_i\ldots}^{\ldots r(\lambda)} \frac{E r'^2 \mathrm{d}r'}{Q(r')\sqrt{E^2 r'^4 - r'^2 Q(r')K}}. \tag{27}$$

Here, we have to choose the sign of the root in accordance with the r motion and the dots in the limits of the integration indicate that we have to split the integral at the turning points. The procedure to integrate (27) is straight forward. We have to distinguish the same types of motion as for $r(\lambda)$ in Section 3.1. First we perform a partial fraction decomposition of $r'^2/Q(r')$. Then we follow the procedure described in Refs. 13 and 17 to express (27) in terms of elementary functions and elliptic integrals. Note that some of the elliptic integrals cannot immediately be expressed in form of elementary functions and elliptic integrals of first, second and third kind. However, we can easily rewrite them using the procedures described in Appendix B in Ref. 17 and Appendix A in Ref. 13.

3.3. *The ϑ Motion*

Again we start by rewriting (7) in terms of the potential $V_\vartheta(\vartheta)$

$$\frac{\sin^2\vartheta}{K}\left(\frac{\mathrm{d}\vartheta}{\mathrm{d}\lambda}\right)^2 + V_\vartheta(\vartheta) = -\frac{L_z^2}{K}, \tag{28}$$

where

$$V_\vartheta(\vartheta) = -\sin^2\vartheta(1 - 2\alpha m\cos\vartheta + \alpha^2 e^2\cos^2\vartheta). \tag{29}$$

Fig. 3 shows the potentials $V_\vartheta(\vartheta)$ of the ϑ motion for the C-(de Sitter) metric (left) and the charged C-(de Sitter) metric (right). Although in the right plot we set $e = m$ the differences are invisibly small. The potential has always a minimum at a

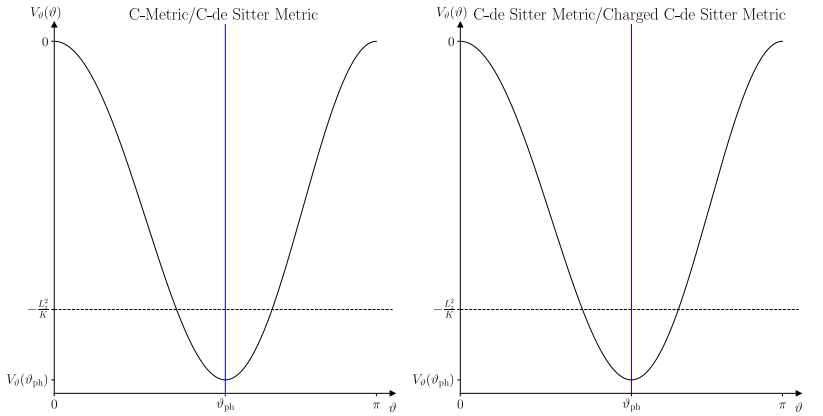

Fig. 3. Potential $V_\vartheta(\vartheta)$ of the ϑ motion in the C-metric/C-de Sitter metric (left) and the charged C-metric/C-de Sitter metric (right) for $e = m$ and $\alpha = 1/(10m)$. The axes have the same scale in both plots.

single value ϑ. At this minimum we have $\mathrm{d}\vartheta/\mathrm{d}\lambda = \mathrm{d}^2\vartheta/\mathrm{d}\lambda^2 = 0$. Combining both conditions leads to the determining equation

$$\cos^3\vartheta - \frac{3m}{2\alpha e^2}\cos^2\vartheta + \frac{1-\alpha^2e^2}{2\alpha^2e^2}\cos\vartheta + \frac{m}{2\alpha e^2} = 0. \tag{30}$$

We determine the roots of this equation using Cardano's method. Within the permissible range $0 \leq \vartheta \leq \pi$ the equation has exactly one real root $\vartheta_{\rm ph}$. This is the photon cone of the charged C-(de Sitter) metric. Note that we cannot determine the limits $e \to 0$ or $\alpha \to 0$ from the calculated $\vartheta_{\rm ph}$ directly. When we approach these limits we see that for $e \to 0$ $\vartheta_{\rm ph}$ reduces to[12, 13]

$$\vartheta_{\rm ph} = \arccos\left(\frac{-2\alpha m}{1+\sqrt{1+12\alpha^2m^2}}\right) \tag{31}$$

and for $\alpha \to 0$ it reduces to $\vartheta_{\rm ph} = \pi/2$. The photon cone is unstable. Here unstable means that when light rays on the photon cone are infinitessimally perturbed in ϑ direction they will begin to oscillate between a minimum $\vartheta_{\rm min}$ and a maximum $\vartheta_{\rm max}$. Based on the potential $V_\vartheta(\vartheta)$ we can distinguish two different types of motion. From (7) we can immediately read that we have $L_z = 0$ when $K = 0$ and the right-hand side of (7) vanishes. Because $L_z = 0$ implies $\mathrm{d}\varphi/\mathrm{d}\lambda = 0$ these are the already in Section 3.1 mentioned principal null geodesics. Also for lightlike geodesics on the photon cone ($-L_z^2/K = V_\vartheta(\vartheta_{\rm ph})$) the right-hand side of (7) vanishes because we have two coinciding roots at $x = \cos\vartheta_{\rm ph}$. Thus for principal null geodesics and lightlike geodesics on the photon cone the solution to (7) reads $\vartheta(\lambda) = \vartheta_i$. For all other lightlike geodesics we have $-L_z^2/K \neq V_\vartheta(\vartheta_{\rm ph})$. These geodesics oscillate between a minimum $\vartheta_{\rm min}$ and a maximum $\vartheta_{\rm max}$ and each geodesic can potentially have arbitrary many turning points. In this case we first rewrite (7) in terms of

$x = \cos\vartheta$. It is easy to see that in the new parameterisation (7) reduces to a polynomial of third order in x when $e = 0$. This case was already treated in Ref. 13 and thus we do not reproduce it here. For $e \neq 0$ we always have two turning points, however, depending on the choice of L_z and K the right-hand side of (7) has two different root structures. In the first case two of the roots are real. We label them such that $x_2 = \cos\vartheta_{\max} < x_1 = \cos\vartheta_{\min}$. The other two roots are complex conjugated and we label them as $x_3 = \bar{x}_4 = X_3 + iX_4$. As first step to solve (7) we now substitute[18]

$$x = \frac{x_1\bar{X} + x_2 X + (x_1\bar{X} - x_2 X)\cos\chi_\vartheta}{\bar{X} + X + (\bar{X} - X)\cos\chi_\vartheta}, \tag{32}$$

where X and $\bar{X}$ are given by (16). In the second step we again follow the steps described in Appendix B of Ref. 13. We obtain $\vartheta(\lambda)$ in terms of Jacobi's elliptic cn function. It reads

$$\vartheta(\lambda) = \arccos\left(\frac{x_1\bar{X} + x_2 X + (x_1\bar{X} - x_2 X)\mathrm{cn}\left(a_\vartheta\left(\lambda - \lambda_i\right) + \lambda_{\vartheta_i,k_3}, k_3\right)}{\bar{X} + X + (\bar{X} - X)\mathrm{cn}\left(a_\vartheta\left(\lambda - \lambda_i\right) + \lambda_{\vartheta_i,k_3}, k_3\right)}\right), \tag{33}$$

where $i_{\vartheta_i} = \mathrm{sgn}\left(\mathrm{d}\vartheta/\mathrm{d}\lambda|_{\vartheta=\vartheta_i}\right)$ and

$$a_\vartheta = i_{\vartheta_i}\sqrt{\alpha^2 e^2 K X\bar{X}}, \qquad \lambda_{\vartheta_i,k_3} = F_L(\chi_{\vartheta_i}, k_3), \tag{34}$$

$$\chi_{\vartheta_i} = \arccos\left(\frac{(\cos\vartheta_i - x_1)\bar{X} + (\cos\vartheta_i - x_2)X}{(x_1 - \cos\vartheta_i)\bar{X} + (\cos\vartheta_i - x_2)X}\right),\ k_3 = \frac{(x_1 - x_2)^2 - (X - \bar{X})^2}{4X\bar{X}}.$$

In the second case all four roots are real and we label them such that $x_4 = \cos\vartheta_{\max} < x_3 = \cos\vartheta_{\min} < x_2 < x_1$. In this case we substitute[18]

$$x = x_1 - \frac{(x_1 - x_3)(x_1 - x_4)}{x_1 - x_3 + (x_3 - x_4)\sin^2\chi_\vartheta}. \tag{35}$$

We again follow the steps described in Appendix B of Ref. 13. This time we obtain $\vartheta(\lambda)$ in terms of Jacobi's elliptic sn function

$$\vartheta(\lambda) = \arccos\left(x_1 - \frac{(x_1 - x_3)(x_1 - x_4)}{x_1 - x_3 + (x_3 - x_4)\mathrm{sn}^2\left(b_\vartheta\left(\lambda_i - \lambda\right) + \lambda_{\vartheta_i,k_4}, k_4\right)}\right), \tag{36}$$

where

$$b_\vartheta = \frac{i_{\vartheta_i}}{2}\sqrt{\alpha^2 e^2 K(x_1 - x_3)(x_2 - x_4)}, \qquad \lambda_{\vartheta_i,k_4} = F_L(\chi_{\vartheta_i}, k_4) \tag{37}$$

$$\chi_{\vartheta_i} = \arcsin\left(\sqrt{\frac{(\cos\vartheta_i - x_4)(x_1 - x_3)}{(x_1 - \cos\vartheta_i)(x_3 - x_4)}}\right),\ k_4 = \frac{(x_1 - x_2)(x_3 - x_4)}{(x_1 - x_3)(x_2 - x_4)}.$$

3.4. *The φ Motion*

The φ motion is governed by (8). We immediately read that for $L_z = 0$ the right-hand side vanishes. For $K = 0$ these are the principal null geodesics. In this case we obtain the solution to (8) as $\varphi(\lambda) = \varphi_i$. If $K \neq 0$ these are geodesics crossing the axes. What happens to these geodesics now depends on whether we assume that

the string and the strut are opaque or transparent. In the former case the lightlike geodesics terminate at the string and we observe it as a black line blocking out all light emitted by sources located behind it. In the latter case the lightlike geodesics pass through the string. To see what happens when a lightlike geodesic passes through the axes we consider a series of lightlike geodesics continually approaching the axes for $L_z > 0$ and $L_z < 0$.[13] We observe that for $L_z > 0$ and $L_z < 0$ the φ coordinate has different limits. Hence geodesics crossing the axes have two different continuations and the φ coordinate is not continuous.

Next we turn to lightlike geodesics with a double root at $x = \cos\vartheta_{\mathrm{ph}}$ ($-L_z^2/K = V_\vartheta(\vartheta_{\mathrm{ph}})$). These are lightlike geodesics on the photon cone with $\vartheta(\lambda) = \vartheta_{\mathrm{ph}}$. In this case the right-hand side of (8) is constant and the solution $\varphi(\lambda)$ reads

$$\varphi(\lambda) = \varphi_i + \frac{L_z(\lambda - \lambda_i)}{\sin^2\vartheta_{\mathrm{ph}} P(\vartheta_{\mathrm{ph}})}. \tag{38}$$

Last we turn to lightlike geodesics with $-L_z^2/K \neq V_\vartheta(\vartheta_{\mathrm{ph}})$. In this case we want to express $\varphi(\lambda)$ in terms of elementary functions and elliptic integrals. For this purpose we first substitute $x = \cos\vartheta$ in (7) and (8). Then we divide (8) by the root of (7) and integrate. Now $\varphi(\lambda)$ reads

$$\varphi(\lambda) = \varphi_i + \int_{\cos\vartheta_i \ldots}^{\ldots \cos\vartheta(\lambda)} \frac{L_z \mathrm{d}x'}{(1-x'^2)P(x')\sqrt{(1-x'^2)P(x')K - L_z^2}}. \tag{39}$$

Here, we have to choose the sign of the root such that it corresponds to the sign of the $\cos\vartheta$ motion and the dots in the limits indicate that we have to split the integral at the turning points. Again we rewrite the elliptic integral using elementary functions and the canonical forms of the elliptic integrals. For this purpose we now perform a partial fracion decomposition of $(1-x^2)^{-1}P(x)^{-1}$. Then we use (41) in Ref. 13 and (32) and (35) to rewrite (39) in terms of elementary functions and elliptic integrals of first, second and third kind. Note that we again encounter elliptic integrals which do not immediately have a canonical form. Again we rewrite them using the procedures described in Appendix B in Ref. 17 and Appendix A in Ref. 13 (although here we have $n^2/(n^2-1) < 1$ and not $1 < n^2/(n^2-1)$ the basic integration procedure is the same).

4. Gravitational Lensing

4.1. *Celestial Sphere*

In astronomy the position of a light source on the sky is identified using latitude and longitude coordinates. For this purpose astronomers fix the main target of their observation at the centre of their image and measure the position of all other objects relative to the centre. In our discussion of gravitational lensing in the charged C-de Sitter metric we follow this approach. For this purpose we first fix an observer at coordinates $(x^\mu_O) = (t_O, r_O, \vartheta_O, \varphi_O)$ in the region of outer communication between photon sphere and cosmological/acceleration horizon. Then we choose the black hole

as main target of our observation and introduce an orthonormal tetrad following Refs. 8 and 13:

$$e_0 = \frac{\Omega(r,\vartheta)}{\sqrt{Q(r)}}\partial_t\Big|_{(x^\mu_O)}, \quad e_1 = \frac{\Omega(r,\vartheta)\sqrt{P(\vartheta)}}{r}\partial_\vartheta\Big|_{(x^\mu_O)}, \tag{40}$$

$$e_2 = -\frac{\Omega(r,\vartheta)}{r\sin\vartheta\sqrt{P(\vartheta)}}\partial_\varphi\Big|_{(x^\mu_O)}, \quad e_3 = -\Omega(r,\vartheta)\sqrt{Q(r)}\partial_r\Big|_{(x^\mu_O)}.$$

We will call the angles on the celestial sphere surrounding the observer Σ (latitude) and Ψ (longitude). The angle Σ is measured from the axis along e_3 connecting lens and observer and the angle Ψ is measured in the direction of e_2 from the axis along the direction of e_1.

Before we can investigate gravitational lensing in the charged C-de Sitter metric we first have to derive the relations between the constants of motion E, L_z and K and the angles on the observer's celestial sphere Σ and Ψ. For this purpose we consider a lightlike geodesic ending at the position of the observer. Now we first write down the tangent vector to this geodesic. It reads

$$\frac{\mathrm{d}\eta}{\mathrm{d}\lambda} = \frac{\mathrm{d}t}{\mathrm{d}\lambda}\partial_t + \frac{\mathrm{d}r}{\mathrm{d}\lambda}\partial_r + \frac{\mathrm{d}\vartheta}{\mathrm{d}\lambda}\partial_\vartheta + \frac{\mathrm{d}\varphi}{\mathrm{d}\lambda}\partial_\varphi. \tag{41}$$

At the position of the observer we can also express the tangent vector of the geodesic by the angles on the observer's celestial sphere and the tetrad vectors e_0, e_1, e_2 and e_3

$$\frac{\mathrm{d}\eta}{\mathrm{d}\lambda} = \sigma\left(-e_0 + \sin\Sigma\cos\Psi e_1 + \sin\Sigma\sin\Psi e_2 + \cos\Sigma e_3\right), \tag{42}$$

where σ is a normalisation constant

$$\sigma = g\left(\frac{\mathrm{d}\eta}{\mathrm{d}\lambda}, e_0\right). \tag{43}$$

In our convention we have $E > 0$ and thus σ has to be negative. Because the Mino parameter λ is defined up to an affine transformation without loss of generality we can choose $\sigma = -r_O^2/\Omega(r_O,\vartheta_O)^2$.[13] Now we insert σ in (42) and (43). Then a comparison of the coefficients of (41) and (42) leads to[13]

$$E = \frac{\sqrt{Q(r_O)}}{\Omega(r_O,\vartheta_O)},\ L_z = \frac{r_O\sqrt{P(\vartheta_O)}\sin\vartheta_O\sin\Sigma\sin\Psi}{\Omega(r_O,\vartheta_O)},\ K = \frac{r_O^2\sin^2\Sigma}{\Omega(r_O,\vartheta_O)^2}. \tag{44}$$

4.2. *Angular Radius of the Photon Sphere*

The shadow of a black hole is a higly idealised concept. It is constructed as follows. First we place an observer in the region of outer communication between photon sphere and cosmological/acceleration horizon. Then we distribute light sources everywhere except between observer and the black hole. Therefore the former region is associated with brightness on the observer's sky while the latter is associated with

darkness. Now we shoot back light rays exactly on the boundary between these areas of brightness and darkness. These are geodesics asymptotically going to the photon sphere. They have the same constants of motion as light rays on the photon sphere and thus a double root at r_{ph}. We now use this fact to calculate the angular radius of the shadow. For this purpose we first insert (44) in (6). Then we employ that $\mathrm{d}r/\mathrm{d}\lambda|_{r=r_{\mathrm{ph}}} = 0$. Now we solve for Σ and get as angular radius of the shadow[13]

$$\Sigma_{\mathrm{ph}} = \arcsin\left(\frac{r_{\mathrm{ph}}}{r_O}\sqrt{\frac{Q(r_O)}{Q(r_{\mathrm{ph}})}}\right). \tag{45}$$

4.3. *Lens Map*

The lens map or lens equation maps images on the observer's sky back to the source surface. This article is an extension of the work presented in Ref. 13 and therefore we will closely follow their definition of the lens map. To set up the lens map we first distribute light sources on a sphere with radius $r_O < r_L$ in the region of outer communication. Then we shoot light rays backwards in time from the position of the observer (x^μ_O). Some of the light rays, but not all, will intersect with the sphere of light sources. These geodesics form a map from the celestial sphere of the observer to the sphere of light sources

$$(\Sigma, \Psi) \to (\vartheta_L(\Sigma, \Psi), \varphi_L(\Sigma, \Psi)). \tag{46}$$

This is our lens equation. Now we have to calculate $\vartheta_L(\Sigma, \Psi)$ and $\varphi_L(\Sigma, \Psi)$ to obtain the lens map for the charged C-de Sitter metric. For this purpose we set $(x^\mu_i) = (x^\mu_O)$ and insert (44) into the solutions of the equations of motion derived in Section 3. Due to the symmetry of the charged C-de Sitter metric we can choose t_O and φ_O arbitrarily. Similarly λ is only defined up to an affine transformation. Therefore, to ease all following calculations we choose them such that $\lambda_O = 0$, $t_O = 0$ and $\varphi_O = 0$.

As first step towards calculating $\vartheta_L(\Sigma, \Psi)$ and $\varphi_L(\Sigma, \Psi)$ we calculate the Mino parameter $\lambda_L < \lambda_O$

$$\lambda_L = \int_{r_O \cdots}^{\cdots r_L} \frac{\Omega(r_O, \vartheta_O)\mathrm{d}r'}{\sqrt{Q(r_O)r'^4 - r_O^2 \sin^2 \Sigma r'^2 Q(r')}}. \tag{47}$$

Again for lightlike geodesics passing through a turning point we have to split the integral and choose the sign of the root in the denominator in agreement with the r motion. Now we insert λ_L in the appropriate solution for $\vartheta(\lambda)$ in Section 3.3 and obtain $\vartheta_L(\Sigma, \Psi)$. Next we count the number of turning points n of the ϑ motion. For this purpose we calculate the Mino parameter up to the first turning point of the ϑ motion λ_0. In the next step we calculate the difference of the Mino parameter between two subsequent turning points of the ϑ motion $\Delta\lambda$. Now we count how many turning points occur while $\lambda_L < \lambda_n = \lambda_0 + n\Delta\lambda$. Finally we calculate $\varphi_L(\Sigma, \Psi)$ from (39) as described in Section 3.4.

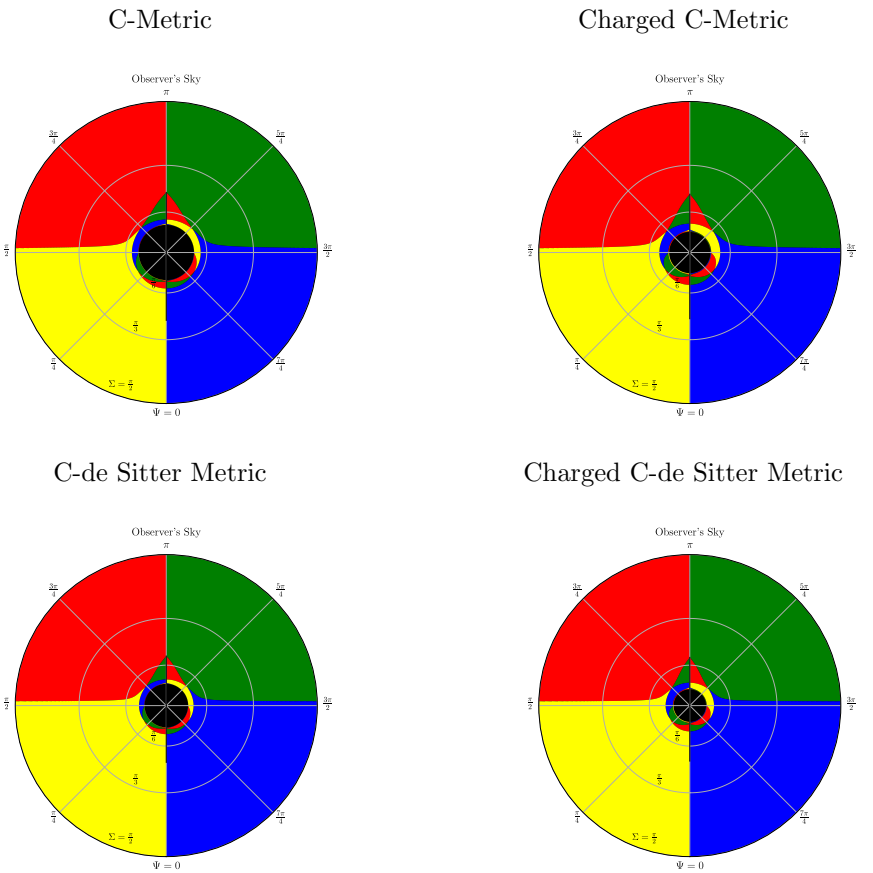

Fig. 4. Lens equation for the C-metric[13] (top left), the charged C-metric (top right), the C-de Sitter metric (bottom left) and the charged C-de Sitter metric (bottom right) for $\Lambda = 1/(200m^2)$, $e = m$ and $\alpha = 1/(10m)$. The observer is located at $r_O = 8m$, $\vartheta_O = \pi/2$ and the sphere of light sources is located at $r_L = 9m$. The colour convention follows Refs. 13 and 14 and is as follows: $0 \leq \vartheta_L \leq \frac{\pi}{2}$: red/green; $\frac{\pi}{2} < \vartheta_L \leq \pi$: yellow/blue $0 \leq \varphi_L < \pi$: green/blue; $\pi \leq \varphi_L < 2\pi$: red/yellow. The black lines at $\Psi = 0$ and $\Psi = \pi$ mark light rays that cross the axes at least once.

Fig. 4 shows plots of the lens equation in stereographic projection for the C-metric (top left), the charged C-metric (top right), the C-de Sitter metric (bottom left) and the charged C-de Sitter metric (bottom right) for $\Lambda = 1/(200m^2)$, $e = m$ and $\alpha = 1/(10m)$. The observer is located at $r_O = 8m$ and $\vartheta_O = \pi/2$. The sphere of light sources is located at $r_L = 9m$. The black lines at $\Psi = 0$ and $\Psi = \pi$ mark lightlike geodesics that cross the string or the strut at least once. The black circle in the centre of each image is the shadow of the black hole. The images clearly show that the angular radius Σ_{ph} of the shadow decreases when $0 < \Lambda$ and $0 < e$. All four images basically show the same features up to a scaling. The symmetry with respect to $\Psi = \pi/2$ and $\Psi = 3\pi/2$ is clearly broken. Thus in all four cases

light rays ending parallel to the surface $\vartheta = \pi/2$ generally come from light sources not located at $\vartheta = \pi/2$. However, the shape of the features shown in the images is clearly symmetric with respect to the line marked by $\Psi = 0$ and $\Psi = \pi$. On the right side of the line of symmetry at the outer boundary of each image we first have a region coloured in blue and green. In this region we find images where the covered angle $0 < \Delta\varphi < \pi$. These are images of first order. Adjacent to these images, closer to the shadow we find a region coloured in yellow and red. In this region we find images for which the light ray covered the angle $\pi < \Delta\varphi < 2\pi$. These are images of second order. If we go closer to the shadow we also find images of third and fourth order. The boundaries between the images of different orders mark the positions of the critical curves. On the left side of the line of symmetry we find the same features, however, the ordering of the colours is reversed. In addition we observe that at $\Psi = \pi$ images of second order already occur further away from the shadow than for $\Psi = 0$. This implies that light rays passing close to the string cover the same angle $\Delta\varphi$ faster than light rays passing close to the strut.

4.4. *Redshift*

The redshift z of a light ray relates its energy at the time of emission by a light source to its energy at the position at which it is detected by an observer. It is directly accessible to observation via the frequency shift of atomic or molecular absorption lines. We will now construct redshift maps. For this purpose we will use the same settings and results we obtained from constructing the lens map in Section 4.3. In this setting observer and light source are static and the corresponding general redshift formula can be found in Ref. 19, pp. 45. After inserting the metric coefficients g_{tt} of the charged C-de Sitter metric it reads[13]

$$z = \sqrt{\frac{g_{tt}|_{x_O}}{g_{tt}|_{x_L}}} - 1 = \sqrt{\frac{Q(r_O)}{Q(r_L)}}\frac{\Omega(r_L, \vartheta_L(\Sigma, \Psi))}{\Omega(r_O, \vartheta_O)} - 1. \tag{48}$$

Fig. 5 shows plots of the redshift maps for the same observer-source geometry as for the lens maps in Fig. 4 In all four plots the outer region is dominated by redshifts. The redshift has two maxima around $\Psi = \pi$ and at $\Psi = 0$ (close to the shadow). In addition in all images we observe a region of blueshifts centered around $\Psi = 0$. Another crescent shaped region of blueshifts can be found at $\Psi = \pi$ close to the shadow. What are now the effects of the cosmological constant Λ and the electric charge e? Comparing the images with $\Lambda = 0$ in the upper row with the images with $\Lambda = 1/(200m^2)$ in the lower row shows that when we turn on the cosmological constant the redshift range shifts from $-1 < z < 2$ to $-0.8 < z < 6$, respectively. The two blueshift areas move to lower latitudes closer to the centre of the shadow. In addition the fraction of the images covered by blueshifts decreases. The effects of the electric charge e are less strongly pronounced. When we compare the images on the left ($e = 0$) to the images on the right ($e = m$) we observe that in the top row the areas with blueshift move to slightly lower latitudes while they still seem

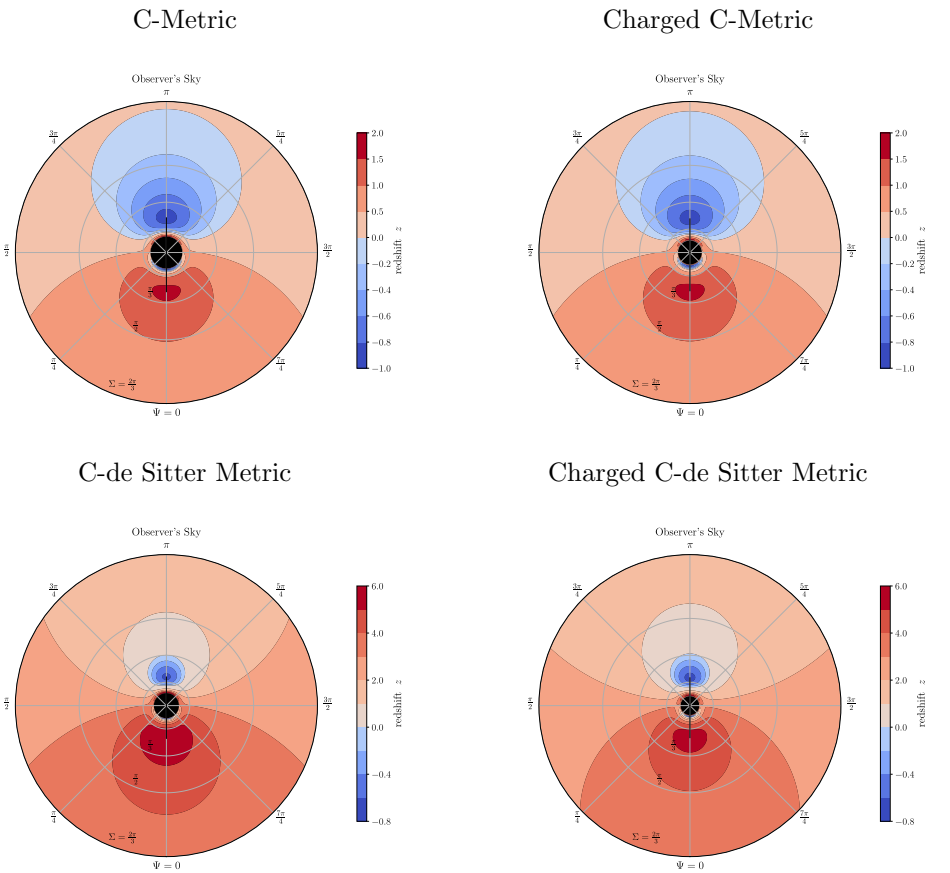

Fig. 5. Redshift maps for the C-metric[13] (top left), the charged C-metric (top right), the C-de Sitter metric (bottom left) and the charged C-de Sitter metric (bottom right) for $\Lambda = 1/(200m^2)$, $e = m$ and $\alpha = 1/(10m)$. The observer is located at $r_O = 8m$, $\vartheta_O = \pi/2$ and the sphere of light sources is located at $r_L = 9m$. The black lines at $\Psi = 0$ and $\Psi = \pi$ mark light rays that cross the axes at least once.

to cover roughly the same fraction of the image. However, comparing both images in the lower row indicates that in the presence of a cosmological constant turning on the electric charge leads to an increase of the fraction of the image covered by blueshifts. In addition the areas of blueshifts shift to lower latitudes but appear to be located at angular distances further away from the shadow.

4.5. *Travel Time*

The travel time $T = t_O - t_L$ measures in terms of the time coordinate t the elapsed time between the emission of a light ray by a source at a time t_L and the detecion of the same light ray by an observer at the time t_O. We obtain the travel time integral

C-Metric/Charged C-Metric C-de Sitter Metric/Charged C-de Sitter Metric

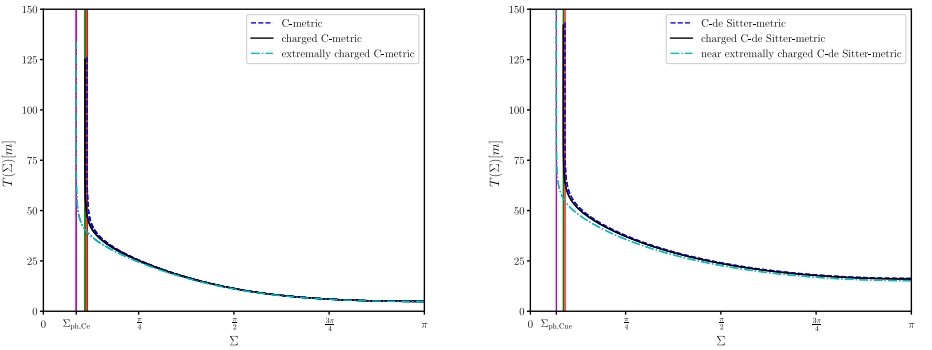

Fig. 6. Travel time $T(\Sigma)$ for the C-metric and the charged C-metric (left), and the C-de Sitter metric and the charged C-de Sitter metric (right) for $\Lambda = 1/(200m^2)$, $e = m$ in the extremal and near extremal case, otherwise $e = m/2$ and $\alpha = 1/(10m)$. The observer is located at $r_O = 8m$ and the sphere of light sources is located at $r_L = 9m$. $\Sigma_{\mathrm{ph,Ce}}$ and $\Sigma_{\mathrm{ph,Cne}}$ mark the position of the angular radius of the shadow on the observer's celestial sphere for the extremally charged C-metric and the near extremally charged C-de Sitter metric, respectively.

by inserting (44) and $t_O = 0$ in (27). We evaluate the travel time as described in Section 3.2. Fig. 6 shows the travel time for the (charged) C-metric (left) and the (charged) C-de Sitter metric (right) for $\Lambda = 1/(200m^2)$, $e = m/2$ in the regular case, $e = m$ in the (near) extremal case and $\alpha = 1/(10m)$. The observer is located at $r_O = 8m$ and the light source is located at $r_L = 9m$. The left plot shows that for $\Sigma > \pi/2$ in the C-metric and the charged C-metric the travel time is roughly the same. When we turn on the cosmological constant this drastically changes. In comparison to the (charged) C-metric the travel time gets significantly longer. However, turning on the electric charge in presence of a positive cosmological constant leads to a decrease of the travel time. In addition both plots indicate that for $e = m/2$ the travel time close to Σ_{ph} is slightly shorter than for $e = 0$ while it is significantly longer for $e = m$.

5. Summary and Implications for Observations

In this article we extended the work presented for the C-metric in Ref. 13 to the charged C-de Sitter metrics. In the first part we discussed and solved the equations of motion using elementary as well as elliptic functions and ellitpic integrals. In the second part we used the derived analytical solutions to investigate gravitational lensing in the charged C-de Sitter metrics.

How can we now use these results in combination with observational data to distinguish between the different black hole spacetimes and in particular to measure the electric charge of a black hole?

In the charged C-de Sitter metrics the shape of the shadow is always circular. Its angular radius decreases with increasing Λ, e and α. However, because the distance between the observer on Earth and the black hole lens is not a priori known it alone cannot be used to determine the nature of the black hole. The length of the travel time in particular close to the shadow is more characteristic for each spacetime. Unfortunately in real astrophysical settings (multiple imaging systems) we can only measure travel time differences leading to similar ambiguities as for the shadow. However, the charged C-de Sitter spacetimes also admit two very characteristic lensing features that distinguish them from their non-accelerating counterparts ($\alpha = 0$). The first characteristic is the breaking of symmetry with respect to the equatorial plane on the celestial sphere of the observer in the lens maps. Here, the most salient feature was the observation that images of second order occur at larger (lower) angular distance from the shadow close to the string (strut). The second characteristic is that the redshift z is a function of the coordinates on the observer's celestial sphere. The breaking of symmetry can be tested by observing multiple images from the same light source gravitationally lensed by a black hole. In such a system we can measure the position of the images on the celestial sphere of the observer relative to the lens and then compare it with theoretical predictions. Similarly although our construction of the redshift map is highly idealised we may be able to find astrophysical systems similar to this configuration. In such a system, we can measure the redshift of known emission lines and construct a partial redshift map to determine if it is a function of the coordinates on the observer's celestial sphere. Observing the symmetry breaking and showing that the measured redshift is a function on the observer's celestial sphere tells us with high certainty that the observed black hole is accelerating and can be described by one of the charged C-de Sitter metrics. However, due to the ambiguity introduced by the a-priori unknown distance between observer and black hole lens we cannot use these measurements alone to determine Λ, e and α. Therefore, to correctly identify the nature of the spacetime describing the black hole we observe, and having the chance to accurately measure the mass parameter m, the cosmological constant Λ, the electric charge e and the acceleration parameter α we need to combine high accuracy measurements of the angular diameter of the shadow, the redshift function on the observer's celestial sphere and of the position of and the travel time differences between two or more multiple images from the same source. Unfortunately even with very high accuracy observations for most black holes the electric charge e is likely to be far to low to be measured and one may only be able to estimate an upper limit.

Ultra-sensitivity of a planet's gravity assist to changes of the test-body impact parameter prompts a space experiment testing the nature of the gravitational field in the Solar system. The Sun, Earth and Venus serve as the space lab with a primitive space probe (space ball) as a test body moving on a ballistic trajectory from the Earth to Venus (rendering GA) and backwards to the Earth's orbit. We explain why in Newton and Einstein gravity, the probe's final positions (reached at the same time) may differ greatly; an Earth's observer can measure the gap.

Keywords: Gravitation; General Relativity; Gravity assist.

Introduction

Recent experiments supporting validity of GR, in our opinion, have at least two weak features. First, we are, in fact, dealing with isolated observations of very rare natural phenomena, mostly it is motion and merging of some massive objects. Second, these objects are very far from the observer. If binary pulsars are observed at distances of "only" 10 thousand light-years, then the sources of the gravitational radiation is determined at about 1.3 billion light-years. So, in fact we examine the past.

This seems to violate the basic principles of an experiment: possibility to repeated it and to deal with physical laws "valid here and now". But it is not the case yet, therefore, the claims about the absolute acceptability of Einstein's theory of gravity are hardly convincing enough.

Well, we understand that a repeatable experiment testing very small GR effects in the near space (in the Solar system) is a very challenging task.

In this presentation we will try to demonstrate that such an experiment (and a series of experiments) aimed to specify the law of the Sun's gravity with good accuracy is quite possible.

The Gravity Assist Maneuver

The main idea of the experiment is to use the so-called gravity assist maneuver of a space probe near a close planet.[1–3]

Reading papers on the space missions (where the gravity assist has become a habitual instrument) we paid attention at a great precision of the impact parameter value (or value of the close parameter — pericenter, the shortest distance between the planet rendering the assistance and a spacecraft). On the Solar system scale of hundred million kilometers, the impact parameter is normally precalculated with the accuracy of one kilometer.

This precision should reflect a great sensibility of results of the gravity assist maneuver to the pericenter value; small deflection must entail great trouble for the mission. However, we could find no sensible information about the gravity-assist sensitivity function. So, we had to determine it ourselves.

The Standard Flight

At first, we designed a scheme of a "standard flight" in Newton's gravity of the Sun. It represents a space probe flight in a planetary system comprising a central star and planets imitating the Sun, Earth, and Venus. For simplicity, it is assumed that the planets move in circular orbits, however, the other physical parameters of the system are very close to the observation data.

The pattern flight looks as follows. A space probe is launched from the Earth (or from the Earth's orbit — since we ignore here non-essential Earth's gravity). From the launch point at initial zero-time moment and azimuth (polar angle) also zero,

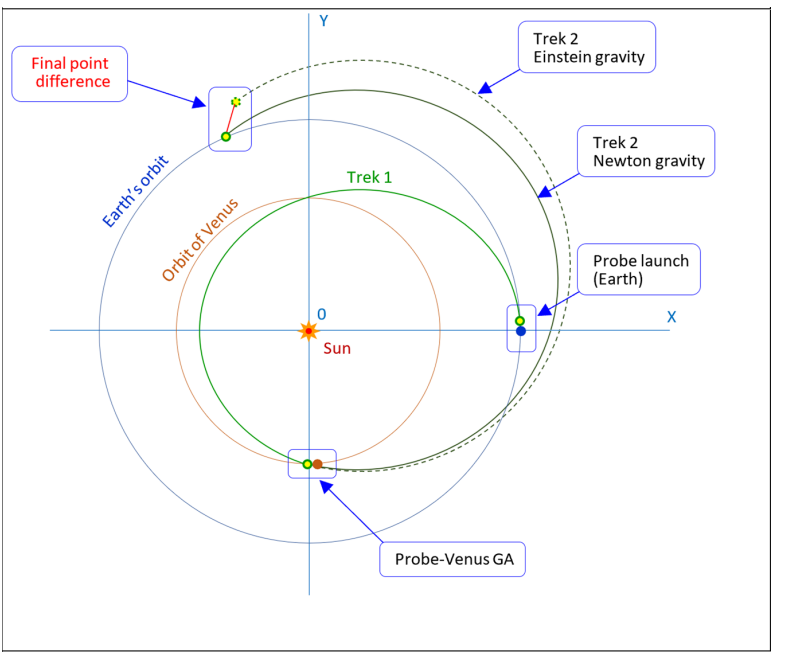

Fig. 1. The standard flight and the Gravity assist effects for different gravity laws.

the probe falls freely towards Venus by a Kepler elliptic leg (trek 1 in Fig. 1), and after a sufficiently prolonged flight it arrives at the Venus gravity-assist point. The initial conditions are chosen so, that the probes' perihelion has azimuth 180 deg, while the gravity assist point has azimuth of 270 deg, and strictly precomputed pericenter value. The Venus gravity assist accelerates the probe so that after flight by another elliptic leg (trek 2 in Fig. 1) it returns to the Earth's orbit, and at the assigned time sends a signal received by the Earth's observer who thus determines the probe's final position.

The Gravity-Assist Sensitivity as a Function of Pericenter Value

Slightly changing the initial conditions, we manage to make the chosen pericenter shorter by 1 km and let it move freely to the final position the same time. Then the calculated distance between the probe's final positions (with the pericenter difference of 1 km) gives us the gravity- assist sensitivity function for the chosen pericenter value.

Subsequently changing the initial conditions, we found the sensitivity values analytically for 20 pericenter lengths (from 18 000 km to 8 000 km — that is from 12 000 km to 2 000 km altitude) and obtained the following result. The sensitivity turns out quite a non-linear function.

At a greater pericenter value (18 000 km) the sensitivity is about 20 000 (this means that one-kilometer difference (i.e. 17 999 km) throws the probe aside its assigned final point at 20 000 km. In other words, the sensitivity is about 104. At smaller pericenter value, about 10 000 km (it is 4 000 km altitude) the sensitivity grows ten times as 105. That is at the final point the probe is thrown aside at 100 000 km.

Thus, the gravity assist maneuver may work as a powerful amplifier of small pericenter changes caused by some physical agents on its first elliptic leg (Trek 1).

We should say that we cross-checked the analytical evaluation of the sensitivity function values by a pure numerical construction of respective probe trajectories with the help of iterative program (realized within Python 3 system), choosing the time interval of 1 second, so that the probe's trajectories are built on 35–50 million points.

The results of analytical calculation and numerical construction of the trajectories turned out quite close.

The plots of GA sensitivity function are represented in Figs. 2–3.

The first physical factor to distort Kepler's Trek 1 is Einstein's general relativistic gravity; so we made preliminary computations, and again by two methods: analytically and numerically (and again the results are very close).

The GR gravity brings three reasons making he pericenter shorter. First, the GR-ellipse slightly shrinks, second, it is subject to a slow precession, and third, on a shorter trajectory the probe arrives at the gravity-assist point a earlier so that Venus is met a bit closer.

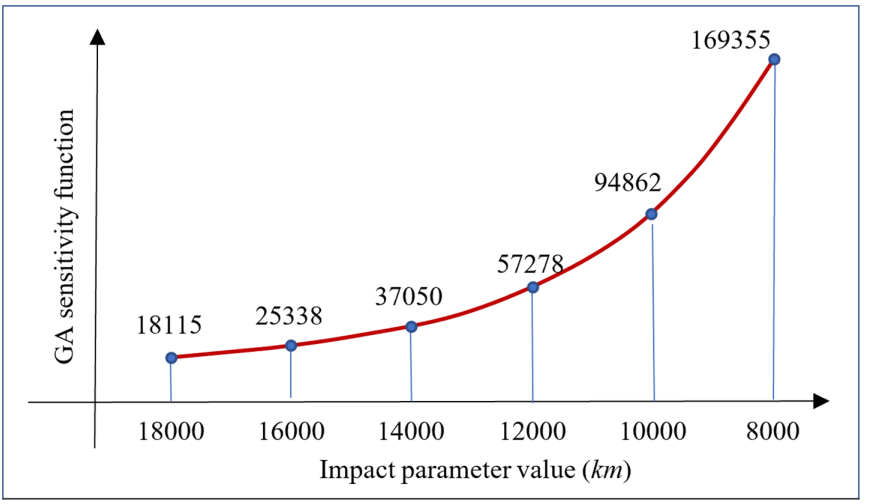

Fig. 2. Math calculation of GA sensitivity as function of IP value.

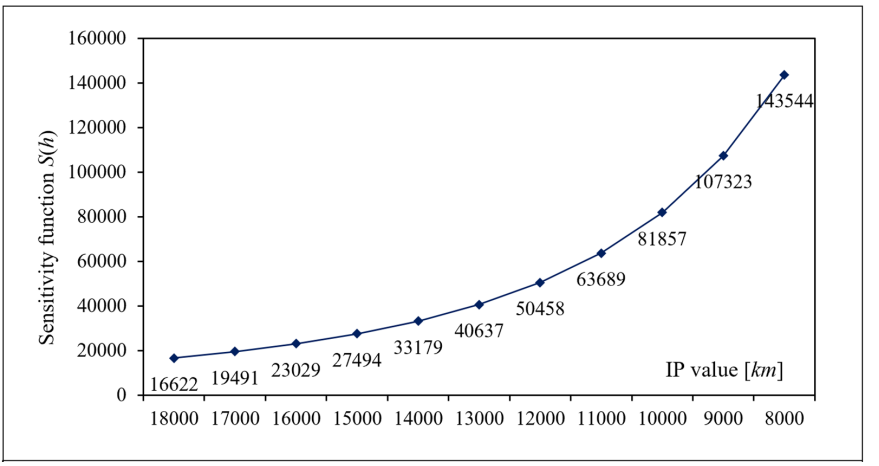

Fig. 3. GA sensitivity function $S(h) = dl/dh$ where dl is FP difference [km] for $dh = 1$ km.

Then under identical initial conditions the probe's pericenter becomes about 40 km shorter. Therefore, if the pericenter is 18 000 km, then at the final point the observer must detect about 800 000 km distance from assigned position. This difference will be much more (millions of km) for shorter pericenter values. These distances are big enough; their experimental detection by the observer should indicate in favor of Einstein's gravity.

Conclusion

The experiment seems not too hard to perform and it does not require excessive costs. Existing computational means allow distinguishing pure gravity effects among other physical agents, influence of other planets, Sun's oblateness, solar wind, etc. The space probe need not be a sophisticated station packed with expensive tools; a primitive space-ball able to send receivable signals is sufficient. We think that many cosmic agencies of different states and private companies can afford this job. We hope, someone will be the first.

Gravitomagnetic field generation using high permittivity materials in superconducting magnetic energy storage devices

G. V. Stephenson
Seculine Consulting
Cupertino, CA 95014, USA
E-mail: seculine@gmail.com

A method is described for creating a measurable unbalanced gravitational acceleration using a gravitomagnetic field surrounding a superconducting toroid as described by Forward.[1] An experimental superconducting magnetic energy storage toroid configuration of wound superconducting nanowire is proposed to create a measurable acceleration field along the axis of symmetry, providing experimental confirmation of the additive nature of a Lense–Thirring derived gravitomagnetic field. In the present paper gravitational coupling enhancement of this effect is explored using high-permittivity material, as predicted by Sarfatti[2] and his modification to Einstein's general relativity field equations for gravitational coupling in matter.

Keywords: Gravitational; Gravitomagnetic; Lense–Thirring; Superconducting magnetic energy storage; SMES; Nanorods; Nanowires; Super dielectric materials; SDM; Super capacitors; High permittivity; Gravitomagnetic permeability; Gravitational coupling.

1. Introduction

When Forward[1] proposed a gravitomagnetic toroid to produce unbalanced gravitational force in 1962, a prototype was quite impractical. Recent advances in high-temperature superconducting (HTSC) nanorod wires (nanowires)[3,4] has enabled a new class of superconducting magnetic energy storage (SMES) devices operating at current densities sufficient to develop measurable gravitomagnetic fields.

In the present paper, an experimental SMES toroid configuration is proposed that uses a super dielectric material (SDM; e.g., high-permittivity super capacitor) to substantially improve gravitational coupling of mass flow to the curvature of spacetime as predicted by Sarfatti.[2] Depending on the nature of gravitational coupling, it is predicted that a set of standard accelerometers could measure acceleration fields along the axis of symmetry of the toroidal coil, thus providing experimental confirmation of the additive nature of the gravitomagnetic fields, as well as the production of a linear component of the overall acceleration field (Fig. 1).

In the instantiation of Forward's gravitational generation coil described in this paper, superconducting electron flow provides the change in mass current in the toroid. A high-permittivity material such as a SDM[5] is added to the space in the center of the toroid to improve gravitational coupling. Alternatively or additionally high-permittivity insulators may be used as an exterior jacket to the conducting portion of the nanowire to further boost gravitational coupling; gravitomagnetic effects are largest adjacent to the mass flow.

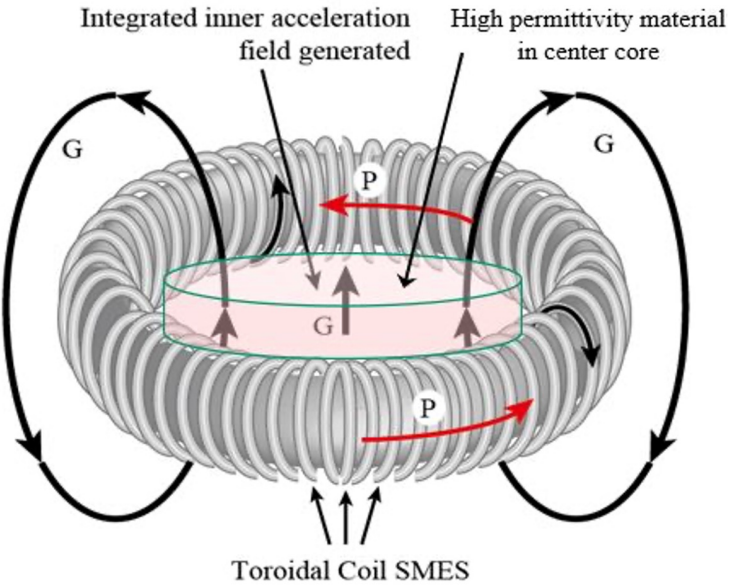

Figure 1. Gravitational force generation coil from Forward[1] with an inspiraling mass current, with a vector potential P, creating gravitomagnetic field G, with high-index material in the center to improve coupling.

2. Gravitomagnetic Force Equation for Toroid Mass Flow

As first developed in Forward,[1] the linear force G_f developed by gravitomagnetic force in the mass flow toroid of Fig. 1 is given by Eq. (1)

$$G_\mathrm{f} = \left(\frac{\eta}{4\pi}\right)\left(\frac{N\dot{T}r^2}{R^2}\right), \tag{1}$$

where η is gravitomagnetic permeability, $\eta = \eta_\mathrm{o}\eta_\mathrm{r}$,[3] N is the number of turns in the toroid coil winding, $\dot{T}$ represents the mass flow, r is the cross-sectional radius of the toroid, and R is the overall radius of the toroid.

Mass flow can be generated by an electrical current by virtue of the electrons' mass in motion. Single-electron mass flow (Fig. 2) is given by mass momentum:

$$T_\mathrm{e} = p_\mathrm{e} = (\Omega \times r)m_\mathrm{e}, \tag{2}$$

where Ω is the angular rate, angular velocity is $v = \Omega \times r$ in the classical case.[6]

Change in mass flow for the single-electron flow shown in Fig. 2 is

$$\dot{T}_\mathrm{e} = \dot{p}_\mathrm{e} = a \cdot m_\mathrm{e} = (\Omega \times v)m_\mathrm{e}. \tag{3}$$

This is equivalent to centripetal force,

$$\dot{T}_\mathrm{e} = F_\mathrm{e} = \frac{m_\mathrm{e}v^2}{r} = m_\mathrm{e}a_\mathrm{e} = m_\mathrm{e}\left(\omega^2 r\right), \tag{4}$$

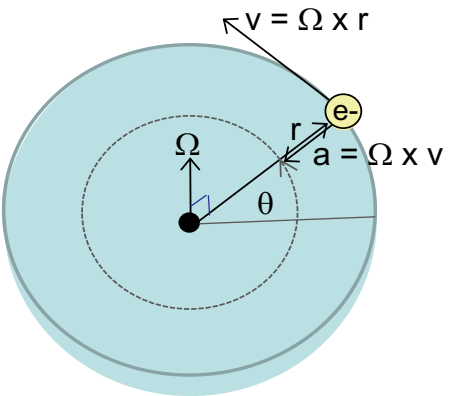

Figure 2. Electron orbit around one loop of SMES toroid.

where ω is the angular rate:

$$\omega = \frac{2\pi}{t_p} = \frac{\mathrm{d}\theta}{\mathrm{d}t}. \tag{5}$$

3. Current in Idealized SMES

We now estimate the possible inspiraling current flux enabled by the emerging SMES technology as it relates to the core geometry constraints described in Fig. 3, a toroid with torus geometry. We start with the assumptions needed to calculate the number of turns, N.

From Eq. (1), the torus assumptions made in Fig. 3 can be factored into Eq. (6):

$$G_{\mathrm{f}} = \left(\frac{\eta_{\mathrm{o}}\eta_{\mathrm{r}}}{4\pi}\right) S \left(\frac{N\dot{T}r^2}{R^2}\right), \tag{6}$$

where

G_{f} = gravitomagnetic force
η_{o} = absolute gravitomagnetic permeability
η_{r} = relative gravitomagnetic permeability
N = number of turns in the torus coil
S = Sarfatti scaling factor
$\dot{T}$ = change in mass or mass flow
r = cross-section radius of torus
R = centerline radius of torus

Note that Eq. (6) differs from Forward's original formulation in that it includes the scaling factor S which accounts for the scaling of gravitational coupling due to high-index matter or metamaterials, which was first expressed by Sarfatti as

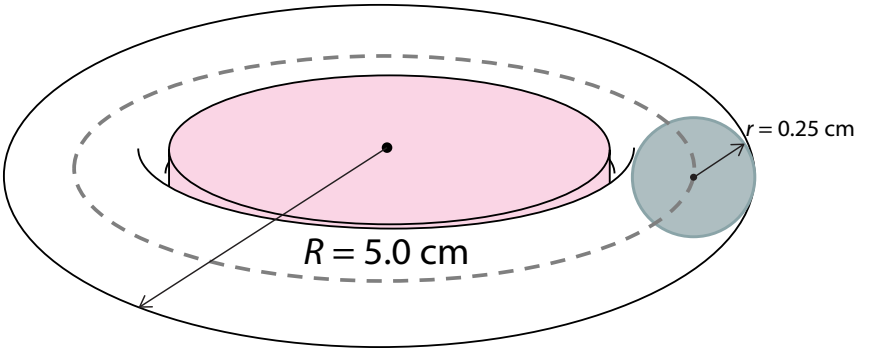

Figure 3. Toroid with a torus-shaped core geometry, including high-permittivity scaling matter in center.

an additional zero-rank tensor in Einstein's field equations[2,7] based on combining Lentz's[8] work with that of Medina and Stephany:[9]

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} = \left(\frac{8\pi G}{c^4}\right) ST_{\mu\nu}, \tag{7}$$

where

$R_{\mu\nu}$ = Ricci curvature tensor,
$Rg_{\mu\nu}$ = Ricci scalar curvature,
G = gravitational constant
c = speed of light
S = Sarfatti scaling tensor
$T_{\mu\nu}$ = Stress Energy Tensor

For the purposes of describing an idealized case with a realistic geometry, we describe a device bounded by a 10 cm toroid (outer mold line diameter), shown in Fig. 3 and Fig. 4, with a 0.5 cm cross-sectional diameter. Furthermore, 16 sectors are defined as shown in Fig. 4.

We further add additional assumptions regarding conductor wrapping around the toroid to determine constraints on the number of conductive loops that can be accommodated using the described technology.[3] As shown in Fig. 5 via cross section, we assume here a conductor winding depth of 0.1 cm.

The inner edge of a single segment of the cross section, C_s, is 1/16 of the toroid's centerline circumference:

$$C_s = \frac{2\pi r_i}{16} = 1.77\,\text{cm} \tag{8}$$

With a depth D, the minimum inner loop cross-sectional area can be described as

$$A_{sec} = D \cdot C_s = (0.1\,\text{cm})(1.77\,\text{cm}) = 0.177\,\text{cm}^2. \tag{9}$$

This area is shown packed with conductors in Fig. 6 in depth and along the sector circumference.

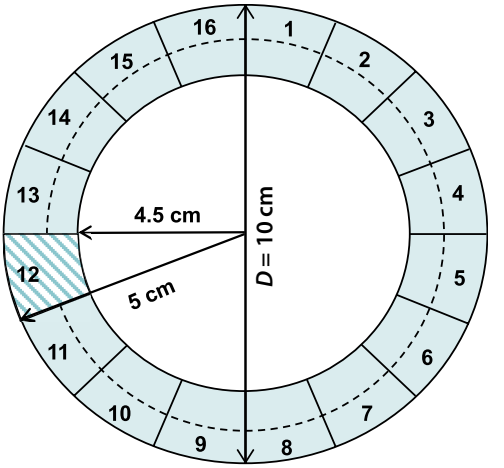

Figure 4. Torus section definition.

Assuming each nanowire conductor has a diameter d_c of 100 µm, the cross-sectional area of each conductor will be given by

$$A_c = \pi r_c^2 = 7.854 \times 10^{-9}\,\mathrm{m}^2. \tag{10}$$

For packing nanowire conductors in a cross-sectional area described in Fig. 6, assume as a worst case a rectangular area described by the shortest edges such that

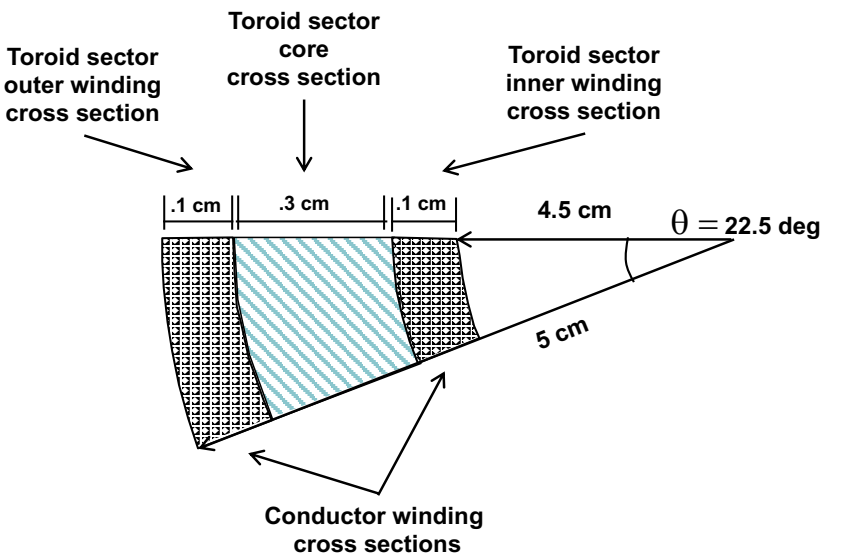

Figure 5. Conductor cross section in each sector.

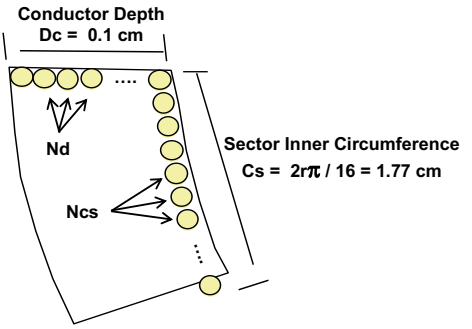

Figure 6. Conductor packing in each sector.

a number of conductors in depth, N_{d}, may be packed in one dimension, with the number of conductors, N_{cs}, packed in the other dimension. These packing counts may be calculated in Eq. (11) and Eq. (12) as follows:

$$N_{\mathrm{d}} = D_{\mathrm{c}}/d_{\mathrm{c}} = \frac{0.1\,\mathrm{cm}}{100\,\mu\mathrm{m}} = 10 \tag{11}$$

$$N_{\mathrm{cs}} = C_{\mathrm{s}}/d_{\mathrm{c}} = \frac{1.77\,\mathrm{cm}}{100\,\mu\mathrm{m}} = 177 \tag{12}$$

The total number of windings by sector will therefore be the product $N_{\mathrm{d}} \times N_{\mathrm{cs}}$:

$$N_{\mathrm{sec}} = N_{\mathrm{d}} \cdot N_{\mathrm{cs}} = (10)(177) = 1770. \tag{13}$$

With 16 sectors, the total number of windings for the entire toroid will be

$$N = 16N_{\mathrm{sec}} = 28{,}320. \tag{14}$$

What is $\dot{T}$ with the forgoing assumptions? In this idealized case electrons circulate about a coil of circumference c_{r}, or slightly larger:

$$c_{\mathrm{r}} = 2\pi r = 1.57\,\mathrm{cm}. \tag{15}$$

3.1. *Electron motion*

Assume further a supply voltage of 16 kV, resulting in 16KeV of kinetic energy for each electron, which corresponds with the upper limit of a nonrelativistic case, where $v = 0.25\mathrm{c}$, so that $\gamma = 1.06 \approx 1.0$.

Then from Eq. (4) for nonrelativistic circular motion, the vector change in DC current flow is

$$\dot{T}_{\mathrm{e}} = \frac{m_{\mathrm{e}} v^2}{r}, \tag{16}$$

which, for a single electron, has the following values

$$m_{\mathrm{e}} = \text{mass of the electron} = 9.11 \times 10^{-31}\,\mathrm{kg}$$
$$v = \text{velocity of the electron} = 0.25\mathrm{c} = 0.75 \times 10^{8}\,\frac{\mathrm{m}}{\mathrm{s}}$$
$$r = 0.25\,\mathrm{cm}$$

for the assumed geometry

The angular acceleration of the electron is

$$a_{\mathrm{e}} = \frac{v^2}{r} = 2.25 \times 10^{18}\,\frac{\mathrm{m}}{\mathrm{s}^2} \tag{17}$$

The change in mass flow represents centripetal acceleration in the case of circular motion:

$$\dot{T}_{\mathrm{e}} = m_{\mathrm{e}} \cdot a_{\mathrm{e}} = 20.48 \times 10^{-13}\,\mathrm{N}. \tag{18}$$

Eq. (18) corresponds to the change in mass flow for one electron in one loop of coil. Total mass flow change is therefore the mass flow change per electron times the number of electrons:

$$\dot{T} = \dot{T}_{\mathrm{e}} \cdot N_{\mathrm{e}}. \tag{19}$$

3.2. *Electron current*

What is the number of electrons, N_{e}, in motion in one loop (part of the mass flow) at a given time for an assumed velocity of $v = .25\mathrm{c}$? N_{e} in one loop can be described by the current I times the period of a single loop circulation Δt:

$$N_{\mathrm{e}} = I \cdot \Delta t, \tag{20}$$

where the period of an orbit can be described by

$$\Delta t = \frac{c_{\mathrm{r}}}{v} = \frac{2\pi r}{v} = 0.2094\,\mathrm{ns}. \tag{21}$$

What is the possible current inside the idealized device for the case where the entire winding is in series? We assume the max current stays below the critical current density of $250\,\frac{\mathrm{MA}}{\mathrm{m}^2}$.[3,4]

Current is limited by the maximum permissible current density and the cross section of the conductor:

$$I = J \cdot A_{\mathrm{c}}, \tag{22}$$

where J is material dependent. For the nanowire assumed in Ref. 3, $J = 250\,\frac{\mathrm{MA}}{\mathrm{m}^2}$ and the cross-sectional area, $A_{\mathrm{c}} = 7.854 \times 10^{-9}\,\mathrm{m}^2$, as given in Eq. (10). Therefore, the maximum current for this conductor diameter is $I = 1.96\,\mathrm{A}$.

Expanding on Eq. (22), the number of electrons N_{e} in circulation in one loop may be calculated by noting that there are 6.2415×10^{18} electrons per Coulomb:

$$N_{\mathrm{e}} = \left(\frac{\text{electron}}{\text{Coulomb}}\right) I \left(\frac{\text{Coulomb}}{\text{second}}\right) \cdot \Delta t = 5.12 \times 10^{9}\,\text{electron} \tag{23}$$

4. Forces in Idealized SMES

Expressing Eq. (19) as force per electron times the number of electrons in motion in one loop:

$$\dot{T} = \dot{T}_{\mathrm{e}} \left(\frac{\mathrm{Newton}}{\mathrm{electron}} \right) \cdot N_{\mathrm{e}} = 5.25\,\mathrm{mN} \tag{24}$$

Thus, each loop experiences about 5.25 mN of integrated centripetal force ($\dot{T}$) due to the electrons in circulation within. We now describe the scale factor to couple this force to the gravitomagnetic effect. Revisiting Eq. (6), which describes the overall linear force developed at the center of the toroidal coil, total gravitomagnetically developed force will be

$$G_{\mathrm{f}} = (\eta_{\mathrm{o}}\eta_{\mathrm{r}})\,(S) \left(\frac{N\dot{T}r^2}{4\pi R^2} \right) = (\eta_{\mathrm{o}}\eta_{\mathrm{r}})\,(S)(0.0295\,\mathrm{N}), \tag{25}$$

where known variables have been grouped on the right and unknown variables have been collected on the left. What are the correct values for η_{o} and η_{r}?

4.1. *Predicted force using gravitational potential scaling*

If η_{o} goes as $G/2\mathrm{c}$ as does gravitomagnetic potential (Ref. 10, Eq. (1.5)), then

$$\eta_{\mathrm{o}} = -\frac{G}{2\mathrm{c}} = 1.11 \times 10^{-19}. \tag{26}$$

This leads to $G_{\mathrm{f}} = (\eta_{\mathrm{r}})3.275 \times 10^{-21}$. Values of η_{r} are experimentally unknown at this time. However, if values of η_{r} track values of ϵr^2, then values as high as $\eta_{\mathrm{r}} = 10^{16}$ may be possible, yielding $G_{\mathrm{f}} = 0.03275$ mN. For a test mass of 1 kg this is equivalent to an easily measurable 3.35 μG. This is for a scaling factor of $G/2\mathrm{c}$. If the scaling factor is G/c^2, then the effect drops to an unmeasurably low 1.12×10^{-14} G, even for $\eta_{\mathrm{r}} = 10^{16}$.

4.2. *Predicted force using gravitational field scaling*

If the scaling factor is G/c^3 or G/c^4, then the effect is negligible for $\eta_{\mathrm{r}} = 10^{16}$, so a much higher-index material will need to be found to improve coupling, or other means must be found to improve either the S tensor or the gravitomagnetic permeability η_{r}.

Consider the case where η_{o} goes as $8\pi\mathrm{G}/\mathrm{c}^4$ as does the coupling constant in Einstein's Field Equations:

$$\eta_{\mathrm{o}} = \frac{8\pi G}{\mathrm{c}^4} = 2.07 \times 10^{-43}, \tag{27}$$

which gives the total gravitational force developed as

$$G_{\mathrm{f}} = (\eta_{\mathrm{o}}\eta_{\mathrm{r}})\,(S)(0.0295\,\mathrm{N}) = (\eta_{\mathrm{r}})\,(S)0.61 \times 10^{-44}\,\mathrm{N}. \tag{28}$$

A value of $\eta_r = 10^{16}$ gives $G_f = (S)4.43 \times 10^{-23}\,\mathrm{N}$, which requires a scalar value of S of at least an additional 10^{16} to obtain a measurable value for G_f. For an isotropic material, S can be written as[7]

$$S = \frac{1}{2}\left(\epsilon^2 + \frac{1}{\mu^2}\right) = \frac{1}{2}\frac{n^4+1}{\mu^2}. \tag{29}$$

Therefore, either a permittivity of $\epsilon = 10^8$ or an index of $n = 10^4$ with $\mu = 1$ would be sufficient to provide the necessary 16 orders of magnitude in coupling improvement. However, care should be taken that effects captured by the S factor are not duplicative of those accounted for in the value of η_r.

Super dielectrics can provide up to $\epsilon = 10^9$,[5] which, if we simultaneously had $\eta_r = 10^{16}$ via some unrelated phenomena, would improve the overall generated gravitational force to a marginally measurable level:

$$G_f = (\eta_r)\,(S) \times 0.61 \times 10^{-44} = 0.061\,\mathrm{nN}. \tag{30}$$

Alternatively metamaterials could also be investigated to establish whether non-isotropic materials may create a more advantageous gravitational coupling.

4.3. *Lenz's law implications*

Is there an equivalent of Lenz's Law for gravitomagnetics? Consider a hypothetical case where a Forward toroid capable of supporting sufficient current and coupling to develop 1 G of acceleration. As a thought experiment, imagine disconnecting the power supply and shorting the toroidal coil to itself, such that it is one continuous closed loop of nanowire, and equip a flying craft with such a coil.

At the surface of the Earth such a properly oriented toroidal coil would be immersed in a 1 G gravitational field. Should not such a field generate a counter-current in a toroidal coil capable of supporting a current of that level, essentially providing a self-powered counter field? If so, a craft so equipped would be able to hover using a counter-field equal but opposite to the Earth's gravitational field without need of additional power sources.

Similarly, additional closed-loop toroidal coils, properly oriented, could also be used to "current charge," collecting energy from a static gravitational field, potentially providing power that could be directed to other propulsive or nonpropulsive functions of such a hypothetical craft.

5. Conclusions

An argument is made for using high-permittivity materials in the core or donut hole or nanowire insulators of an SMES toroid to improve gravitomagnetic coupling for the creation of an acceleration field, possibly of measurable amplitude. Improved coupling will be beneficial for shrinking device scale and complexity and overcoming the very weak coupling between mass flow and gravitomagnetic spacetime curvature.

Ring laser Gyroscopes (RLG) are very versatile devices that find application in many fields as navigation, seismology and geophysics. Moreover, thanks to their sensitivity and accuracy, in the last years they have been used in fundamental physics research field.

GINGER (Gyroscopes IN GEneral Relativity) research group aims to exploit a large RLG to test general relativity theory. Our research team has two working RLG, both with a square shape, one installed in Pisa and named GP2. (1.6 m side), and the other installed in the INFN underground laboratory of Gran Sasso near L'Aquila named GINGERINO (3.6 m side). The final goal of GINGER is to measure the Earth rotation rate with enough precision to take into consideration general relativity predicted corrections.

To reach this target, one of the requirements is the stability of the laser and the optical cavity of the RLG. We will show the last developed techniques aimed to satisfy this stability requirement. Working on GP2 we have tested two different techniques to control the ring shape. One is based on the stabilization of the two Fabry-Pèrot resonators formed along the square diagonals by the opposite mirrors of the RLG. The other, consist in controlling the ring perimeter by monitoring its free spectral range through a beet-note between one of the counterpropagating beams and a frequency stabilized laser source. We will show the characteristics, the potentialities and the tests of these two methods.

Keywords: Large Frame Ring Laser, Sagnac Effect, frequency control, Laser stabilization

1. Introduction

Large frame ring laser gyroscopes (RLG), which exploit Sagnac effect, are the most sensitive devices for detecting absolute angular motions in a huge range of frequency, extending from kHz down to DC.[1] Thanks to their sensitivity and accuracy, in the last years they have been used in the fundamental physics research field.

In this framework, the project GINGER (Gyroscopes IN GEneral Relativity) of the Istituto Italiano di Fisica Nucleare (INFN) was developed in 2010.[2,3] The goal of the project is to measure the Lense-Thirring and De Sitter effects using an on

Earth device via a very precise and accurate measurement of the Earth rotation rate. Binding rigidly a RLG to the ground it is possible to exploit the Sagnac effect to measure the Earth rotation rate. Due to this effect, two counter-propagating beams that circulate in a rotating close path have an optical frequency difference proportional to the rotation rate. This frequency difference, known as the Sagnac frequency (f_S), is linked to the reference frame rotation rate via the geometrical characteristics of the ring as descibed in Eq. (1)

$$f_S = \frac{4A}{\lambda P}\vec{\Omega} \cdot \hat{n} \tag{1}$$

where A and P are respectively the area and the perimeter of the optical path, λ is laser wavelength without the path rotation, $\vec{\Omega}$ is the rotation rate of the reference frame and $\hat{n}$ is the normal area versor of the optical path.

It is possible to demonstrate that Eq. (1) is still valid in General Relativity (GR) with only one difference: $\vec{\Omega}$.[4] In fact, in the relativistic formulation, $\vec{\Omega}$ includes all the gravitational field effects, which is exactly what we want to measure.

$$\vec{\Omega} = \vec{\Omega}_{\oplus} + \vec{\Omega}_G + \vec{\Omega}_{LT} \tag{2}$$

$\vec{\Omega}_{\oplus} = 7.29 \times 10^{-5}$ rad/s is the Earth instantaneous angular rotation velocity, $\vec{\Omega}_G$ is the geodetic (or De Sitter effect), $\vec{\Omega}_{LT}$ is the Lense-Thirring effect.

These terms are estimated to be, respectively, $6.98 \cdot 10^{-10}\Omega_{\oplus}$ the geodetic part and $2.31 \cdot 10^{-10}\Omega_{\oplus}$ the Lense-Thirring one.[5,6] This estimation gives the sensitivity level required to be able to measure the general relativity correction upon the Earth rotation rate.

GINGER research group aims to reach this level of sensitivity with an array of large frame RLGs. In order to reconstruct the Earth rotation rate vector with enough precision to evaluate the De Sitter and Lense-Thirring contribution. To obtain this goal the also the ratio $4A/\lambda P$ of Eq. (1) must be known and stable at a level of 10^{-10}. This ratio is known as *scale factor* (for simplicity in the following we will refer to this quantity as scale factor or k). In the following, we will describe two different techniques to stabilize this value.

2. GP2 and the geometry control

Our research group has two RLGs, the first one, named GP2[7–9] installed in the INFN (Istituto Nazionale di Fisica Nucleare) laboratory in Pisa, and the second one, GINGERINO[10–14] installed in the underground laboratory of LNGS (Laboratori Nazionale del Gran Sasso) near L'Aquila.

This second one is our prototype of high precision large frame RLG. It is a square ring of 3.6m side located inside a quiet environment like those of the underground laboratories of LNGS inside the Gran Sasso mount. It has been built to test the quality of this kind of site for the installation of a device for GR measurements.

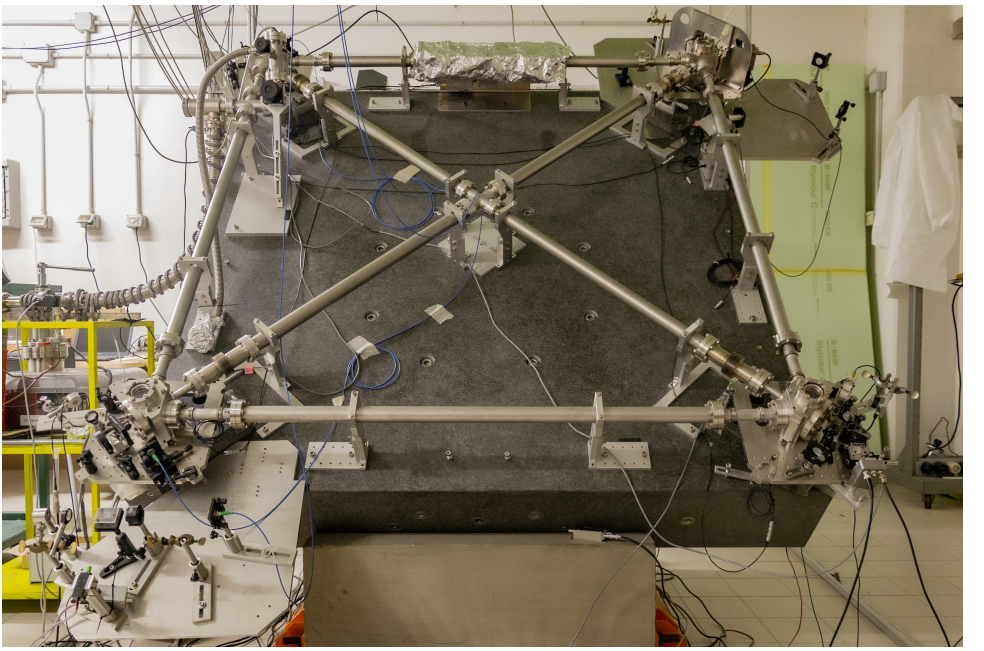

Fig. 1. Pictures of GP2.

Moreover, it has also shown that can be a suitable instrument also for geophysics ad geodesy.[15–17]

In this work we will focus on the first one GP2, that is our *test* ring laser (see Fig. 1). It is a square ring of 1.6m side, tilted of $\sim 45^{o}$ in order to maximize the scalar product in Eq. (1). In addition to the square cavity, it has other two resonance cavities: the diagonals, and 4PZT actuators (one for each corner) able to move the whole corner along the diagonal direction. The structure of both our RLGs is etherolithic. This means that active geometry stabilization is essential to fix the scale factor value during the measurement period.

We have developed two different methods to control the ring geometry, the first is based on controlling the length of square diagonals and the second is based on stabilizing its perimeter length.

2.1. *Diagonal Control*

First of all, we have designed a mathematical model to parameterize all possible deformation that can affect the ring shape.[8] Basing this model on the diagonals deformation we have identified six fundamental deformations. Tn the hypothesis of small perturbation of a perfect square we can reconstruct any kind of shape perturbation using these six fundamental deformations. Using this parametrization

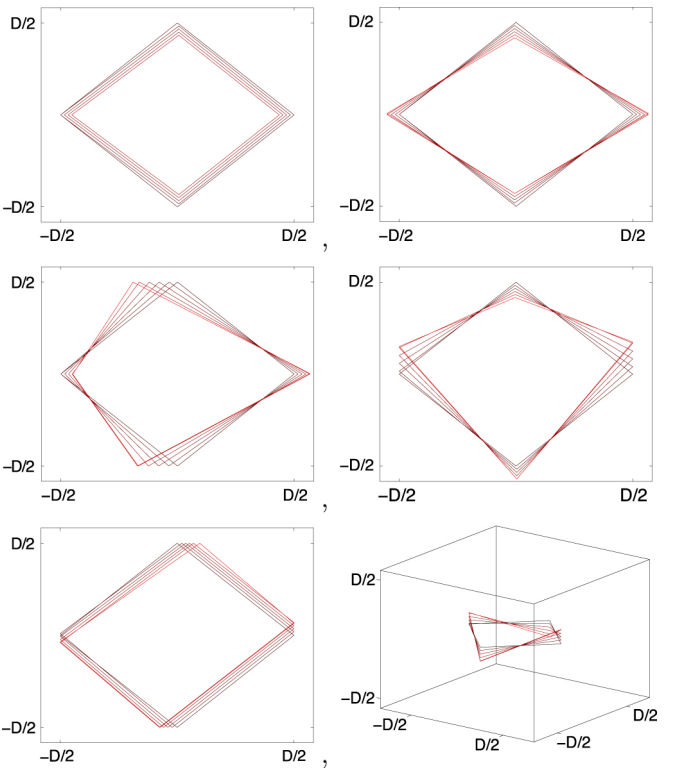

Fig. 2. Graphical representation of the optical paths six fundamental deformation of ring shape. First row: diagonal common mode stretching E_1 (left); differential mode stretching E_2 (right). Second row: shear planar deformations E_3 (left), E_4 (right). Third row: diagonal tilt E_5 (left); out of plane tilt E_6 (right). From Fig. 2 of [8]

we have recalculate the scale factor obtaining:

$$k = \frac{L}{\lambda}\left[1 - \frac{\tau_1}{\sqrt{2}L} + \frac{\tau_1^2}{2L^2} - \frac{\tau_2^2}{4L^2} - \frac{2L+\sqrt{2}r}{4L\left(r-\sqrt{2}L\right)^2}\left(\tau_3^2+\tau_4^2\right) - \frac{L+2\sqrt{2}r}{L\left(4r-\sqrt{2}L\right)^2}\tau_6^2\right] \tag{3}$$

were each τ_α represent the coefficients that quantify the magnitude of each deformation, L the is the unperturbed ring side length and r is the curvature radius of each mirror. The assumption of of small perturbation means that $10^{-2} < \tau_\alpha/L < 10^{-1}$. In view of this, from Eq. (3) it is clear that an accuracy of 1 part in 10^{10} on k can be reached only if the relative amplitude of E_1 deformation is 10^{-10} or less. This means that stabilizing only the diagonals length is enough to reach our purpose.

We have realized an opto-electronic system able to transfer the frequency stability of an He-Ne iodine stabilized laser to the length stability of a Fabry-Pérot cavity (the diagonals). Firstly we have tested this system on two probe cavities on optical bench[7] and then we have implemented it on GP2.[9]

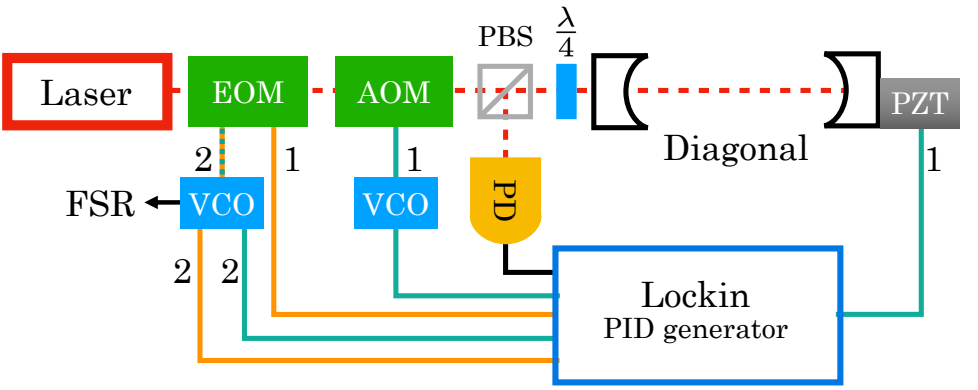

Fig. 3. Control loop scheme. Orange lines are the modulation signals, green lines are the corrections generated by the feedback system and black line is the modulated signal. Lines labeled with 1 are the first control loop and those ones with 2 are the second.

Fig. 3 shows a schematization of a control loop for a single diagonal. The control system is divided into two loops (see lines labeled with 1 and 2 in Fig. 3). The first is the one that fixes the length of the diagonal via two different actuators the piezoelectric (PZT) and the Acousto-Optic Modulator (AOM). The second one is used to measure the cavity Free Spectral Range (FSR) in order to test the control system efficiency.

The results of the measurement with this control technique are summarized in Fig. 4. The plots show the comparison between the measured Earth rotation rate estimated by the reconstructed Sagnac frequency and the Earth rotation rate

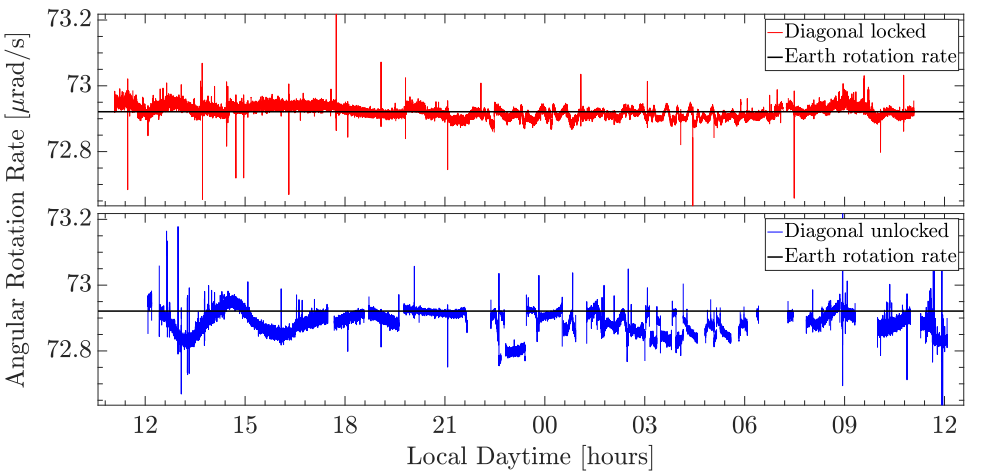

Fig. 4. Reconstructed value of Earth rotation rate from Sagnac frequency in μrad/s compared with the known value while the diagonals are locked (TOP) and free-running (BOTTOM).

nominal value. Both quantities are expressed in μrad/s. On top, the comparison when the diagonals are locked is shown, while on the bottom when the diagonals are unlocked.

A clear improvement due to the presence of the cavity stabilization system is the increase of the duty-cycle of the measurements. In our case, the duty-cycle is defined as the ratio between the period during which it is possible to reconstruct the Sagnac frequency, divided by the entire acquisition time. It is straightforward to see the effect of the stabilization on the so-defined duty-cycle. The "holes" present in the bottom plot are generated by the period of split mode of the RLG. In this condition, we have a duty-cycle of about 78%. This value increases up to 99% when we active the lock as the top plot shows. In addition, the presence of the control loop increases the effectiveness of the frequency reconstruction algorithm reducing the spread of the data with respect to the Earth rotation rate known value.

A more detailed discussion of this technique can be found in [9, 18].

2.2. *Perimeter Control*

Our studies demonstrate that the diagonal control technique is the main way to obtain the necessary stability for GR measurement. Nevertheless, we explored other geometry control methods. One of them consists of keeping fixed the ring perimeter.

There are two possible ways to measure the ring perimeter, the first consists of generating a beat-note between one of the two counter-propagating beams and a frequency stabilized laser. The second is the self-beat-note technique. If the laser inside the ring has enough power to excite the fundamental and the first longitudinal mode, using a fast photodiode we can acquire the beat-note of these two modes that

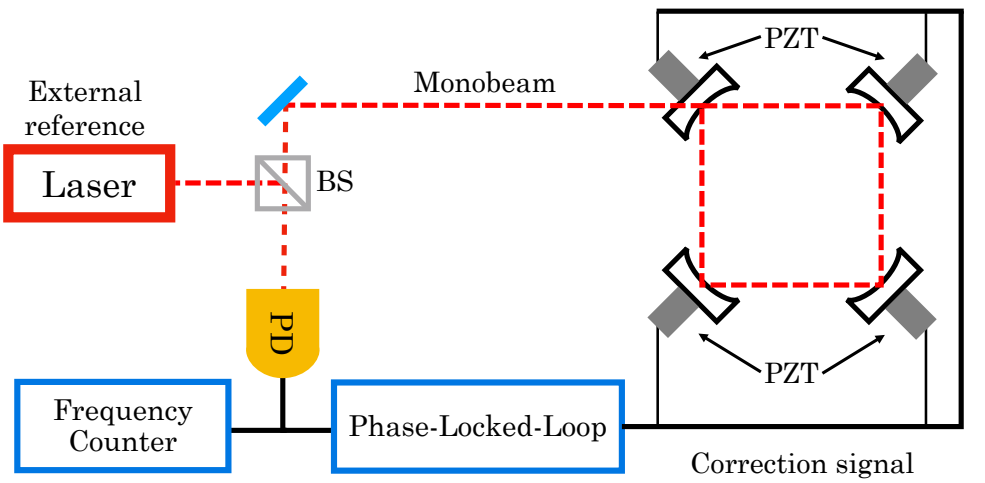

Fig. 5. Scheme of perimeter lock loop via comparison with an external laser source. The one that exploit the self-beat-note is analogous but without the Beam Splitter (BS) and the external laser.

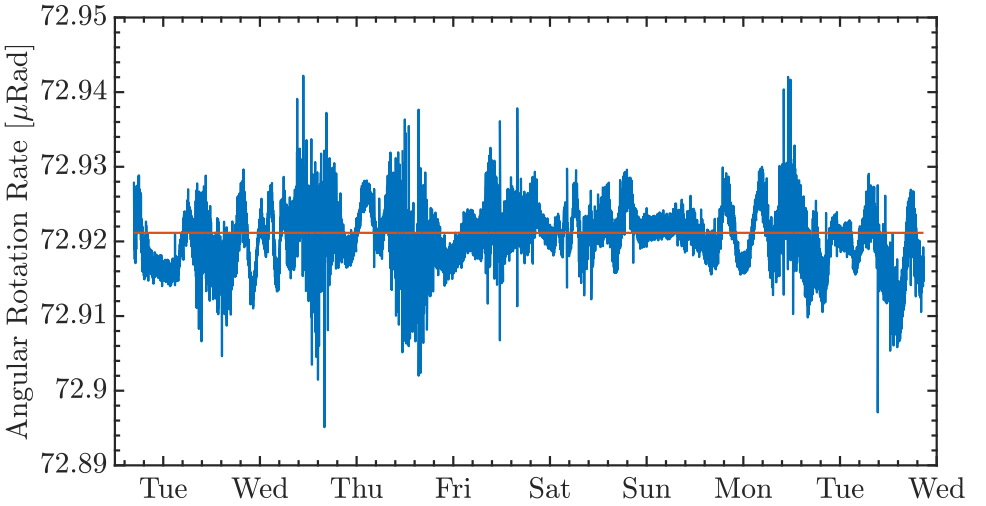

Fig. 6. Reconstructed value of Earth rotation rate from Sagnac frequency in μrad/s compared with the known value while the perimeter is locked.

is exactly the Free Spectral Range (FSR) of the cavity. This method has an intrinsic lower level of stability than the first one. So we chose the external reference laser method.

Fig. 5 shows a schematization of the perimeter control loop. The beat-note between monobeam and reference laser is acquired from a fast photodiode and sent to a frequency counter, used as a monitor, and to a Phased-Locked-Loop (PLL), used to generate the correction signal.

As in the case of diagonal control, we tested the perimeter lock loop acquiring the Sagnac frequency. Fig. 6 shows the result of this test. Also in this case we have both the benefits present in the diagonals control method. The spread of the data around the nominal value of Earth rotation rate is about 0.3‰ and the duty-cycle close to 99%.

3. Conclusions

In this work, we have shown two different methods to stabilize the geometry of a large frame RLG. The diagonal control method is the one suitable for GR application. Our mathematical model demonstrates that we can fix the scale factor value simply by controlling the diagonal length. Also, preliminary tests on GP2 showed important enhanced in the quality of the Sagnac frequency data in view of an application on a new generation device dedicated to measuring De Sitter and Lense-Thirring contribution to the Earth rotation rate.

Despite it is not the chosen one for GR measurement, also the perimeter control method has some interesting features. It is easier to realize, especially if we use the

self-beat-note technique. Moreover, as in the case of diagonal control, it increases the duty-cycle of an RLG at a level neat to 100% and it improves the Sagnac frequency data quality. Thanks to these it can be useful for the geological and geophysical application of an RLG. In this field, the requested stability is lower than the one of GR.

We present here the proposal to use the LISA interferometer for detecting the gravitomagnetic field due to the rotation of the Milky Way, including the contribution given by the dark matter halo. The galactic signal would be superposed to the gravitomagnetic field of the Sun. The technique to be used is based on the asymmetric propagation of light along the closed contour of the space interferometer (Sagnac-like approach). Both principle and practical aspects of the proposed experiment are discussed. The strategy for disentangling the sought for signal from the kinematic terms due to proper rotation and orbital motion is based on the time modulation of the time of flight asymmetry. Such modulation will be originated by the annual oscillation of the plane of the interferometer with respect to the galactic plane. Also the effect of the gravitomagnetic field on the polarization of the electromagnetic signals is presented as an in principle detectable phenomenon.

Keywords: Gravito-magnetism; Galactic halo; Sagnac effect; Space interferometers.

1. Introduction

Among the possible space-times consistent with the Einstein equations and with various matter distributions, a special interest deserve those endowed with a chiral symmetry about the time axis of a given observer. The chiral symmetry may sometime appear as a simple local coordinates artifact, in which case the symmetry disappears with an appropriate choice of the reference frame. Clearly, the most interesting situations are when the symmetry is indeed in the curvature of space-time, which happens when the source of gravity is a spinning mass distribution. In terms of the metric tensor, the presence of the symmetry we are interested in is manifested by non-null time-space off-diagonal terms. It is of course always possible to choose

a local reference frame where all off-diagonal terms are brought to zero, but this is in general not possible *globally*, when the source of gravity is spinning. In weak field conditions (the most common situation in the universe) the symmetry we are considering appears in the form of a *gravito-magnetic* field. The name derives from the fact that in weak field approximation the Einstein equations assume a form quite similar to Maxwell's equations of electromagnetism (e.m.), so that the interaction between moving masses (just as moving charges in e.m.) may be described in terms of forces due to two vector fields: the *gravito-electric* (analogous to the electric field, but always attractive), and the *gravito-magnetic* field (analogous to the magnetic field of classical e.m.). This formalism is well known and we refer to the vast literature and to basic texts of general relativity (GR): see for example Ref. [1].

It is, however, worth remarking that the gravito-magnetic force is usually much weaker than the gravito-electric one, making thus hard to identify measurable effects. So far, physically relevant phenomena associated with the aforementioned symmetry are expected, upstream of any approximation, in strong field conditions such as near Kerr black holes or, when the gravito-electromagnetic approximation is applied, in the behaviour of peculiar systems where gravity is still strong enough to allow the gravito-magnetic component to emerge in an observable way. The latter is the case of the double pulsar, whose internal dynamics, readable from the signals received by our radiotelescopes, indirectly hints to the gravito-magnetic (GM) interactions between the spins and the orbital motions of the two stars in the pair.[2]

In the Solar System, the effects due to the angular momenta of the Sun and of the planets are extremely weak. Until now the only measured effects are those of the terrestrial gravito-magnetic field. They have been observed monitoring the motion of the moon along its orbit by Laser ranging[3] and doing the same with the LAGEOS and LAGEOS2 satellites:[4] what was found was the Lense-Thirring drag[5] on their motion. Direct evidence has been obtained by the dedicated Gravity Probe B experiment which measured the induced precession on gyroscopes carried on a circumterrestrial satellite in polar orbit.[6] Laser ranging is also the main tool used to analyze the orbit of the dedicated LARES mission, which is producing the best accuracy so far for the GM field of the Earth.[7] On the surface of our planet it is expected to measure the GM field using ring lasers.[8–10]

A way to compensate for the weakness of the sought effects is to use very large sensors and measuring devices, that could not be hosted on a single spacecraft or in a laboratory on Earth. This is one of the reasons pushing toward peculiar configurations of a plurality of measuring devices in space, either around the Earth[11] or at the scale of the inner solar system.[12]

An extremely interesting opportunity is the LISA interferometer,[13] designed and under development for detecting gravitational waves. What we propose here is to use LISA, which, as we shall see, is already fit for the purpose, also to reveal the GM field in which the device is immersed. The interesting sources that could be studied

are both the solar angular momentum and the angular momentum of the Milky Way (or, to say better, the part of it which is relevant for the solar system). A further reason of interest for the galactic angular momentum is that it reasonably depends both on the visible and on the dark component of our galaxy. So far, dark matter (DM), which is an important ingredient of the cosmic cocktail, is postulated only on the basis of its direct gravitational (gravito-electric) effect. However, if DM exists and we trust GR, we may expect also phenomena related to the proper rotation of DM distributions. It is currently accepted that most galaxies (including ours) are immersed in huge DM halos; if so, it is also reasonable to expect such halos to rotate together with the visible part of the galaxy: in fact, if dark and visible interact gravitationally, any little localized inhomogeneity on one side or the other acts as a hook that drags or brakes the other component so that, after some remote transitory, both end up revolving together. The consequence is that DM should represent a relevant contribution to the angular momentum of the whole, then to the GM component of the gravitational interaction.

In what follows we outline how LISA could be used to measure both the angular momentum of the Sun and of the Milky Way. Reliable estimates of the angular momentum of the visible Milky Way exist: by difference, we could thus measure the galactic Dark content.

2. Internal space-time of the Milky Way

Globally and in the first instance we can attribute an axial symmetry to the distribution of matter of the Milky Way and imagine also that it is in uniform rotation condition (stationary space-time). If so the typical line element may be written as follows:

$$ds^2 = U(r,z)c^2dt^2 - 2N(r,z)rd\phi cdt - W(r,z)r^2d\phi^2 - Q(r,z)(dr^2 + dz^2) \qquad (1)$$

Cylindrical space coordinates have been used. An additional symmetry we assume is reflection symmetry about the galactic plane. U, N, W, Q are dimensionless functions of r and z only. They are everywhere regular (except possibly in the origin). The only constraint expressing the reflection symmetry is

$$\frac{\partial U}{\partial z}\Big|_{z=0} = \frac{\partial N}{\partial z}\Big|_{z=0} = \frac{\partial W}{\partial z}\Big|_{z=0} = \frac{\partial Q}{\partial z}\Big|_{z=0} = 0 \qquad (2)$$

Our interest is on the view point of an observer at rest with the Sun, so for the moment it is convenient to assume that the r axis is corotating with the Milky Way. This assumption does not spoil the symmetry we have assumed, but implies that the U, N, W, Q functions implicitly include also the effects of the choice of the observer (which in general treatments is assumed to be at rest with the center of the mass distribution and located at infinity, whereas here it is co-moving with the Sun).

We cannot a priori say more about the shape of the functions because we are considering an observer inside the mass distribution (visible or dark it may be) and

we do not know exact solutions of Einstein's equations within a rotating distribution of matter. Nonetheless, if we succeed in detecting specific effects of the rotation of the Milky Way, we may also deduce relevant information on the way DM is distributed. This is because the non trivial parts of the elements of the metric tensor contain the mass density of the Milky Way and the rotation curve of the stars in it: since we know how the visible mass is distributed and the rotation curve of the galaxy (which we have assumed to be the same for DM also), from the evaluation of the total GM field we may deduce relevant information on the DM density distribution, which contributes to the effect.

2.1. *Galactic gravito-magnetism*

Line element (1) is quite general, but we may equally well adopt the language and the images of the weak field, since that is indeed the case. We may also focus our attention on the situation on and near the galactic plane considering that the Sun is not far from it. This said, we read the ratio N/U as the only non-zero component of a three-vector, which is the analog of the vector potential $\bar{A}$ of classical electromagnetism.[14]

Under the above conditions, whenever the metric tensor is independent of time the equation of geodesic motion can be written in a form analogous to Lorentz's equation of e.m.

$$\frac{d^2\bar{x}}{dt^2} = -c^2\left(\bar{\nabla}U - 2\frac{\bar{v}}{c}\times\bar{\nabla}\times\bar{A}_g\right) \tag{3}$$

$\bar{v}$ and $\bar{x}$ are the three-dimensional velocity and position of the test mass with respect to the observer. The functions U and $\bar{A}_g$ are given in terms of the elements of the metric tensor $g_{\mu\nu}$ by:

$$U = g_{00};\quad A_{(g)i} = \frac{g_{0i}}{g_{00}} \tag{4}$$

In our case it is

$$\bar{A}_g = \left(0, \frac{N}{U}, 0\right)\quad \text{or}\quad \bar{A}_g = \frac{N}{U}\hat{\phi} \tag{5}$$

Here $\hat{\phi}$ is the unit transverse vector in the direction of rotations about the symmetry axis. Our space basis for covariant vectors is $(dr, rd\phi, dz)$ so that all components of $\bar{A}_g$ are dimensionless and the field lines of the vector are circles centered on the space symmetry axis, contained in planes perpendicular to that axis. The next step, formally recognizing the weak field approximation, is to calculate a *gravito-magnetic field* $\bar{B}_g$ from $\bar{A}_g$ just in the same way we would do in classical electromagnetism:

$$\bar{B}_g = \bar{\nabla}\times\bar{A}_g = \frac{N}{U}\left(\frac{\partial_z U}{U} - \frac{\partial_z N}{N}\right)\hat{r} + \frac{N}{U}\left(\frac{\partial_r N}{N} - \frac{\partial_r U}{U}\right)\hat{z} \tag{6}$$

∂_r and ∂_z are a shorthand notation for $\partial/\partial r$ and $\partial/\partial z$; each component of $\bar{B}_g$ has the dimension of the inverse of a length.

If we limit ourselves to the symmetry plane (the galactic plane) the r component of the field vanishes and the vector turns out to be perpendicular to the plane, then parallel to the axis of the Milky Way.

3. The propagation of light

In the peculiar space-time we are considering, the propagation of light displays an interesting behaviour. Whenever some physical device (mirrors, waveguides or else) constrains light to move along a closed path, the time of flight (ToF) it takes to make a full turn is different depending on whether the travel is right- or respectively left-handed. The sense of the circulation is with respect to the field lines of $\bar{B}_g$.

Actually this asymmetry is not peculiar of light only. It holds true for any signal or voyager, provided its velocity is locally the same in both directions at any position along the path.[15] The effect we are recalling is sometimes improperly called 'Sagnac effect', though the latter is an effect of special instead of general relativity and concerns the non inertial rotational motion of the observer rather than the curvature of space-time.

When considering the situation from a four-dimensional viewpoint, light leaves the source at a given event of the worldline of the observer, then comes back to the observer at a different point along its worldline: the path is of course open. When starting in the opposite direction, the light ray will meet again the observer at a different event of its worldline. Locally measuring the proper time (τ) difference between the arrivals (the length of the intercepted interval of the observer's worldline) we deduce an information concerning the proper angular momentum of the source of gravity (possibly combined with rotational motion of the observer, if it is present).

The difference in proper time can be expressed in terms of the components of the metric tensor. Using the standard notation of GR we have:[16]

$$\Delta\tau = -\frac{2}{c}\sqrt{g_{00}} \oint \frac{g_{0i}}{g_{00}} dx^i \qquad i = 1, 2, 3 \tag{7}$$

The square root of g_{00} is evaluated at the position of the observer and accounts for the gravitational field there; it does not coincide with the g_{00} under the integral sign, since the latter expresses the gravitational field along the integration path. Here x^i is a generic space coordinate and the integration is performed along the space closed contour traveled by the light beam.

Restricting the description to the space-time with the symmetries described above, and using the typical notation of gravito-electromagnetism, the time delay becomes:

$$|\Delta\tau| = \frac{2}{c}\sqrt{U} \oint A_{gi} dx^i = \frac{2}{c}\sqrt{U} \int \bar{B}_g \cdot \hat{u}_n dS \tag{8}$$

The last term on the right is obtained applying the Stokes theorem of usual three-dimensional geometry and converts the line integral into a flux; dS is the surface element of the area contoured by the closed path in space and $\hat{u}_n$ is the unit three-vector perpendicular to the given surface element.

3.1. *Galactic gravito-magnetism in the Solar System*

Our purpose is to consider an experiment carried out at the scale of the inner solar system and indeed at the Earth's orbit. The galactic GM field $\bar{B}_g$ does in fact depend on the distance from the center of the Milky Way. The Sun is approximately $R_S \cong 2.35 \times 10^{20}$m (28,000 light years) away from the center of the Milky Way. If we think of an instrument revolving around the Sun in correspondence of the orbit of our planet, its distance from the center of the Milky Way changes at most by plus or minus 1 astronomical unit (AU), i.e. $\Delta R_S \sim 3 \times 10^{11}$ m. The relative fluctuation of the distance, under these conditions, would then be $\Delta R_S/R_S \sim 10^{-9}$. Even though we have no explicit expression for the functions appearing in line element (1), just looking at what happens in electromagnetic analogies, we may reasonably expect $\Delta B_g/B_g$ to be of the same order of magnitude as $\Delta R_S/R_S$. If so, if we additionally assume such a relative change to be negligible for our purposes, it follows that in practice $\bar{B}_g$ of the Milky Way is a constant for our experiment. Under this assumption eq. (8) simplifies to:

$$|\Delta\tau| \cong \frac{2}{c}\sqrt{U}B_g S \cos\gamma \tag{9}$$

S is now the total area enclosed in the path of light, assuming that the contour is contained in a plane; γ is the angle between the perpendicular to that plane and the direction of the gravito-magnetic field of the Milky Way at the Sun. As far as the Sun may be considered to lay in the galactic plane, the direction of $\bar{B}_g$ coincides with that of the axis of the Milky Way.

If we are able to measure $|\Delta\tau|$, we may then deduce from eq. (9) information on U and in particular on N, since U, being related to the local ordinary gravitational potential, can also be obtained by other means.

4. Space interferometers and LISA

It follows from previous considerations and from eq. (9) that a good strategy to detect the presence of a gravito-magnetic field is to resort to the measurement of time asymmetries in the propagation of light; eqs. (8) and (9) show that we need a vast area S in order to enhance the sensitivity of the experiment. This is why appropriate configurations of receivers and transponders in space are particularly interesting. For instance, it has been proposed[11] to use constellations of satellites around the Earth (such as the Galileos), but even more appropriate and promising may be the opportunity to use LISA, an orbiting interferometer designed to detect gravitational waves around the mHz frequency band.

LISA will monitor the distance between pairs of free falling test masses (TM) at a distance $L = 2.5$ million km with a continuous interferometric laser ranging scheme to detect strain distance variation due to gravitational waves. The TM pairs will be lodged in three spacecraft arranged to form a big equilateral triangular constellation. So far we considered the observer as being co-moving with the Sun, but actually the plane of the LISA constellation will form an angle $\beta = 30^o$ with the ecliptic plane and that plane is at an angle $\alpha \simeq 60^o$ with respect to the galactic plane; the whole constellation will rotate around the Sun at a distance of 1 AU, lagging by 20^o the orbit of the Earth; it will also rotate on its plane, around the center of mass, with the same 1 year period. The geometry of such configuration is shown in Fig. 1.

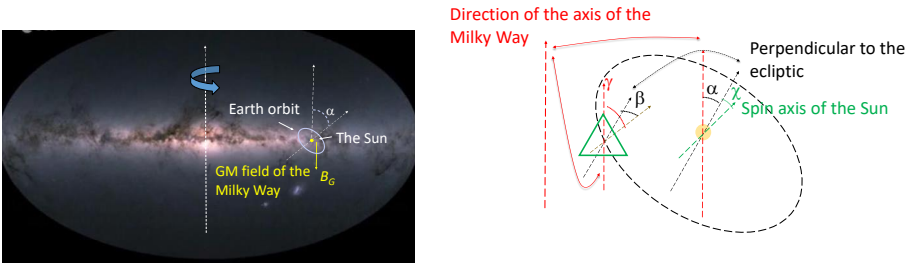

Fig. 1. The LISA interferometer in the Milky Way. a) (left) Freely falling constellation in the terrestrial orbit. b) (right) Orientation of the triangular constellation with respect to the galaxy and to the ecliptic.

Keplerian dynamics causes, in the yearly rotation period, changes of up to 10^4 km in armlength and 10 m/s in spacecraft velocity: this phenomenon, called *flexing* of the arms, forbids equal path interferometry. However, the use of post-processing techniques (Time Delay Interferometry: TDI)[17,18] allows to synthesise equal arm interferometry to better than 1 ns. Among TDI combinations there are several that mimic the output of a Sagnac interferometer,[19,20] thus suppressing the GW signals. By interfering electromagnetic signals traveling in opposite directions along the LISA triangle, we could measure the ToF difference at one of the corners: Eq. (8) will then allow us to deduce the intensity of the gravito-magnetic flux through the interferometer.

In the reference frame comoving with the spacecraft, $\bar{B}_g$ will contain various contributions including those due to the proper and orbital motion of the device (Sagnac effect). The components of interest would be the galactic contribution (both from visible and dark matter) and the gravito-magnetic field originating from the angular momentum of the Sun. In principle also the Earth and other planets would contribute, but it is easily verified that those components would indeed be much weaker than the galactic and solar ones.

4.1. *Gravito-magnetism from the Sun*

The GM field of the Sun, $\bar{B}_{g\odot}$, has a simple form, as long as our star is treated as a compact spherical spinning source. The configuration of the field is dipolar and in the solar equatorial plane, where $\bar{B}_{g\odot}$ is perpendicular to the plane, it is (net of kinematic contributions, i.e. for a non-rotating observer in a Sun-centered reference frame)[8]

$$\bar{B}_{g\odot} = \frac{2G}{c^3 r^3}\bar{J}_{\odot} = 2.8 \cdot 10^{-28}\mathrm{m}^{-1} \tag{10}$$

G is Newton's constant and $\bar{J}_{\odot}$ is the angular momentum of the Sun; r is the observer's distance from the center of the star.

In our approximation, we can take $U = 1 - 2\frac{GM_{\odot}}{c^2 r} \simeq 1$, and the ToF asymmetry, for the solar effect alone, would then be:

$$|\Delta\tau|_{\odot} \simeq \frac{2}{c}\int |\bar{B}_{g\odot}| \cos\eta dS \simeq \frac{4G}{c^4}\int \frac{|\bar{J}_{\odot}|}{r^3}\cos\eta dS \tag{11}$$

The flux is calculated over the LISA triangle: actually, the area of the constellation is tilted with respect to the ecliptic, and this has two consequences: 1) part of the area is slightly above and part slightly below the ecliptic plane so that there $\bar{B}_{g\odot}$ has also a small radial component; and 2) the three spacecrafts have different instantaneous distances from the Sun ($\delta r/r \lesssim 0.6\%$) and therefore experience a different strength of the dipolar field. In the following, we shall neglect, for sake of simplicity, both corrections. η is the angle between the normal to the plane of the triangle and the axis of the Sun. Since the latter is in turn inclined with respect to the north of the ecliptic[21] by the angle $\chi \simeq 7^{\circ}$, η changes periodically during the year oscillating between $\eta_{min} = \beta - \chi$ and $\eta_{max} = \beta + \chi$; β and χ are shown in Fig. 1b.

5. Proposed measurements

The experiment we would like to consider uses LISA as the triangular closed path along which e.m. signals are sent in opposite directions, in order to measure the ToF difference. Letting, for the moment, all practical problems aside, we note a multiplicity of contributions simultaneously acting upon the interferometer. GR is a non-linear theory so that, in principle, it is not an easy task to disentangle the various terms. In particular, beside the solar and galactic contribution, we have the kinematic terms related to the rotational movements of the configuration, i.e. the proper rotation of the triangle, its orbital motion around the Sun and the rotation of the Sun about the axis of the Milky Way. These kinematic terms may legitimately be considered as manifestations of the Sagnac effect; in a treatment that wanted to be "exact" all terms (both kinematic signals and "physical" i.e. GM terms)

combine non-linearly with each other, so that it is extremely difficult to distinguish them. Fortunately, the fact that all effects are small or very small (the GM terms are expected to be much weaker than the kinematic ones) helps us, in the sense that in an approximate treatment we are allowed to truncate the expansion at the lowest order. Indeed the lowest approximation is the linear one where a simple superposition principle is applied.

Even accepting the linear approximation, the problem remains of separating the different addends of the sum. This separation would be possible if we knew at least the kinematic terms with an accuracy better than the size of the unknown "physical" contributions. This is a difficult task, because the gravitomagnetic effect is expected to be many orders of magnitude smaller than the Sagnac effect; we need some sort of signature that highlights the terms of interest and the "marking" we may exploit is the time dependence of the signals. Looking at Fig. 1b we see that our triangle oscillates yearly with respect to the galactic plane between an angle $\gamma_{max} \simeq \alpha + \beta$ and an angle $\gamma_{min} \simeq \alpha - \beta$, where $\alpha \simeq 60^o$ is the angle between the ecliptic and galactic planes. The oscillation is not simply sinusoidal and we use $\simeq$ instead of just $=$ because the axes of the Milky Way, of the ecliptic and of the LISA triangle never turn out to be exactly co-planar. Furthermore, when looking at the solar contribution, we find the already mentioned oscillation with respect to the solar spin axis.

Thus, both GM contributions exhibit yearly periodicity but with a different phase, whereas the Sagnac effect is nearly constant with small harmonic components (including the yearly one) due to flexing, which can be, in principle, calculated and subtracted.

As for the detectable signal, we may estimate its minimal amplitude for the Sun GM from eq. (11), with a LISA constellation area, neglecting the above mentioned oscillations, $S = (\sqrt{3}/4)L^2 \simeq 2.7 \times 10^{18}\mathrm{m}^2$. The target displacement sensitivity for LISA, is $c|\Delta\tau_{min}| \sim 10^{-11}$ m. With this sensitivity both the solar GM and the galactic one should be detectable by LISA (see Fig. 2), although with marginal signal to noise ratio.

Eq. 9 shows that the minimum detectable GM field would then be

$$B_{(min)} \sim 1.8 \times 10^{-30}\mathrm{m}^{-1} \tag{12}$$

In order to see what this number means, consider that the terrestrial GM field on the surface of the Earth (at the equator) is $\sim 10^{-22}\mathrm{m}^{-1}$. Proper Sagnac terms (which depend on the angular velocities around the Sun, around the constellation center and around the galactic center) are many orders of magnitude larger than the value in eq.(12), whereas the solar contribution is only a factor 100 above the minimum detectable signal. On the basis of estimates of the angular momentum of the visible mass, the galactic GM field is expected to be just above the edge of detectability.

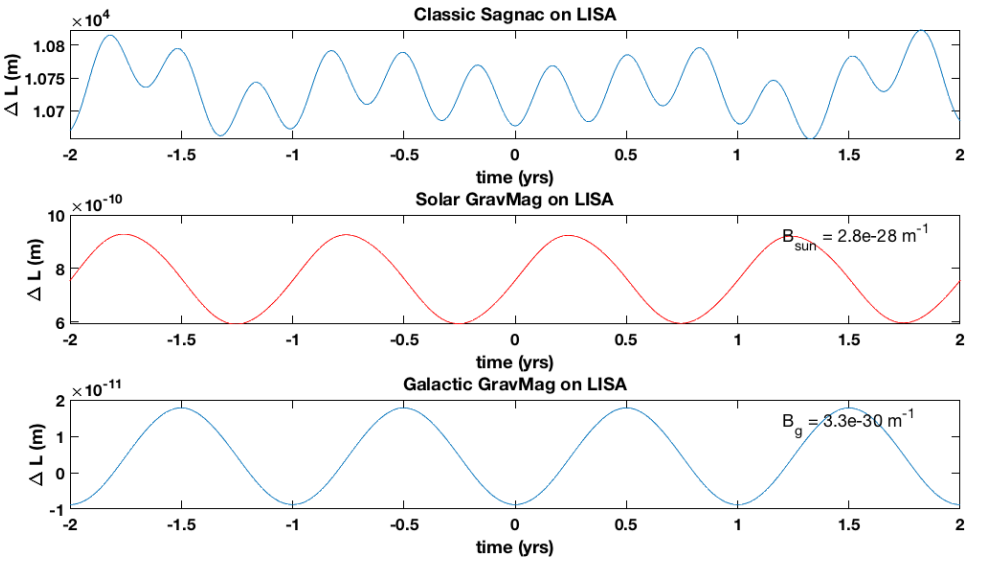

Fig. 2. Time dependence of the expected signals (expressed as lengths) on a noiseless LISA constellation:
TOP: Sagnac effect, due to the triangle rotations both around the Sun and around its center. The signal has an almost constant value, with small ($\sim 1\%$) oscillations due to the flexing of the arms and ensuing change of the area.
MIDDLE: GM effect from the Sun; the yearly modulation is due to the inclination of $J_\odot$ with respect to the ecliptic.
BOTTOM: signal from the galactic Gravito Magnetism; this measurement would be performed *within* the source mass current, and no certainties can be offered about its strength. We hypothized, for this plot, a field $B_{MW} = 3 \cdot 10^{-30} m^{-1}$, neglecting the contribution of the external part of the Milky Way (that would actually act to reduce this strength).

6. GM effect on light polarization

The only GM effect we have considered so far is the asymmetry in the ToF of light, but there are other consequences to be considered. The analogy with classical e.m. suggests that we may also expect the analog of the Faraday effect. In other words, if a linearly polarized light beam propagates along the field lines of a GM field the direction of the polarization vector should rotate around the direction of the propagation.[23]

Using the formalism of GR, the electromagnetic field is described (in four dimensions) by the so called Faraday anti-symmetric tensor $F_{\mu\nu}$ and, regardless of any approximation, when there is propagation producing a four-dimensional area $\delta S^{0i} = (\delta\tau \delta x^i) = (\delta x^i)^2/c$ (movement along the direction of x^i at the speed of light) the corresponding change in $F_{\mu\nu}$ is

$$\delta F^{\mu\nu} = (R^\mu_{\epsilon 0 i} F^{\epsilon\nu} + R^\nu_{\epsilon 0 i} F^{\mu\epsilon}) \delta S^{0i} \tag{13}$$

$R^\mu_{\nu\lambda\rho}$ are the components of the Riemann tensor which account for the curvature of space-time.

Whenever the propagation takes place over a distance l in a direction non-perpendicular to the GM field, the change in the Faraday tensor corresponds to a rotation of the polarization vector of the wave around the propagation line by an angle ψ:[23]

$$\psi \simeq -\frac{\sqrt{g_{00}}}{2}\bar{B}_g \cdot \bar{l} = \pm\frac{l}{2}\frac{N}{\sqrt{U}}\left(\frac{\partial_r N}{N} - \frac{\partial_r U}{U}\right) \tag{14}$$

The last expression in Eq. (14) refers to the case of the Milky Way and uses the notation introduced in Eq. (6) applied on the galactic plane and for light travelling in a direction perpendicular to that plane.

The solar GM will produce, in any LISA arm, a rotation of the polarization plane of $\sim 3 \cdot 10^{-19}$ prad. The two laser beams propagating in each arm in opposite directions would undergo opposite rotations. In principle the effect would cumulate with the laser beam going around the constellation if the transmission of the light from satellite to satellite preserves the polarization. LISA will use linearly polarized light for the strain measurements. The unwanted polarisation component present in the received beam will be removed, when entering the measurement chain, by a PBS (polarising beam splitter); this fraction, containing the GM signal, could be in principle detected by an additional, dedicated photo diode. In fact, in the LISA-Pathfinder (LPF) mission it has been observed that, because of non perfect performance of the PBS, part of this light can still contaminate the strain measurement, yielding additional noise in the form of read-out noise and spurious laser pressure. Thus the GM rotation effect in LISA would possibly result in a decreased sensitivity of the observatory. That signal could be reconstructed in post-processing, as it was done in LPF, using a well shaped model of the measurement chain.[22]

7. Conclusion

We have discussed the relevant sources that could contribute to the gravito-magnetic field in the solar system far from the planets and within 1 AU from the Sun. In particular we have considered the relevance of the field in producing an asymmetry in the propagation of electromagnetic signals along closed space paths. We have then discussed the possibility to use the big triangle formed by the LISA satellite constellation applying an approach similar to that of the Sagnac effect.

A quantitative evaluation of the effects shows that the sensitivity of such an arrangement would be sufficient to measure the solar GM field. Such measurement would give an important information on the internal structure of the Sun, from which the angular momentum of our star depends. But LISA, used *à la Sagnac*, would probably be able to reveal the weak GM field of the Milky Way as well. This is increasingly interesting and important since the galactic gravitomagnetism depends of course on the distribution of visible matter in the Milky Way, but also,in a non marginal way, on the presence of dark matter, that, on the whole, is expected to have a mass much greater than that visible.

The GM field also causes a rotation of the polarization of the e.m. signals that will travel along the arms of the interferometer. The effect is tiny, and its detection is extremely challenging, but should in principle be considered, in view of future technological advances. This would yield additional and complementary information on the intensity of the field.

LISA will send its "raw" data to Earth, to be off-line processed and syntethized in interferometric signals: in view of this strategy, pursuing the search for GM signatures on the data, a challenging, though not impossible task, should require no further hardware development, and no additional task for the mission.

For these reasons and for the importance of the objectives pursued it would be worthwhile to carry out the experiment.

Geometric optics approximation is sufficient to describe the effects in the near-Earth environment. In this framework Faraday rotation is purely a reference frame (gauge) effect. However, it cannot be simply dismissed. Establishing local reference frame with respect to some distant stars leads to the Faraday phase error between the ground station and the spacecraft of the order of 10^{-10} in the leading post-Newtonian expansion of the Earth's gravitational field. While the Wigner phase of special relativity is of the order 10^{-4}–10^{-5}. Both types of errors can be simultaneously mitigated by simple encoding procedures. We also present briefly the covariant formulation of geometric optic correction up to the subleading order approximation, which is necessary for the propagation of electromagnetic/gravitational waves of large but finite frequencies. We use this formalism to obtain a closed form of the polarization dependent correction of the light ray trajectory in the leading order in a weak spherically symmetric gravitational field.

Keywords: Geometric optics; Wigner phase; Gravitational Faraday rotation; Post-Newtonian expansion; Gravitational spin Hall effect.

1. Introduction

Space deployment of quantum technology[1–3] brings it into a weakly relativistic regime. As an unintended but fortunate side effect, low-Earth orbit (LEO) quantum communication satellites provide new opportunities to test fundamental physics. Once the tiny putative physical effects fall within the sensitivity range of these devices, they may impose constraints on practical quantum communications, timekeeping, or remote sensing tasks.[4–6] A more futuristic technology, such as the proposed solar gravity telescope[7–9] actually needs the general-relativistic effects for its operation.

For flying qubits that are implemented as polarization states of photons[10] the dominant source of relativistic errors in this setting is the Wigner rotation (or phase), an effect special relativity (SR).[4,6] Gravitational polarization rotation, also known as the gravitational Faraday effect[11,12] occurs in a variety of astrophysical systems, such as accretion disks around astrophysical black hole candidates[13] or gravitational lensing.[14] This effect was the subject of a large number of theoretical investigations, primarily within the geometric optics approximation,[11,12,14–17] and also from the perspective of quantum communications.[18] Interpretation of these results was until recently sometimes contradictory, as it is important to carefully analyze the relation between the reference frames of the emitter and the detector. Moreover, even if at the leading order the gravitationally induced polarization

rotation in the near-Earth environment is pure gauge effect, it cannot be simply dismissed. We provide a simple estimation of this emitter- and observer-dependent phase and give its explicit form in several settings.

Already in the leading post-eikonal order trajectories of light beams are affected by polarization.[19–21] The optical gravitational spin Hall effect has recently received a comprehensive treatment in Refs. 22, 23. Using this formalism we obtain a closed form of the leading correction in case of a weak spherically symmetric gravitational field. As expected, on the scale of the Solar system — be it the near-Earth environment or a focal plane of the solar gravity telescope at 600a.u.— the effect is negligible. However, it is interesting conceptually and its scaling indicates that it may play a much more important role in the strong gravity regions.[23]

The rest of this article is organized as follows. In Sec. 2 we review the SR effects. Polarization rotation in general stationary spacetimes is described in Sec. 3, where we also evaluate the effects in communication with Earth-orbiting satellites. In Sec. 4 we briefly summarize the main techniques of Refs. 22, 23 and then obtain the polarization-dependent changes in the light ray trajectories in the solar system experiments.

We work with $c = \hbar = G = 1$. The constants G and c are restored in a small number of expressions where their presence is helpful. The spacetime metric $g_{\mu\nu}$ has a signature $-+++$. The four-vectors are distinguished by the sans font, k, $k^\mu = (\mathsf{k})^\mu$. The three-dimensional spatial metric is denoted as γ_{mn}, and three-dimensional vectors are set in boldface, $\mathbf{k}$, or are referred to by their explicit coordinate form, k^m. The inner product in the metric γ is denoted as $\mathbf{k}\cdot\mathbf{f}$, and the unit vectors in this metric are distinguished by the caret, $\hat{\mathbf{k}}$, $\hat{\mathbf{k}}\cdot\hat{\mathbf{k}} \equiv 1$. Post-Newtonian calculations employ a fiducial Euclidean space. Euclidean vectors are distinguished by arrows, $\vec{k}$. Components of the two types of vectors may coincide, $(\mathbf{v})^m = (\vec{b})^m$, but $\vec{b}\cdot\vec{k} = \sum_{k=1}^{3} v^m k^m$. Accordingly, the coordinate distance is the Euclidean length of the radius vector, $r \equiv \sqrt{\vec{x}\cdot\vec{x}}$.

2. Wigner rotation and special relativistic effects

Consider one round of communications between the ground station (GS) and a low energy orbit spacecraft (SC). The problem is most conveniently analyzed in the geocentric system, the origin of which coincides with the centre of the Earth at the moment of emission. If we direct the z-axis of the system along the Earth's angular momentum, then the velocity $\mathbf{v}$ of the GS lies in the xy-plane. Whereas, the velocity $\mathbf{u}$ of the SC and the initial propagation direction $\hat{\mathbf{k}}$ are arbitrary when expressed in the global frame. This setting is depicted in Fig. 1.

Quantum states of a photon with a definite four-momentum $\mathsf{k} = (|\mathbf{k}|, \mathbf{k})$ can be represented either as Hilbert space vectors or as complex polarization vectors in the usual three-dimensional space,

$$|\Psi_{\mathsf{k}}\rangle = f_+|\mathsf{k},+\rangle + f_-|\mathsf{k},-\rangle \quad \Leftrightarrow \quad \hat{\mathbf{f}}_{\mathbf{k}} = f_+\hat{\mathbf{b}}^+_{\hat{\mathbf{k}}} + f_-\hat{\mathbf{b}}^-_{\hat{\mathbf{k}}}, \tag{1}$$

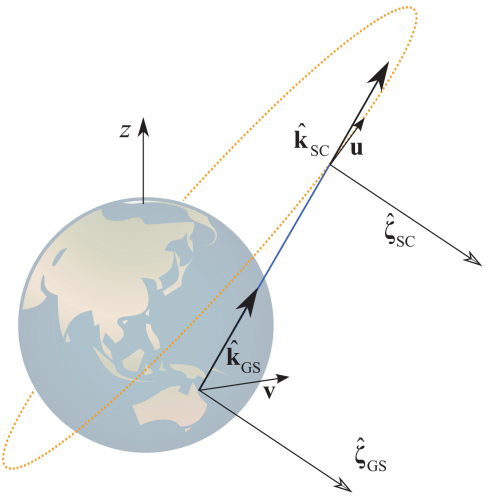

Fig. 1. Scheme of the communication round between the ground station (GS) and the spacecraft (SC). The light ray is highlighted in blue. All the vectors are indicated in the Earth-centered inertial frame. In the flat spacetime approximation the unit tangent vectors to the ray $\hat{\mathbf{k}}_{GS}$ and $\hat{\mathbf{k}}_{SC}$ at the GS and the SC, as well as the direction to an infinitely distant guide star, $\hat{\boldsymbol{\zeta}}_{GS}$ and $\hat{\boldsymbol{\zeta}}_{SC}$, respectively coincide. Velocity of the GS at the emission of the signal is $\mathbf{v}$ and velocity of the SC at the moment of detection is $\mathbf{u}$.

with the transversal vectors $\hat{\mathbf{b}}^{\pm}_{\hat{\mathbf{k}}}$, $\mathbf{k}\cdot\hat{\mathbf{b}}^{\pm}_{\hat{\mathbf{k}}}=0$. The correspondence is rooted in the relationship between finite-dimensional and unitary representations of the Poincaré group.[24,25]

Unitary operators U that describe the state transformation between the Lorentz frames are obtained via the induced representation of the Poincaré group. Basis states that correspond to an arbitrary momentum $(\mathsf{k})^{\mu}\equiv k^{\mu}$ are defined with the help of standard Lorentz transformation $L(k^{\mu})$, that takes the four momentum from the standard value k^{μ}_{S} to k^{μ}. For massless particles, $k^{\mu}_{\mathrm{S}}=(1,0,0,1)$ and

$$L(k^{\mu})=R(\hat{\mathbf{k}})B_z(\xi_{|\mathbf{k}|}), \tag{2}$$

where $R(\hat{\mathbf{k}})=R_z(\phi)R_y(\theta)$ rotates the z-axis into the direction $\hat{\mathbf{k}}$ by performing rotations around the y- and z-axis by angles θ and ϕ, respectively. These rotations follow the boost $B_z(\xi_{|\mathbf{k}|})$ along the z-axis, that brings the magnitude of momentum to $|\mathbf{k}|$.

The states of an arbitrary momentum are defined via

$$|\mathsf{k},\pm\rangle:=U\big(L(\mathsf{k})\big)|\mathsf{k}_{\mathrm{S}},\pm\rangle, \tag{3}$$

while the standard right- and left-circular polarization vectors are defined as

$$\hat{\mathbf{b}}^{\pm}_{\hat{\mathbf{k}}}:=R(\hat{\mathbf{k}})(\hat{\mathbf{x}}\pm i\hat{\mathbf{y}})/\sqrt{2}, \tag{4}$$

where the linear polarization vectors are $\hat{\mathbf{b}}_1:=R(\hat{\mathbf{k}})\hat{\mathbf{x}}$ and $\hat{\mathbf{b}}_2:=R(\hat{\mathbf{k}})\hat{\mathbf{y}}$, respectively.

Alternatively, these vectors can be obtained as

$$\hat{\mathbf{b}}_2 = \frac{\hat{\mathbf{z}} \times \hat{\mathbf{k}}}{|\hat{\mathbf{z}} \times \hat{\mathbf{k}}|}, \qquad \hat{\mathbf{b}}_1 = \hat{\mathbf{b}}_2 \times \hat{\mathbf{k}}. \tag{5}$$

The explicit form of the polarization four-vector f_k, $\mathsf{f}_\mathsf{k} \cdot \mathsf{k} = 0$ depends on the gauge.[4, 18, 26]

Under arbitrary Lorentz transformation, states transform (apart from the normalization factor) via

$$U(\Lambda)|\mathsf{k}, \pm\rangle = U(\Lambda L(\mathsf{k}))|\mathsf{k}_\mathrm{S}, \pm\rangle = U(L(\Lambda\mathsf{k}))U(W)|\mathsf{k}_s, \pm\rangle, \tag{6}$$

where the transformation $W = L^{-1}(\Lambda\mathsf{k})\Lambda L(\mathsf{k})$ to the subgroup (Wigner's little group) group that leaves k_s invariant,

$$U(W)|\mathsf{k}_\mathrm{S}, \sigma\rangle = \sum_{\pm'} D(W)_{\sigma\sigma'}|\mathsf{k}_\mathrm{S}, \sigma'\rangle. \tag{7}$$

The matrices $D(W)_{\sigma\sigma'}$ form the representation of the little group. For massless particles an element of the little group W can be decomposed as

$$W = SR_z(\varpi), \tag{8}$$

where S is a translation in the (xy)-plane and $R_z(\varpi)$ a rotation. As translations do not contribute to the physical degrees of freedom of photons, the state $|\mathsf{k}, \pm\rangle$ transforms as

$$U(\Lambda)|\mathsf{k}, \pm\rangle = e^{\pm i\varpi}|\Lambda\mathsf{k}, \pm\rangle. \tag{9}$$

There are no generic explicit expressions for ϖ. Their evaluation is not considerably simpler if $\Lambda = \mathcal{R}$, where $\mathcal{R}$ is a rotation (as there is no risk of confusion we use the same designation for the four-dimensional matrices of spatial dimensions and for their 3×3 blocks). However, as the transformation law of $\hat{\mathbf{f}}$ can be obtained from the three-dimensional form of the Lorentz transformations of the transversal electromagnetic wave, in this case[4, 27]

$$U(\mathcal{R})|\Psi_\mathsf{k}\rangle \Leftrightarrow \mathcal{R}\hat{\mathbf{f}}_\mathbf{k}. \tag{10}$$

Moreover, an arbitrary rotation around the direction $\hat{\mathbf{b}}_2$, $R_{\hat{\mathbf{b}}_2}(\alpha)$, does not introduce a phase ϖ.[16] This provides the motivation for introduction of the so-called Newton gauge that we review below.

In communications with the Earth-orbiting satellites settings of Fig. 1 the Wigner phase is the dominant relativistic effect.[28] While the Wigner phase is of the order 10^{-4}–10^{-5}, we will see below that establishing the local reference frame with respect to some distant stars leads to the Faraday phase error of the order of 10^{-10}.

3. Faraday rotation and general relativistic effects

Here we describe the effects of gravity on polarization in the geometric optics approximation, wave it can be considered a vector that is simply affected by the geodesic motion of null particles to which it is attached. We present the gravitational Faraday effect in a way that clearly separates the gauge-independent part from the effects of the reference frame choices[16] and is convenient for the near-Earth calculations that use the post-Newtonian approximation. Then we demonstrate that at the leading order the polarization rotation is a purely gauge effect and evaluate it for a practically useful choice of the reference frames.

The equation of geometric optics are obtained by performing the short wave expansion of the wave equation in the Lorentz gauge,[29,30]

$$A^{\mu} = a^{\mu} e^{i\psi}, \tag{11}$$

where a^{μ} is the slowly varying complex amplitude and ψ is the rapidly varying real phase. In later calculations, we use the wave vector $k_{\mu} := \psi_{,\mu}$, the squared amplitude $a = (a^{\mu *} a_{\mu})^{1/2}$ and the polarization vector $f^{\mu} = a^{\mu}/a$ is transverse to the trajectory, $f^{\mu} k_{\mu} = 0$.

The eikonal equation

$$g^{\mu\nu} \frac{\partial \psi}{\partial x^{\mu}} \frac{\partial \psi}{\partial x^{\nu}} = 0, \tag{12}$$

is the leading term in the expansion of the wave equation[29,30] is the Hamilton-Jacobi equation for a free massless particle on a given background spacetime. It allows description of light propagation in terms of fictitious massless particles.

The wave vector k_{μ}, which is normal to the hypersurface of constant phase is null $k^{\mu} k_{\mu} = 0$, and is geodesic

$$k^{\mu} \nabla_{\mu} k^{\nu} = 0, \tag{13}$$

as it is the gradient of a scalar function. Similarly, the polarization vector f^{μ} is parallel propagated along it

$$k^{\mu} \nabla_{\mu} f^{\nu} = 0. \tag{14}$$

A convenient three dimensional representation of the evolution of polarization vectors is possible in stationary spacetimes. Static observers follow the congruence of timelike Killing geodesics that define projection from spacetime manifold $\mathcal{M}$ onto the three dimensional space Σ_3, $\Pi : \mathcal{M} \to \Sigma_3$. The metric $g_{\mu\nu}$ on $\mathcal{M}$ can be written in terms of three dimensional scalar h, a vector $\mathbf{g}$ with component g_m and a metric γ_{mn} on Σ_3 as

$$ds^2 = -h \left(dx^0 - g_m dx^m \right)^2 + dl^2, \tag{15}$$

where $h = -g_{00}$, $g_m = -g_{0m}/g_{00}$, and the three dimensional distance $dl^2 = \gamma_{mn} dx^m dx^n$, where

$$\gamma_{mn} = g_{mn} - \frac{g_{0m} g_{0n}}{g_{00}}. \tag{16}$$

Using the relationships between the three and four dimensional covariant derivatives, the propagation equations in a stationary spacetimes result in the following three dimensional equations

$$\frac{D\hat{\mathbf{k}}}{Ds} = \mathbf{\Omega} \times \hat{\mathbf{k}}, \qquad \frac{D\hat{\mathbf{f}}}{Ds} = \mathbf{\Omega} \times \hat{\mathbf{f}}, \tag{17}$$

where D/Ds is the covariant derivative in three dimensional space with metric γ_{mn}. Thus, both the polarization and propagation vectors are rigidly rotated with an angular velocity

$$\mathbf{\Omega} = 2\boldsymbol{\omega} - (\boldsymbol{\omega}.\hat{\mathbf{k}})\hat{\mathbf{k}} - \mathbf{E}_g \times \hat{\mathbf{k}}, \tag{18}$$

where $\boldsymbol{\omega}$ and $\mathbf{E}_g$ could be interpreted as the gravitoelectric and gravitomagnetic field respectively

$$\boldsymbol{\omega} = -\frac{1}{2} k_0 \nabla \times \mathbf{g}, \qquad \mathbf{E}_g = -\frac{\nabla h}{2h}. \tag{19}$$

In flat spacetimes, polarization basis is uniquely fixed by the Wigner little group construction. However, in general curved background, Wigner construction must be performed at every point. This is because, in the absence of a global reference direction, the standard polarization triad $(\hat{\mathbf{b}}_1, \hat{\mathbf{b}}_2, \hat{\mathbf{k}})$ is different at every locations. Given such choice, the net polarization can be found by starting with the initial polarization $f_{\text{fin}}(x_{\text{in}})$, parallel propagating it according to the rule Eq. (17) and then using the decomposition

$$f_{\text{fin}}(x_{\text{fin}}) = \cos\chi \hat{\mathbf{b}}_1 + \sin\chi \hat{\mathbf{b}}_2, \tag{20}$$

to read off an angle. For Schwarzschild spacetime, $\boldsymbol{\omega} = 0$, and thus differentiation of this equation gives

$$\frac{d\chi}{ds} = \frac{1}{\hat{\mathbf{f}} \cdot \hat{\mathbf{b}}_1} \hat{\mathbf{f}} \cdot \frac{D\hat{\mathbf{b}}_2}{Ds}. \tag{21}$$

This equation implies that polarization rotation is a pure gauge effect. The phase remains zero if the standard directions are set with the help of the local free fall acceleration $\mathbf{w}$ of a stationary observer. At each point in the spacetime we choose the direction of the standard reference momentum, or equivalently the z-axis of our standard polarization triad, to be $\hat{\boldsymbol{\zeta}} := \mathbf{w}$. For a photon with momentum $\mathbf{k}$ we choose the linear polarization vector $\hat{\mathbf{b}}_2$ to point in the direction $\hat{\boldsymbol{\zeta}} \times \hat{\mathbf{k}}$, and finally we choose $\hat{\mathbf{b}}_1 := \hat{\mathbf{b}}_2 \times \hat{\mathbf{k}}$ such that it completes the orthonormal triad $(\hat{\mathbf{b}}_1, \hat{\mathbf{b}}_2, \hat{\mathbf{k}})$. This construction is known as the Newton gauge.[16] With this convention $\mathbf{\Omega} = -\mathbf{E}_g \times \mathbf{k} \equiv \Omega \hat{\mathbf{b}}_2$ and thus $\chi \equiv 0$ along the trajectory. However, such choice of standard polarization direction is practically unfeasible. We will see below the consequences of setting the z-axis with the help of a guide star.

Electromagnetic radiation and massless particles are not affected by Newtonian gravity. The post-Newtonian expansion[31] is conveniently organized in powers of $\epsilon^2 \sim GM/c^2\ell \sim v^2/c^2$, where $-GM/\ell$ is the (maximal) typical potential and v is

a typical velocity of massive particles. The parameter ϵ helps to keep track of the orders and is set to unity at the end of the calculations. The leading post-Newtonian contributions are of order ϵ^2; to take gravitomagnetic effects into account, we need contributions up to ϵ^3.

The post-Newtonian expansion of the metric near a single slowly rotating quasi-rigid gravitating body, up to ϵ^3, assuming that the underlying theory of gravity is general relativity is

$$ds^2 = -V^2(r)c^2dt^2 + \vec{R}\cdot d\vec{x}cdt + W^2(r)d\vec{x}\cdot d\vec{x}, \tag{22}$$

where

$$V(r) = 1 - \epsilon^2\frac{U}{c^2}, \qquad W(r) = 1 + \epsilon^2\frac{U}{c^2}. \tag{23}$$

The Newtonian gravitational potential $-U = -GMQ(r,\theta)/r \simeq -GM/r$ depends on the mass M and the higher order multipoles. The frame-dragging term is

$$\vec{R} = -\epsilon^3\frac{4G}{c^3}\frac{\vec{J}\times\vec{x}}{r^3}, \tag{24}$$

where $\vec{J}$ is the angular momentum of the rotating body. Hence, we see that the gauge invariant polarization rotation is absent in the leading order post-Newtonian expansion and the Faraday phase at order ϵ^2 is a reference frame effect. We again revert to the units $G = c = 1$. To obtain leading order contributions to the phase and polarization, photon trajectories only need to be expanded up to ϵ^2

$$\vec{k} = \vec{n} - \epsilon^2\frac{2M}{r(t)}\vec{n} - \epsilon^2\frac{2M\vec{d}}{d^2}\left(\frac{\vec{x}(t)\cdot\vec{n}}{r(t)} - \frac{\vec{x}_0\cdot\vec{n}}{r_0}\right), \tag{25}$$

where $\vec{x}(t) = \vec{x}_0 + (t-t_0)\vec{n} + \mathcal{O}(\epsilon^2)$ and $\vec{d} = \vec{x}_0 - (\vec{x}_0\cdot\vec{n})\vec{n}$ is the vector joining the centre of the earth and the point of closest approach of the unperturbed ray. Here, $\vec{n}$ is the initial propagation direction, $\vec{n}\cdot\vec{n} = 1$.

The leading order post-Newtonian metric is spherically symmetric. Note that the initial polarization that is perpendicular to the propagation plane remains perpendicular to it. So, we select the reference frame differently from that we have done in special relativistic calculations. Here we focus only on gravitational effects and treat them separately from the effects of rotation and relative motion. We take $z = 0$, the plane where the ray from GS to SC lies, set their velocities zero and consider the polarization vector

$$\vec{f} = (0,0,1) = \text{const}. \tag{26}$$

The gauge dependent Faraday phase results from the change in the definitions of standard polarization directions along the trajectory. The reference directions $\hat{\boldsymbol{\zeta}}_i$ (unit vector pointing to the distant star), $i =$ GS, SC are obtained from the tangents to the rays from the fixed guide star that arrive to the GS and SC respectively.

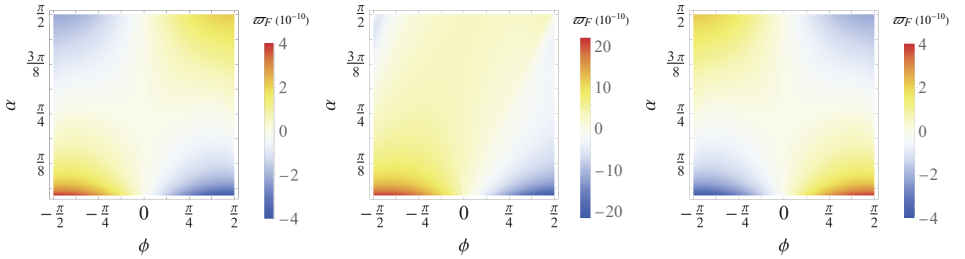

Fig. 2. Faraday phase $\varpi_{\rm F}$ depends on the choice of the reference direction $\vec{\zeta}(\alpha,\beta)$ and the initial propagation direction $\vec{n}(\phi)$. The angles are defined in Eqs. (31) and (32). *(left)* $\beta = 0$. *(center)* $\beta = 7\pi/16$. *(right)* $\beta = \pi$.

We assume the reference star to be infinitely far. Approximating the differences in reference directions as arising solely form the gravitational field of the earth,

$$\vec{\zeta}_i = \vec{l}\left(1 - \epsilon^2 \frac{2M}{r_i}\right) - \epsilon^2 \frac{2M\vec{d}_i}{d_i^2}\left(\frac{\vec{x}_i\cdot\vec{l}}{r_i} - 1\right), \tag{27}$$

where $\vec{l}\cdot\vec{l} = 1$; $-\vec{l}$ is the flat spacetime direction from the infinitely distant star to the observers. Standard polarization vectors at GS and SC could be defined as

$$\hat{\mathbf{b}}_{2i} = \frac{\vec{\zeta}_i \times \vec{k}}{|\vec{\zeta}_i \times \vec{k}|}, \qquad \hat{\mathbf{b}}_{1i} = \hat{\mathbf{b}}_{2i} \times \hat{\mathbf{k}}. \tag{28}$$

So, from Eq. (21), we get

$$\Delta\chi \cos\chi = \hat{\mathbf{f}}_{SC}\cdot\hat{\mathbf{b}}_{2SC} - \hat{\mathbf{f}}_{GS}\cdot\hat{\mathbf{b}}_{2GS} \tag{29}$$

or,

$$\Delta\chi = \frac{1}{\hat{\mathbf{f}}_{GS}\cdot\hat{\mathbf{b}}_{1GS}}(\hat{\mathbf{f}}_{SC}\cdot\hat{\mathbf{b}}_{2SC} - \hat{\mathbf{f}}_{GS}\cdot\hat{\mathbf{b}}_{2GS}). \tag{30}$$

If we choose the x-axis to pass through GS, then

$$\vec{n} = (\cos\phi, \sin\phi, 0), \qquad -\frac{1}{2}\pi < \phi < \frac{1}{2}\pi, \tag{31}$$

$$\vec{l} = (\cos\alpha, \sin\alpha\sin\beta, \sin\alpha\cos\beta), \qquad 0 \le \alpha \le \frac{1}{2}\pi, \tag{32}$$

where the altitude of the guided star is $\pi/2 - \alpha$. When the reference direction $\vec{\zeta}$ and the propagation direction $\vec{k}$ are collinear, then the standard polarization directions are undefined. If $\vec{\zeta}$ lies in the plane determined by GS, SC and centre of earth, then the Faraday phase is zero. Moreover, the post-Newtonian phase fails in the limit of $\alpha = 0$ or $\beta = \pi/2, 3\pi/2$. The plot of the Faraday phase for different reference and propagation direction is shown in Fig. 2.

4. Polarization-dependent trajectory

Taking into account the post-eikonal terms modifies the description of light propagation along the null rays that are geodesic trajectories of massless particles. These particles are still null, but their motion is no more geodesic. It is most conveniently described by using a specially designed null tetrad.[17,32] It is introduced as follows.

Trajectory $X(s)$ of a null particle with the tangent vector K can be written as

$$\frac{dX^\mu}{ds} = K^\mu, \qquad K^\mu K_\mu = 0. \tag{33}$$

This trajectory is typically is not a geodesic,[22,23] and the acceleration vector w is defined by

$$w^\mu := K^\nu K^\mu_{;\nu}, \qquad K^\mu w_\mu = 0. \tag{34}$$

The second tetrad vector n, $\mathsf{n}^2 = 0$ is chosen to satisfy

$$\mathsf{K} \cdot \mathsf{n} = -1. \tag{35}$$

A pair of complex conjugated null vectors, m and $\bar{\mathsf{m}} = \mathsf{m}^*$, are built from two spacelike vectors and satisfy

$$\mathsf{m} \cdot \bar{\mathsf{m}} = 1. \tag{36}$$

All other inner products vanish and the metric can be expressed as

$$g_{\mu\nu} = -K_{(\mu} n_{\nu)} + m_{(\mu} \bar{m}_{\nu)}. \tag{37}$$

It is possible to reparameterize the null curves and rescale the vectors of the null tetrad while preserving orthonormality relations,[17,32]

$$\mathsf{K} \to A\mathsf{K}, \qquad \mathsf{n} \to A^{-1}\mathsf{n}, \tag{38}$$

$$\mathsf{K} \to \mathsf{K}, \quad \mathsf{m} \to \mathsf{m} + a\mathsf{K}, \quad \bar{\mathsf{m}} \to \bar{\mathsf{m}} + a^*\mathsf{K}, \quad \mathsf{n} \to \mathsf{n} + a^*\mathsf{m} + a\bar{\mathsf{m}} + aa^*\mathsf{K}, \tag{39}$$

$$\mathsf{m} \to e^{i\phi}\mathsf{m}, \qquad \mathsf{m} \to e^{-i\phi}\bar{\mathsf{m}}. \tag{40}$$

Using this freedom it is possible to choose the tetrad in such a way[23] that the vector n is parallel propagated along the ray,

$$\nabla_{\mathsf{K}} \mathsf{n} = 0, \tag{41}$$

while

$$\nabla_{\mathsf{K}} \mathsf{m} = -\kappa \mathsf{n}, \qquad \nabla_{\mathsf{K}} \bar{\mathsf{m}} = -\kappa^* \mathsf{n}, \tag{42}$$

where

$$\kappa = -\mathsf{w} \cdot \mathsf{m} = -m^\mu K^\nu K_{\mu;\nu}. \tag{43}$$

With this choice of the null tetrad the polarization-dependent correction to the trajectory that takes into account the frequency ω is finite, and given by[23]

$$\frac{D^2 X^\mu}{Ds^2} = K^\nu K^\mu_{;\nu} = -\frac{i\sigma}{\omega} R^\mu{}_{\nu\alpha\beta} K^\nu m^\alpha \bar{m}^\beta =: F^\mu, \tag{44}$$

where $R^{\mu}{}_{\nu\alpha\beta}$ is the Riemann tensor. At this stage no assumptions about the spacetime were made. Effects of this term in the solar system are adequately described by the weak field expansion of the Schwarzschild metric. We will shortly see that in the leading order the polarization-dependent acceleration is of the order of ϵ^2. We also treat Eq. (44) as a correction to the null geodesic. Thus the uperturbed motion can be confined to the equatorial plane.

The trajectory is decomposed as

$$X^{\mu}(s) = x^{\mu}(s) + \alpha x^{\mu}_{\sigma}(s), \tag{45}$$

where $x^{\mu}(s)$ is a null geodesic (that we assume can be affinely parameterized by s), $x^{\mu}_{\sigma}(s)$ is the polarization-dependent correction, and the formal arbitrary infinitesimal parameter α is introduced to ease the perturbative manipulations. The tangent vector

$$K^{\mu} = k^{\mu} + \alpha\Lambda^{\mu}, \tag{46}$$

is null so,

$$k^{\mu}\Lambda_{\mu} = 0. \tag{47}$$

For the weak gravity regime it is convenient use the usual post-Newtonian expansion (the standard choice of the coordinates (t, x, y, z), but without switching to the coordinate time t as an evolution parameter). On the dimensional grounds we expect as the famous light deflection[29,31] is the ϵ^2 effect ($\Delta\phi = 2r_g/\ell$, where ℓ is the impact parameter and $r_g = 2M$ is the gravitational radius), the leading polarization-dependent effect is of the order $\alpha = \epsilon^2\lambda/\ell$, where λ is the characteristic wave length. Taking this into account and writing M explicitly, we note that at the leading order

$$k^{\mu} = k^{\mu}_{(0)} + Mk^{\mu}_{(1)}, \tag{48}$$

$$\Lambda^{\mu} = Mq^{\mu}, \tag{49}$$

where the components $k^{\mu}_{(0)}$ are constant. Taking into account that $q^{\mu}_{;\nu} = q^{\mu}_{,\nu} + \mathcal{O}(M)$, we have

$$K^{\nu}K^{\mu}_{;\nu} = Mk^{\nu}_{(0)}q^{\mu}_{,\nu} + \mathcal{O}(M^2). \tag{50}$$

It is convenient to describe the unperturbed null geodesic using the full Schwarzschild solution. The symmetry allows to restrict the motion to the equatorial plane. The tangent can be taken as

$$k^{\mu} = \left(\frac{1}{f(\bar{r})}, \pm\sqrt{1 - \frac{\ell^2}{\bar{r}^2}f(\bar{r})}, 0, \frac{\ell}{\bar{r}^2}\right), \tag{51}$$

where $f(\bar{r}) = 1 - 2M/r$. Here $\bar{r}$ is the Schwarzschild radial coordinate (i.e. the circumferential radius). In the weak field regime it is related to the isotropic radial coordinate $r = \sqrt{\vec{x}\cdot\vec{x}}$ as $\bar{r} \approx r + M$.

We used the freedom of rescaling the null vectors to set the energy of a fictitious photon to $E = 1$, so the reduced angular momentum $\ell := L/E$ equals to the impact

parameter.[17] The sign of k^r depends on whether the photon approaches the origin (i.e. the Sun), or moves away from it. In the equatorial plane we have $\mathsf{k}\nabla_{\mathsf{k}}\mathsf{k} = 0$.

The second vector of the null tetrad

$$n^\mu = \left(\frac{\bar{r}^2}{2\big(\bar{r}^2 - \ell^2 f(\bar{r})\big)}, \mp \frac{\bar{r} f(\bar{r})}{2\sqrt{\bar{r}^2 - \ell^2 f(\bar{r})}}, 0, \frac{\ell f(\bar{r})}{2\big(\bar{r}^2 - \ell^2 f(\bar{r})\big)} \right), \tag{52}$$

is chosen so that $\mathsf{k}\cdot\mathsf{n} = -1$, and the complex-conjugate pair of null vectors is given by

$$m^\mu = \frac{1}{\sqrt{2}} \left(\frac{i\ell}{\sqrt{\bar{r}^2 - \ell^2 f(\bar{r})}}, 0, \frac{1}{r}, \frac{i}{\sqrt{\bar{r}^2 - \ell^2 f(\bar{r})}} \right), \qquad \bar{m}^\mu = m^{\mu *}. \tag{53}$$

These three vectors are to be adjusted to satisfy the conditions required for the validity of Eq. (44). This adjustment is quite straightforward, as in our setting

$$\nabla_{\mathsf{k}}\mathsf{n} = i\alpha(\mathsf{m} - \bar{\mathsf{m}}), \tag{54}$$

and

$$\nabla_{\mathsf{k}}\mathsf{m} = i\alpha\mathsf{k}, \qquad \nabla_{\mathsf{k}}\bar{\mathsf{m}} = -i\alpha\mathsf{k}, \tag{55}$$

where

$$\alpha = \pm \frac{\ell(r - 3M)}{\sqrt{2} r (\bar{r}^2 - \ell^2 f(\bar{r}))}, \tag{56}$$

where the sign of α coincides with that of k^r.

In the leading order approximation the trajectories are geodesic, and the parallel transport of k results in $\kappa = 0$. In turn it enables the parallel transport of the tetrad if the function a satisfies

$$a_{,r} = -i\alpha/k^r = \frac{i\ell(\bar{r} - 3M)}{\sqrt{2}\big(\bar{r}^2 - \ell^2 f(\bar{r})\big)^{3/2}}, \tag{57}$$

where the sign does not change on transition from decreasing to increasing distance.

Null geodesics in the Schwarzschild spacetime are classified[17] according to the behaviour of the three roots of the equation $C(\bar{r}) = r^3 - \ell^2(\bar{r} - 2M) = 0$. Only one root is relevant for the trajectories we study,

$$\bar{r}_0 = \ell - M + \mathcal{O}(M^2). \tag{58}$$

Up to the terms of the third order in M the roots are $2M$ and $r \pm \bar{r}_0$. Using this we find

$$\int a_{,r} dr = \frac{i\ell(3rM - \bar{r}_0^2)}{\sqrt{2(\bar{r}^2 - \bar{r}_0^2)}\bar{r}_0^2} + \mathcal{O}(M^3), \tag{59}$$

that is sufficient to obtain the desired $a(\bar{r})$ at any point of the trajectory apart from $r = \bar{r}_0$.

The same expression is valid for both increasing and decreasing r. For $r > \ell \sim \bar{r}_0 \gg M$ we can approximate it as

$$a = -\frac{i\ell}{\sqrt{2}\sqrt{\bar{r}^2 - \ell^2}} - \frac{3iM}{\sqrt{2}\ell}\left(1 - \frac{\bar{r}^3}{(\bar{r}^2 - \ell^2)^{3/2}}\right) + \mathcal{O}(M^2). \tag{60}$$

It is convenient to express the acceleration F^μ in terms of the original tetrad vectors as

$$F^\mu = -\frac{i\sigma}{\omega} R^\mu{}_{\alpha\beta\gamma}(k^\alpha m^\beta \bar{m}^\gamma + a k^\alpha k^\beta \bar{m}^\gamma + a^* k^\alpha m^\beta k^\gamma). \tag{61}$$

Only one component is non-zero at the leading order:

$$F^\theta = -\frac{\sigma}{\omega}\frac{3\ell M}{\bar{r}^4}\left(\frac{1}{\sqrt{\bar{r}^2 - \ell^2 f(\bar{r})}} + \frac{\sqrt{2}a(\bar{r})\ell}{\bar{r}^2}\right). \tag{62}$$

Using again the decomposition of $C(\bar{r})$ it becomes

$$F^\theta \approx \frac{\sigma}{\omega}\frac{3\ell M}{\bar{r}^4\sqrt{\bar{r}^2 - \bar{r}_0^2}}\left(-1 + \frac{\ell^2}{\bar{r}^2}\right) = -\frac{\sigma}{\omega}\frac{3\ell M}{\bar{r}^6}\frac{\bar{r}^2 - \ell^2}{\sqrt{\bar{r}^2 - \bar{r}_0^2}}, \tag{63}$$

We evaluate the correction $x_\sigma(s)$ using the post-Newtonian formalism that was outlined above. It is important to note that to use only the leading order ϵ^2 while using the order of α polarization correction to describe a particular trajectory is unjustified, as the next post-Newtonian correction for the geometric optics term is still higher. Using the setting that is described below $\epsilon^2 = r_g/\ell = 4.2 \times 10^{-6}$, while $\lambda/\ell = 1.4 \times 10^{-9}$ for $\lambda = 1$m. However, as the exact general relativistic calculation within the geometric optics approximation leads to polarization-independent results, calculation of the polarization-dependent shift can be done using only the ϵ^2 expansion.

To obtain an estimate of the effect we neglect the difference between $\bar{r}_0$ and ℓ, essentially regularizing the expressions near the closest approach radius. The difference between the isotropic radial coordinate that is used in the post-Newtonian analysis and the Schwarzschild radial coordinate is of the order of $2M \ll \ell$ and affects only the higher-order terms. The unperturbed motion is confined to the z-plane. We can assume that $\vec{k} = (-1, 0, 0)$, that corresponds to $\ell > 0$. In this approximation

$$F^z = +\frac{3\sigma\ell M}{\omega r^5}\sqrt{r^2 - \ell^2} + \mathcal{O}(M^2), \tag{64}$$

while all other components are zero at the leading order. Then the explicit equation for the leading polarization-dependent correction is

$$q^z_{,x} = -\frac{3\sigma\ell}{\omega r^5}\sqrt{r^2 - \ell^2}. \tag{65}$$

We are interested in a light ray that comes from afar ("minus infinity"), grazes the sun and is detected at some finite (but large) distance $r_2 \gg \ell$, the initial off-plane displacement and velocity are zero. Similarly to the calculations of corrections

for the classical tests of general relativity[29,31] we use the unperturbed (i.e. flat spacetime trajectory with $r_0 = \ell$

$$y = \ell, \qquad x = -t. \tag{66}$$

Then the correction $\delta z = Mq^z$ is obtained by an elementary integration. For the far field ($r \gg \ell$) the trajectory approaches a straight line with

$$\theta_\infty = \frac{2\sigma}{\omega}\frac{M}{\ell^2}, \tag{67}$$

giving at the distance r from the sun the transversal shift

$$\Delta z = \frac{4M}{\omega\ell^2} r. \tag{68}$$

This shift coincides with the result obtained using the polarization-dependent part of the angle of deflection $\Delta\phi$ between in-and outgoing polarized rays that was reported in Ref. 20. On the other hand, this approximation is too crude to identify a convergence of the initially divergent trajectories that was reported in Ref. 22), and a more delicate approximations will be investigated in the follow-up work.

5. Summary

Describing propagation of electromagnetic waves in vacuum in terms of rays that follow null geodesics is a very good approximation in the high-frequency regime. Within this approximation the polarization rotation in the Schwarzschild metric, and as a result in the leading post-Newtonian approximation, is a purely gauge effect. This phase will be present as a consequence of practical methods of setting up reference frames in the Earth-to-spacecraft communications. However, for the near-Earth experiments these effects are typically about 10^{-5} weaker than the SR effects. Observable gravity-induced deviations from the geometric optics approximation are expected only in ultra-strong gravitational fields.

GINGER (Gyroscopes IN General Relativity) project aims to directly measure the Lense–Thirring (LT) and de Sitter (dS) effects on the Earth and it is based on an array of underground Ring Laser Giroscopes (RLG), the most sensitive inertial sensors to measure the rotation rate of the Earth. Since LT and dS act on a ring laser as angular rotation vectors summed to the earth rotation rate, by using at least two gyroscopes it is possible to retrieve the General Relativity (GR) contribution to the rotation rate. The kinematic component is independently measured by the International Earth Rotation and Reference Systems Service (IERS) with very high accuracy. Ginger could also make it possible to discriminate among different theories, minimizing modeling. The measurement of the Earth angular rotation rate, in order to be fruitful for a fundamental physics test, has to have sensitivity of 1 part in 10^9 or better. The most recent analysis of our prototype GINGERINO data indicate a sensitivity better than 1 part 10^{12}, i.e. 0.1% of the LT term.

Keywords: Ring laser gyroscope, Lense–Thirring, gravito-magnetic effect, length of the day

1. Introduction

The debate on gravitational theories, to extend or modify General Relativity is very active for the issues related to ultra-violet and infra-red behavior of Einstein's theory. The first is connected to the Quantum Gravity problem, the other to Dark Matter and Dark Energy governing large scale structure and cosmology. Up to now, no final theory, capable of explaining gravitational interaction at any scale, has been formulated, and it is important to say that for the discrimination between different theories sensitivity breakthrough is certainly required. Earth based experiments can be in principle advantageous allowing a thorough analysis of the systematic, little modelling of external perturbation and the feasibility of upgrades. The GINGER project, an array of Sagnac gyroscopes, can be used for Earth based gravity measurements, in particular to constrain parameters of gravity theories, like scalar-tensor or

Horava-Lifshitz gravity, by considering their post-Newtonian limits matched with experimental. This effect has been measured by the Gravity Probe B space experiments (10% level)[1] and by Lageos and Lares, reaching the 4% level.[2,3] Gravity Probe B has finished its operational life, while Lares is still providing data, and Lares II will be launched soon. This test is based on reconstructing the trajectories of geodetic satellites, i.e. mechanical simple objects to minimise the effect of the different drags affecting the trajectories, and combining laser ranging data coming from different stations. The Lense-Thirring test using the reconstruction of the nodes of the trajectories, requires the independent map of the Earth gravity fields, independently measured, and the final result at the end is limited by the accuracy of the accuracy of the map. It is necessary to accurately model the zonal tides, since their influence on the nodes of the geodetic satellites is larger than the Lense Thirring itself. The test provided by GINGER, which being Earth based provides the measurement at fixed latitude, is very different. The Lense-Thirring, relying on the Sagnac effect, does not require to combine data coming from different places or to use the accurate map of the Earth gravitational field. Recently, it has been pointed out by Jay Tasson of Carlton that RLG can effectively contribute to the Lorentz Violation quest. In this respect Jay has shown that a level of sensitivity of 1 part in 10^9 for the Earth rotation rate would provide interesting measurements of two Lorentz-violating terms in the framework of the Standard-Model Extension. In one case, sensitivities that are competitive with recent laboratory and perhaps solar system tests would result.[4]

The Earth rotation is a tool to investigate fundamental physics, since it is related to GR terms, as de Sitter and Lense–Thirring, and can provide unique data to investigate Lorentz violation. Its usefulness for fundamental physic is connected to sensitivity, which is quite often express in relative to the average Earth rotation rate; the boundary to be meaningful to fundamental physics is to reach 1 part in 10^9 and long term continuous operation. Present high sensitivity ring laser gyroscope have already fulfilled those requirements.

The Sagnac effect states that two light beams counter propagating inside a closed path complete the path at different times, t_c and t_{cc} for clockwise and anti-clockwise beam respectively, if the closed path rotates; in general the Sagnac effect, $\Delta t = t_c - t_{cc}$ is proportional to the non reciprocity between the two paths. Based on the Sagnac effect, several devices have been developed mainly for inertial navigation. The closed path of the devices with higher sensitivity is defined by an optical ring cavity, and two different technology are feasible: passive and active. The Sagnac gyroscope is identified by its area vector, and measures the scalar product between the local angular rotation and its area vector, in return the gravitomagnetic, and geodetic components act as angular rotations summed to the cinematic ones. The passive gyroscopes requires an external laser source. The active device, called Ring Laser Gyro (RLG), has an active medium inside the cavity, to feed the two counter propagating beams. It is a rather convenient solution, since external laser source

with high spectral purity is not required. At present the RLGs, with perimeter from 10 up to 36 m, have the sensitivity record for angular rotation rate measurement.

RLGs are a very promising tool for GR measurements given their features:

- since the effect of the Earth is a function of the latitude, they works at a fixed latitude, can be oriented at will and an independent gravity map of the Earth is not needed;
- they are not averaged, the synchronization of different clocks is not necessary.

Moreover the working prototypes demonstrated unattended continuous operation for months, typically sub-prad/s sensitivity in 1 second of measurement, very large bandwidth, fast response, in principle as fast as milli-seconds and very large dynamic range. High sensitivity RLG are attached to the Earth crust, so are able to measure the Earth rotation rate Ω_{geo}; at present several RLGs are operative: in Germany, G[5] of the geodetic observatory of Wettzell and ROMY in the geophysical observatory of Bavaria,[6] GINGERINO in the underground Gran Sasso laboratory, in Italy,[7] ER1 of the University of Canterbury,[8] in New Zealand, and HUST-1[9] passive gyroscope at HUST, part of the TianQin project, at Wuhan in China.

2. Our text bench: The Earth rotation

The GINGER project is devoted to fundamental physics and it is based on an array of RLG, a first prototype, GINGERINO was built inside the underground Gran Sasso laboratory to validate the site for GINGER. The Earth angular rotation is the natural "test bench" of our prototype. The device is taking data with high duty cycle since several years. Being an inertial sensor, it is sensitive to Ω_{geo} and its variations as polar motion, annual and Chandler wobbles, tides and crust deformations; quantities constantly measured with very high accuracy by the international system IERS. All this signal can be used to investigate the characteristics and the sensitivity of GINGERINO. Its sensitivity has been carefully investigated with standard statistical means, using 103 days of continuous operation and the available geodesic measurements of the Earth angular rotation rate. Sensitivity of 0.1 frad/s appears, with 600 s bandwidth at frequency of 40 days, indicating the feasibility of 1 part 10^{13} of the Earth rotation rate, and accordingly for GINGER the gravitomagnetism test on Earth at the 0.1% level or even better. Fig. 2 shows a view of the experimental apparatus. The general relativity test will require high accuracy, not only sensitivity. It is certainly challenging, but it is an apparatus which will be able to provide unique information for fundamental physics, and to other research fields, as geodesy and geophysics in general.

RLGs have the drawback to deal with the non linear dynamic of the laser, a problem that has highly limited their diffusion. Our analysis of the data from

GINGERINO shows that the large disturbances induced by the dinamic of the laser can be subtracted by a suitable tecnique. We are confident that the technique is finally mature to propose GINGER, a project based in 10 years experience and which contains many experimental details aiming at improving the long term stability, reducing instrumental disturbances.

The true Sagnac signal ω_s is recovered taking into account the laser dynamic, and assuming that it is $\omega_s = \omega_{geo} + \omega_{local}$, where ω_{geo} indicates the scalar product of the total variations of the Earth with the RLG area vector, ω_{local} the signals of local origin, related to temperature fluctuations and local tilts. Comparing the recorded data with the IERS measurements, the different terms are recovered using linear regression and standard statistical means based on minimum square, providing clear indication about the sensitivity of the apparatus, for example see Fig. 1.[10]

GINGERINO operates far from external disturbances and protected from large thermal excursions in the deep underground environment of Gran Sasso. Its data are compared with the evaluated global signal provided by IERS. he analysis takes into account and eliminates the nonlinear laser disturbances and recovers the global IERS signal with all tiny features.[11,12] At the same time disturbances of an instrumental and local origin are estimated using the environmental signals as temperature and local tilts. The obtained residuals, i.e. the unmodeled part of the Sagnac signal indicate a rotational sensitivity below the frad/s level. Disturbances are mainly of an instrumental origin, suggesting the need for improvements in the mechanical design of the RLG structure. By injecting probe signals in the GINGERINO data, we conclude that the sensitivity is 0.1 frad/s with 600 s integration time, more than a factor one hundred below the expected noise for this class of instruments.[13,14] In the near future it will be necessary to investigate this aspect from a theoretical side, and to develop a detailed Monte Carlo study in order to carefully investigate the analysis procedure.

3. Next step

We are ready to build a large-frame 3-dimensional array of ring laser gyroscopes to be mounted inside the under- ground Gran Sasso Laboratory (LNGS). The Ginger final aim is to measure the Earth angular velocity in the laboratory co-rotating frame and to compare it with the Earth angular velocity as observed in the Cosmic inertial frame. GR foresees that, in low field approximation, the De Sitter or geo-electric effect and Lense–Thirring or geo-magnetic effect have to be taken into account. For this purpose it is necessary an instrumental accuracy of the order of 10^{-14} rad s^{-1}. Such an accuracy offers also the possibility of measuring fundamental geodetic parameters related to the fluctuations of the Earth rotational velocity and of the Earth axis orientation, the so-called 'length of the day' and 'polar motion'. In parallel to the experimental studies onto our running prototypes, we have investigated different array configurations. The goal was finding the most simple and

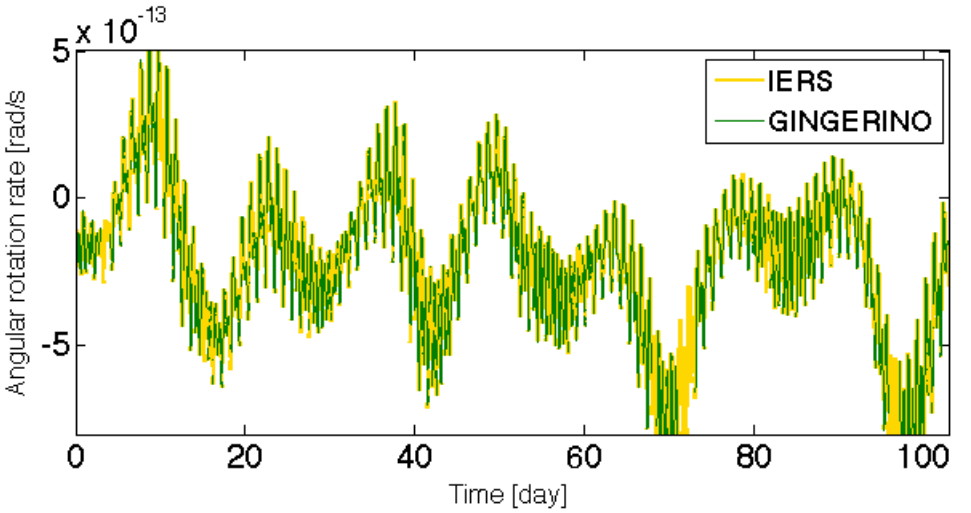

Fig. 1. Agreement of the variations of the LoD Earth rotation rate variations with higher frequency effects due to deformations, evaluated with the linear regression and the data provided by the international system IERS.

cost-effective setup, a sort of minimal instrument that enables the measurement of GR effects with the required reliability. We are fully aware that for this kind of very high sensitivity measurements, redundancy, i.e., the possibility of correlating measurements coming from different instruments and possibly different locations, is a key feature for reducing the influence of systematic as well as stochastic noise sources. In a "future scenario" a second apparatus, not necessarily co-located with the first one, is an option for further reducing the measurement uncertainty and, possibly, accessing further very tiny gravitational effects. As already stated, the final aim of GINGER is to reconstruct, with the required precision, the Earth rotation vector. In principle, measuring a 3D vector by scalar quantities, like the Sagnac frequencies, would require three independent measurements that fixes a local 3D frame. From this basic concept, we arrived, in 2011, at the octahedral configuration mentioned above. To reduce the number of required rings one should have an "external" information or measurement on the vector, or should be able to set two rings so that the plane defined by their oriented area vectors contains the Earth rotation one.[15] So doing this, the pair of rings define a plane where the rotation vector locally lies, and the problem dimensionality reduces from 3 to 2. We note that this plane, in the case of the Earth rotation, is nothing but the meridian one. Thus, in principle, a pair of rings would play the game and, if the conditions on their positioning are fulfilled with a given precision, the full vector can be reconstructed. Then, the problem movesto a different perspective, how to properly align the two rings so that the plane defined by their area vectors contains the Earth angular velocity vector.

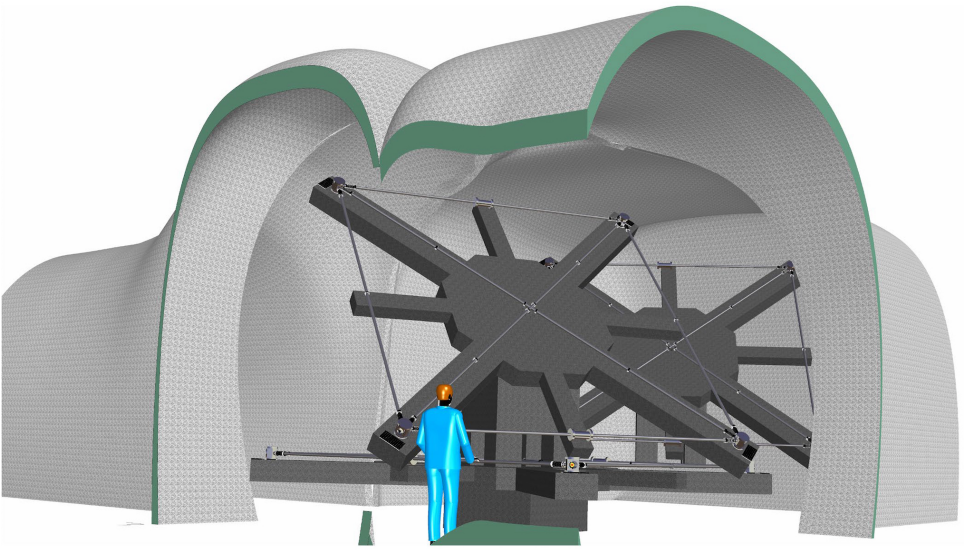

Fig. 2. Pictorial view of GINGER (Gyroscopes IN GEneral Relativity), based on an array of RLG, underground located in order to reduce the environmental disturbances and provide suitable very low frequency measurements

We have proven that the best configuration for the two rings is to orient one along the Earth rotation axis. With this choice, the Sagnac frequency of the ring is at its maximum value (a saddle point). As a consequence, orientation errors will affect only quadratically the measured signal and, very important fact, the RLG at maximum provides the modulus of the angular rotation rate. The relative orientation of the second ring is not so critical, although a horizontal ring can be preferable, owing to the possibility of locally defining its orientation by the local vertical. This is, however, a critical issue because its orientation with respect to the angular rotation axis must be known with a very high precision. The comparison with the RLG at the maximum value of the Sagnac frequency provides with adequate sensitivity the absolute orientation with respect to the rotational axis. The addition of a third RLG completes the measurement in all three degrees of freedom and provides redundancy, which is certainly welcome taking into account the very small signals we are looking for.

The observational evidence for the recent acceleration of the universe shows that canonical theories of cosmology and particle physics are incomplete and that new physics is out there, waiting to be discovered. A compelling task for astrophysical facilities is to search for, identify and ultimately characterize this new physics. I present very recent developments in tests of the stability of nature's fundamental constants, as well as their impact on physics paradigms beyond the standard model. Specifically I discuss new observational constraints at low redshifts and at the BBN epoch, and highlight their different implications for canonical quintessence-type models and for non-canonical string-theory inspired models. Finally I also present new forecasts, based on realistic simulated data, of the gains in sensitivity for these constraints expected from ELT-HIRES, on its own and in combination with Euclid.

Keywords: Cosmology; Fundamental constants; Dark energy.

1. Introduction

The observational evidence for the acceleration of the universe shows that our canonical theories of cosmology and particle physics are at least incomplete, and possibly incorrect. Is dark energy a cosmological constant (i.e. vacuum energy)? If the answer is yes, it is ten to some large power times smaller than our Quantum Field Theory based expectations. If the answer is no, then the Einstein Equivalence Principle must be violated. Either way, new physics is out there, waiting to be discovered; we must search for, identify and characterize this new physics.

The CosmoESPRESSO team uses the universe as a laboratory to address, with precision spectroscopy and other observational, computational and theoretical tools, 6 grand-challenge questions:

(1) Are the laws of physics universal?
(2) Is gravity just geometry (i.e., a fictitious force)?
(3) What makes the universe accelerate?
(4) Can we find fossil relics of the early universe?
(5) How do we optimize next-generation facilities?
(6) How do we prepare next-generation (astro) physicists?

In what follows I will highlight recent contributions of the CosmoESPRESSO team to this fundamental quest, pertaining to fundamental constants.

2. Scalars, because they are there

We know since 2012 (thanks to the LHC) that fundamental scalar fields are among Nature's building blocks. Even before this discovery they were already widely used in cosmology, e.g., to describe inflation, cosmic defects, dynamical dark energy, and dynamical fundamental couplings. We also expect that cosmological scalar fields will naturally couple to the rest of the model, leading to long-range forces and "varying constants".[1–3] Of particular interest in what follows are electromagnetic sector couplings, which yield spacetime variations of the fine-structure constant, with multiple testable fingerprints. A recent theoretical and observational overview of the field can be found in Ref. 4.

One of the most actively pursued test of the stability of fundamental couplings consists of high resolution astrophysical spectroscopy measurements of the fine-structure constant α, the proton to electron mass ratio μ, the proton gyromagnetic ratio g_p, or combinations thereof. A recent joint likelihood analysis of all currently available data[5] leads to a very mild (one to two standard deviations of statistical significance) preference for astrophysical variations (as compared to the local laboratory values), at the parts per million level of relative variation, All this data spans the redshift range $0.2 < z < 4.2$. However, it is also known that, at least in the case of α measurements which make up most of the full dataset, there are systematics at the level of at least parts per million. A new generation of more robust measurements is therefore necessary.

3. Aiming higher

In the most natural and physically realistic models for time (redshift) variations of fundamental couplings, such variations are monotonic. Moreover, one expects that the putative scalar field driving this variation will be significantly damped at the onset of the dark energy domination phase of the universe (i.e., the recent acceleration phase). Both of these are theoretical motivations for testing the stability of fundamental constants such as α, though direct measurements, at higher redshifts—in other words, deep into the matter era, where any relative variations are expected to be larger.

An example of work towards this goal relies on using observations of the redshift $z = 7.085$ quasar J1120+0641[6] to constrain variations of α over the redshift range $z = 5.51$ to $z = 7.06$. These led to the four highest redshift direct measurements of α (the previous highest redshift direct measurement was at $z = 4.18$), with the latter corresponding to a look-back time 12.96 Gyr (for the current best-fit cosmological parameters in the standard ΛCDM model). A total of about 30 hours of data from the X-SHOOTER spectrograph on the European Southern Observatory's Very Large Telescope (VLT) was used, which also makes this the first direct measurement of α in the infrared. Finally, the analysis relied on a new AI-based method, aiming to remove some possible dependency of the final result on human-made choices.

The weighted mean strength of the electromagnetic force over this redshift range in this location in the universe, reported in Ref. 7, is measured to be

$$\frac{\Delta\alpha}{\alpha} = \frac{\alpha(z) - \alpha_0}{\alpha_0} = (-2.18 \pm 7.27) \times 10^{-5}\,, \tag{1}$$

where α_0 denotes the local laboratory value, i.e. we find no evidence for a time variation. The sensitivity of the combined measurement is only at the tens of parts per million level, as compared to the parts per million (nominal) sensitivity of optical measurements at lower redshifts, but this first result should primarily be seen as a proof of concept analysis, demonstrating that such high redshift measurements can indeed be done.

As for measurements in the optical, the arrival of the ESPRESSO spectrograph,[8] operating at the combined Coudé focus of the VLT, enables new and more stringent tests. Preliminary analyses already demonstrate that the dominant sources of systematics limiting previous high resolution spectrographs are not present,[9] and the first results of its measurements of the fine-structure constant should be reported soon.

Broadly speaking, the direct impact of ESPRESSO on cosmology and fundamental physics will come from at least five different types of observations:

(1) Direct measurements of the fine-structure constant α, at redshifts between $z \sim 1$ and $z \sim 4$, using various ions
(2) Direct measurements of the proton to electron mass ratio μ, at redshifts between $z \sim 2$ and $z \sim 4$, using molecular Hydrogen and Carbon Monoxide
(3) Direct measurements of the cosmic microwave background temperature at redshifts, at redshifts between $z \sim 2$ and $z \sim 4$, using Carbon Monoxide and neutral Carbon
(4) New measurements of the primordial Deuterium abundance (of relevance for BBN, as discussed in what follows)
(5) Additional probes, including deep spectra, lensed QSOs and precursor redshift drift measurements.

In addition to their direct fundamental relevance, these will also impact the quest to characterize dark energy properties.[10]

4. BBN with GUTs

Big Bang Nucleosynthesis is one of the cornerstones of the Hot Big Bang model, but its success has been limited by the long-standing Lithium problem;[11] more recently, a possible Deuterium discrepancy has also been suggested.[12]

If a fiducial theoretical model is chosen and the relevant sensitivity coefficients are known, BBN can be studied perturbatively. This approach is Well-known for relevant cosmological parameters, such as the neutron lifetime, number of neutrinos and baryon-to-photon ratio.[12] More recently, this has been self-consistently

extended for a broad class of Grand Unified Theories,[13–15] where all couplings are allowed to vary.

The Lithium problem can be expressed as a statistical preference for a 70% depletion of its theoretically predicted primordial (cosmological) abundance, with respect to the astrophysically measured one,[15] with otherwise standard physics. When the analysis is repeated for a broader class of GUT models, one finds[15] a mild (ca. two to three standard deviations) statistical preference for larger values of the fine-structure constant at the BBN epoch, at the parts per million level of relative variation, while the preferred Lithium depletion drops to about 65%. These results are qualitatively consistent across various models, although quantitatively the best-fit values of the relevant parameters do have a mild model dependence, further discussed in Ref. 15.

This means that the preference for a $\Delta\alpha/\alpha > 0$ is not due to the Lithium problem, but to the aforementioned Deuterium discrepancy. A few ppm variation of α solves D discrepancy, given their positive correlation. Such a variation is consistent with all other currently available cosmological, astrophysical and local constraints. This helps with the Lithium problem, reducing the astrophysical depletion required, but only by a moderate amount. Thus the most likely explanation for the Lithium problem is an astrophysical one, and Ref. 15 further shows that the amount of depletion needed to solve the Lithium problem can be accounted for by transport processes of chemical elements in stars—specifically, the combination of atomic diffusion, rotation and penetrative convection. On the other hand, the Helium4 abundance has relatively little statistical weight in the above analysis, given the very tight observational constraints on the primordial Deuterium abundance.

These results show that BBN is a very sensitive probe of new physics: it is quite remarkable that one can constrain the strength of the electromagnetic interaction, to parts per million level, when the universe was seconds to minutes old. Going forward, improving observed abundances of Deuterium and Helium4 by a factor of 2 to 3 will lead to stringent tests of this GUT class of models, and in particular will confirm or rule out the current preference for a $\Delta\alpha/\alpha > 0$. A cosmological measurement of the Helium3 abundance (which is currently not possible) would also provide a key consistency test of the underlying physics. These will be crucial tasks for the next generation of high-resolutions ultra-stable astrophysical spectrographs.

5. Dynamical dark energy

Realistic models for a varying fine-structure constant usually rely on a fundamental or effective scalar field, and can be phenomenologically divided into two broad classes, dubbed Class I and Class II, for which astrophysical tests of the stability of α will play different roles as probes of the underlying cosmological model.[4]

Class I contains the models where the same degree of freedom yields dynamical dark energy and the varying α. In this case the cosmological evolution of α is

parametrically determined, meaning that its redshift dependence can be expressed as a function of cosmological parameters (including the matter density and those describing the dark energy equation of state) together with one or more parameter describing the coupling of the scalar field to the electromagnetic sector. In these models, constraints on α constrain the dark energy equation of state,[16–18] and in particular may enable an observational discriminating test between freezing and thawing dark energy models.[19] The simplest example of this class are quintessence models, provided one does not forget the coupling to the electromagnetic sector.

A recent example are the Euclid forecast constraints on dark energy coupled to electromagnetism, with astrophysical and laboratory data.[20] These show that α measurements improve the Euclid dark energy Figure of merit by between 8 and 26 percent, depending on the correct fiducial model (with larger improvements occurring in the null case, where the fiducial model is ΛCDM). Inter alia, these forecasts confirm the expectation[21] that increasing redshift lever arm of the measurements, which the α data enables, is crucial.

Class II contains the models where the dynamical degree of freedom responsible for the varying α has a negligible effect on cosmological dynamics, and therefore has little or no contribution to the acceleration of the universe. Such models are identifiable through consistency tests comparing cosmological and astrophysical (or local) data, and in this case α measurements still constrain model parameters. Typically they do not directly constrain cosmological parameters, but they may still indirectly help constrain them by breaking degeneracies in the overall parameter space (which will include cosmological and particle physics parameters). The simplest example of this class are the Bekenstein type models.[22,23] In some cases, such as the Dirac-Born-Infeld type models, astrophysical measurements of α may be the only possible observational probe that, given already available constraints, can distinguish these models from ΛCDM.[24]

Importantly, in all these models the scalar field inevitably couples to nucleons, leading to Weak Equivalence Principle violations.[2,3] Therefore measurements of α constrain the Eotvos parameter η. The current bound, including the available α measurements together with the MICROSCOPE bound,[25] has been reported in Ref. 26, and is

$$\eta < 4 \times 10^{-15} \,. \tag{2}$$

This is three times stronger than the bound from MICROSCOPE alone, and 30 time tighter than the best ground-based direct bounds, with the caveat that the constraint includes a mild model dependence (ca. factor of 2). This will be further improved by ESPRESSO, and later on by ELT-HIRES. ESPRESSO observations can probably reach a sensitivity of 2×10^{-16} (about 5 times better than the final MICROSCOPE results, due to appear imminently) while the ELT-HIRES expected sensitivity is at the few times 10^{-18} level, similar to that of proposed STEP.

6. So what's your point?

The acceleration of the universe shows that canonical theories of cosmology and particle physics are incomplete, if not incorrect. Precision astrophysical spectroscopy provides a direct and competitive probe of the (still unknown) new physics that must be out there. This already provides highly competitive constraints, and will take an increasingly stronger role in the coming years.

So far one can say that nothing is varying at the few parts per million level of relative variation. This is already a very tight bound. It is orders of magnitude stronger than the few percent level of the constraints on the deviation of the dark energy equation of state from a cosmological constant, and also one order of magnitude stronger than the Cassini bound on the Eddington parameter. Tests of the stability of α also lead to the best available Weak Equivalence Principle constraint, a situation that is expected to remain even after MICROSCOPE's final results.

The ESPRESSO spectrograph is here, and new and more robust measurements are coming soon. Together with the final MICROSCOPE results, stringent new tests will become possible. In the longer term, the ELT will be the flagship tool in a new generation of precision consistency tests of fundamental physics, leading to competitive 'guaranteed science' implications for dark energy as well as unique synergies with other facilities, including Euclid and the SKA.

Testing the general relativistic nature of the Milky Way rotation curve with Gaia DR2

Mariateresa Crosta
Italian National Institute for Astrophysics, OATo, Turin, Italy
E-mail: mariateresa.crosta@inaf.it

The ESA mission Gaia directly measures the kinematics of the stellar component of the Galaxy with the goal to create the largest, most precise three-dimensional map of the Milky Way. The very core of the Gaia data analysis and processing involves General Relativity to guarantee accurate scientific products. In parallel, any Galactic model should be developed consistently with the relativistic-compliant kinematics delivered by Gaia. In this respect, this contribution presents the first test for a relativistic Galactic rotation curve with the Gaia second release products. Both a general relativistic model and a classical analogue were fit to the best-ever kinematics, derived exclusively from Gaia data, of a carefully selected homogenous sample of disk stars tracing the axisymmetric part of the Galactic potential. The relativistic rotation curve results statistically indistinguishable from its state-of-the-art dark-matter-based analogue. This supports the ansatz that the background geometry could drive the stellar velocities in the plane of our Galaxy far away from its center and mimic dark matter. Furthermore, one of Einstein's equations provides the necessary baryonic matter density to close the observed gap with respect to the expected Newtonian velocities without the need of extra mass.

Keywords: Gravitation; Galaxy: kinematics and dynamics; General Relativity; Relativistic Astrometry; Gravitational Astrometry; Local Cosmology; Dark Matter

1. General Relativity in the Gaia context

Gaia is the ESA cornerstone astrometric mission[1] - a wide European effort involving almost 450 scientists - launched in December 2013. Gaia implements Relativistic Astrometry for the data analysis and processing that, as part of fundamental physics, can be named Gravitational Astrometry.

Astrometry is the oldest branch of astronomy, it provides positions and motions of stars since Babilonian times. Astrometrists have compared tiny movements in the sky with increasing accuracy through the ages. In practice they measured smaller and smaller angles. The same measurement principle applies for the Gaia mission, but in order to achieve high precision, nowadays we need to operate from space. Gaia provides positions (direction and distance) along with velocities of over 1 billion stars in our Galaxy with an accuracy of up to 10 millionths-of arcsecond, i.e. 1-microarsecond (μas), that corresponds to the angular size of the star on the top of Mole as seen from Jupiter. At the end-of-mission the astrometric accuracies will be better than 5-10 μas for brighter stars and 130-600μas for faint targets. Nevertheless, smaller angles mean larger distances. In astrometry the location of an

object is considered reliable if the relative parallax error is less 10%. This implies that with 1 microsecond of accuracy we obtain reliable distances up to the Galactic scale.[2] Then, the final goal is unraveling the structure, the formation, and the evolution of the Milky Way (MW). As matter a fact, since Gaia is continuously scanning the sky, the main goal is to produce a map of about 1-2 billion celestial objects in 3 dimensions. Each celestial object will be observed on average 70 times (a true Galilean method applied to the sky!). Thanks to the combinations on the focal plane of astrometry (positions, proper motions parallaxes), photometry (spectral classification, photometric distances, brightness, temperature, mass, age, chemical composition) and spectroscopy (radial velocity, chemical abundances), the Gaia survey is detailed star by star along with the knowledge of their intrinsic properties.

According to different parallaxes accuracies, the Gaia scientific outputs span from the Solar System scale to the MW one and comprise, among many others, tests on General Relativity (GR), ten thousands exoplanet detections within 200 pc, accurate calibration of the HR diagram, accurate distance scale, cosmological tests such as local Λ-CDM predictions.[2] However, to guarantee all its scientific outputs Gaia requires an appropriate relativistic modelling of the observable and the observer. Gaia is operating at L2 point of the Earth-Sun system and the few-microarcsecond level of its measurements requires to consider the overlapping non-stationary weak gravitational fields due to the Solar System masses, in particular to account for the off-diagonal terms of the IAU metric. Then, Relativistic Astrometry implies a fully general-relativistic analysis of the light trajectory, from the observational data back to the positions of light-emitting stars.[3] Since Gaia is implementing absolute Relativistic Astrometry for the first time, inside the Gaia consortium for the Gaia data processing and analysis (DPAC) there exist two GR models, which set up two independent astrometric solutions for the celestial sphere. Among the six DPAC centers across Europe, the only one specialized in the treatment and validation of the satellite astrometric data is run by ALTEC (located at Turin) under the scientific supervision of the astromeric group INAF-OATo for ASI. The DPCT hosts the systems of the Astrometric Verification Unit (AVU), which is in charge, for DPAC, of the verification, through the Global Sphere Reconstruction (GSR), of the absolute astrometry achieved through the baseline astrometric model. The adoption of these two models applied to the same set of data, besides to be an independent verification tool to guarantee the Gaia scientific outputs (for example to control systematics), are in itself a GR test.[4] Discrepancies that cannot be fixed by the models deserve to be investigated as possible GR shortcomings.

2. Gravitational Astrometry at Milky Way Scale

For the Gaia-like observer the weak gravitational regime turns out to be "strong" when one has to perform high accurate measurements. The position and velocity data, comprising the outputs of the Gaia mission, are fully GR compliant. Given a

relativistic approach for the data analysis and processing, any subsequent exploitations should be consistent with the precepts of the theory underlying the astrometric model. Therefore, a fully relativistic model for the MW structure should be applied as well.

A GR structure of MW can assure a coherent laboratory for Local Cosmology, in particular for testing how well distances and kinematics at the scale of the MW disk compare with the Λ-CDM model predictions based on the Concordance Cosmological Model.[2]

Although the Λ-CDM considers homogeneous and isotropic solutions of the Einstein Equations (EE), in the most advanced simulations Λ-CDM cosmology assumes an average FRLW evolution while growth in structure is treated by Newtonian N-body simulations. Ray-tracing as true observables from Gaia can provide constraints on the parameters included in the simulations and the use of Gaia data must be parallel with the utilisation of the most advanced cosmological simulations with baryonic matter (gas and stars). In such a context, flat galactic rotation curves, a longest outstanding problem for astronomy, provide the main observational support to the hypothesis of a surrounding dark matter. The simplest explanation is that galaxies contain far more mass than can be accounted by the bright stellar objects residing in the galactic disk. Adding a surrounding "dark matter" halo allows a good fit to data.

On the other hand, stellar kinematics, as tracer of gravitational potential, is the most reliable observable for gauging different matter contributions. Rotation curves (RC) are distinctive features of spiral galaxies like our Milky Way, a sort of a kinematical/dynamical signature, like the HR diagram for the astrophysical content. And since Gaia by routinely scanning individual sources throughout the whole sky directly measures the (relativistic) kinematics of the stellar component, the rotation curve of the MW lends itself as a first test for a GR Galaxy with Gaia data. This seems to contradict the common assumption that at MW scale the relativistic effects are usually negligible and locally Newton approximation for the gravitational potential is retained valid at each point. In fact, the dynamics of galaxies is usually treated by considering the Newtonian limit of EE, in practice it boils down to solving Poisson's equation in order to derive the velocities tracing the observed RC. However, if one supposes a MW background geometry due a flat Minkowskian metric plus small perturbations as done for the Gaia relativistic models, the typical velocity of stars in our Galaxy is $v_{Gal} = 250$ km/s, thus the lowest order of accuracy of the perturbation terms to be retained for an hypothetical pN Galaxy metric is $(v_{Gal}/c)^2 \approx 100$mas and $(v_{Gal}/c)^3 \approx 120\mu$as. Since the individual DR2 astrometric error is $\leq 100\mu$as throughout most of its magnitude range,[16] "weak" relativistic effect could be relevant for a Gaia-like observer. This indicates that is worth investigating the small curvature limit in GR at MW scale, bearing in mind that it may not coincide with the Newtonian regime. To answer one needs to compare classical and GR models for the MW that derive from different field equations.

3. Classical and General Relativistic Models for the Milky Way

The classical model (MWC) for the MW structure takes into account several substructures, comprising a bulge, a thin and thick disc, and an halo. For the bulge one can adopt a Plummer density profile[5]

$$\rho_b = \frac{3b_b^2 M_b}{4\pi(r^2+b_b^2)^{5/2}}, \tag{1}$$

where, in cylindrical coordinates, the bulge spherical radius is $r=\sqrt{R^2+z^2}$, with $b_b = 0.3$ kpc the Plummer radius and M_b is the total bulge mass.

As for the thin and thick MW disks, one can consider a double-component stellar disk modelled as two Miyamoto-Nagai potentials. This function is also approximated with a double exponential disk as in McMillan[6] and Korol et al.[7] The most general description[5,8,9] is expressed in the form

$$\rho_d(R,z) = \frac{M_d b_d^2}{4\pi} \frac{\left[a_d R^2 + (a_d + 3\sqrt{z^2+b_d^2})(a_d+\sqrt{z^2+b_d^2})^2\right]}{\left[R^2+(a_d+\sqrt{z^2+b_d^2})^2\right]^{5/2}(z^2+b_d^2)^{3/2}}, \tag{2}$$

where M_d is the total (thin or thick) disk mass, a and b are the scale–length and scale–height, $b_{td} = 0.25$ kpc and $b_{Td} = 0.8$ kpc the thin and thick disk scale–heights, respectively.

Finally, for the MWC, a standard Navarro-Frank-White (NFW) model describes the DM halo (McMillan[6], Bovy[8], Navarro et al.[10])

$$\rho_h(r) = \rho_0^{halo} \frac{1}{(r/A_h)(1+r/A_h)^2}, \tag{3}$$

where ρ_0^{halo} is the DM halo density scale and A_h its (spherical) scale radius.

Each component contributes to define the potential in the Poisson's equation

$$\nabla^2\Phi = 4\pi G\rho_{tot} = 4\pi G(\rho_b + \rho_{td} + \rho_{Td} + \rho_h) \tag{4}$$

from which the velocity profile is derived

$$V^2 = R\,(d\Phi_{tot}/dR)\,. \tag{5}$$

On the other hand, Einstein's equation is in general very difficult to solve analytically, making it even the more difficult to detail a metric for the whole Galaxy as a multi-structured object. As first attempt, we adopted in Crosta et al.[11] an axisymmetric and stationary Galactic metric-disk and a simple relativistic model suitable to represent the Galactic disk as dust in equilibrium at a large distance from the centre.[12]

As well known, in a stationary and axisymmetric space-time there exist two commuting killing vector fields, k^α (time-like) and m^α (always zero on the axis of symmetry) and a coordinate system $\{t,\phi,r,z\}$ adapted to the symmetries,[13,14] whose line element for a rotating perfect fluid takes the form:

$$ds^2 = -e^{2U}(dt+Ad\phi)^2 + e^{2U}\left(e^{2\gamma}(dr^2+dz^2) + Wd\phi^2\right), \tag{6}$$

where $e^{2U}, e^{2\gamma}$ are conformal factors and U, A, W depend only on coordinates $\{r, z\}$. The time coordinate t (time-like far enough from the metric source) spans in the range $[-\infty, +\infty]$ and ϕ is the azimuthal angular coordinate in the range $[0, 2\pi]$.[13] For the general dust solution[14] we have[a]:

$$-e^{2U} = (k|k),\ -Ae^{2U} = (k|m),\ e^{-2U}W^2 - A^2e^{2U} = (m|m). \tag{7}$$

In addition

$$m^\alpha = \partial^\alpha_\phi,\ k^\alpha = \partial^\alpha_t,\ \partial_t g_{ij} = \partial_\phi g_{ij} = 0,\ g_{\phi a} = g_{ta} = 0, \tag{8}$$

where $a = r, z$. Because of the two dimensional Laplace equation one can choose $W = r^2$. For rigidly rotating dust (i.e. shearfree and expansionfree) $U = 0$ and there exist a time-like Killing vector (linear combination of k^α and m^α with constant coefficient) parallel to the four-velocity of the fluid u^α, i.e. the co-rotating one chosen by Balasin and Grumiller,[12] proportional to ∂^α_t.[14] Then, by setting $e^{2\gamma} \equiv e^\nu$, $N = -A$ and $e^{2U} = 1$, eq. (6) becomes the line element adopted by Balasin and Grumiller[12]:

$$ds^2 = g_{\alpha\beta}dx^\alpha dx^\beta = -dt^2 + 2Nd\phi dt + (r^2 - N^2)d\phi^2 + e^\nu(dr^2 + dz^2). \tag{9}$$

Such a model may serve as a crude model for galaxies with the stars considered as dust grains. A rigidly rotating disk of dust is the universal limit of rigidly rotating perfect fluid configurations where the pressure-to-energy-density ratio vanishes. The dust assumptions implies that the masses inside a large portion of the Galaxy interact only gravitationally and reside far from the central bulge region. As a matter of fact, stellar encounters become effective below the parsec scale, on the other hand the Galaxy could be considered globally isolated around 25 kpc where flaring effects emerge, indicating the onset of external gravitational perturbations.

Given a stationary and axisymmetric space-time, the unit tangent vector field of a general spatially circular orbit can be expressed as

$$u^\alpha = \Gamma\left(k^\alpha + \beta m^\alpha\right), \tag{10}$$

where β is the constant angular velocity (with respect to infinity) and Γ the normalization factor. Equation (10) represents a class of observers that includes static ones ($\beta = 0$), and can be parametrized either by β or equivalently by the linear velocity, say ζ, with respect to the ZAMOs (Z^α), the locally non-rotating observer with zero angular momentum as:

$$u^\alpha = \gamma\left(e^\alpha_{\hat{0}} + \zeta^{\hat{\phi}} e^\alpha_{\hat{\phi}}\right), \tag{11}$$

where $\gamma = -(u|Z)$ is the Lorentz factor, $e^\alpha_{\hat{0}}$ is the unit normal to the t=constant hypersurfaces, and $e^\alpha_{\hat{\phi}}$ the ϕ unit direction of the orthonormal frame adapted to the ZAMOs. ZAMO frames, indeed, have a non-zero angular velocity with respect to flat infinity and move on worldlines orthogonal to the hypersurfaces t=constant.

[a]Symbol (|) stands for the scalar product relative to the chosen metric.

The line element (9) can be rewritten in terms of the lapse $M = r/\sqrt{(r^2 - N^2)}$ and the shift factor $M^\phi = N/(r^2 - N^2)$ as follows

$$ds^2 = -M^2 dt^2 + (r^2 - N^2)\left(d\phi + M^\phi dt\right)^2 + e^\nu (dr^2 + dz^2), \tag{12}$$

where

$$Z^\alpha = (1/M)(\partial_t - M^\phi \partial_\phi). \tag{13}$$

Then,[15]

$$\zeta^{\hat{\phi}} = \frac{\sqrt{g_{\phi\phi}}}{M}(\beta + M^\phi). \tag{14}$$

In order to trace the relativistic velocity profile from Gaia data, one has to consider that the local (static) barycentric observer as defined in the Barycentric Celestial Reference System (BCRS)[3] reduces to be $\propto \partial_t^\alpha$ far away from the Solar System.

In such a context the spatial velocity of the co-rotating dust of the BG model ($\beta = 0$) turns out to be proportional to the off-diagonal term of the chosen metric, indicated with N, which could imply gravitational dragging, namely

$$|V(r,z)| \equiv \zeta^{\hat{\phi}} = \frac{N(r,z)}{r} \propto g_{0\phi}. \tag{15}$$

The metric function N has been determined by Balasin and Grummiller by solving the set of the Einstein field equations and results as

$$N(r,z) = V_0(R_{out} - r_{in}) + \frac{V_0}{2}\sum_{\pm}\left(\sqrt{(z \pm r_{in})^2 + r^2} - \sqrt{(z \pm R_{out})^2 + r^2}\right), \tag{16}$$

which is limited by the constraint $|z| < r_{in}$ and depends only on parameters V_0, R_{out}, r_{in}, corresponding, respectively, to the flat regime velocity, the extension of the MW disk and the bulge radius.

Finally, the velocity profiles on the equatorial plane is

$$V^{BG}(R) = \frac{V_0}{R}\left(R_{out} - r_{in} + \sqrt{r_{in}^2 + R^2} - \sqrt{R_{out}^2 + R^2}\right). \tag{17}$$

4. Testing the Geometry-Driven Rotation Curve of the Milky Way with Gaia DR2

To study if the flatness of the MW RC is geometry driven, we selected stars from the Gaia DR2 archive[16] according to the following strict criteria: i) a complete Gaia DR2 astrometric dataset; ii) parallaxes good to 20%; iii) Gaia-measured velocity along the line of sight, namely radial velocity, with better than 20% uncertainties; iv) materialization of the sample by means of a cross-matched entry in the 2MASS catalog.[17] These steps allow to reconstruct a proper 6D phase-space location occupied by each individual star as derived by the same observer.

The requirements above left us with a very homogenous sample of 5277 early type stars and 325 classical type I Cepheids, where 99.4% of the sample span in a range

of 11 kpc and is below 1 kpc from the galactic plane (a characteristic scale height for the validity of the BG-RC model). To date it represents the best angular-momentum sustained stellar population of the Milky Way that better traces its observed RC. The quantities extracted from the Gaia DR2 archive are transformed from their natural ICRS reference frame to its galactocentric cylindrical counterpart.[18]

Since the parameter space is too large, a simple nonlinear fit could not be adeguate, the Markov Chain Monte Carlo method to determine the unknown parameters and their uncertainties was used.[11] There are several literature works providing the parameter values for each component. For the fit the more recent ones were adopted. In the following tables the best fit estimates as the median of the posteriors and their 1σ level credible interval are reported.

Table 1. Parameters of BG's model.[11] θ, σ_θ^- and σ_θ^+ are the mean and the 1σ credible interval limits from the posteriors of the parameters.

BG model	θ	σ_θ^-	σ_θ^+
r_{in} [kpc]	0.39	-0.25	+0.36
R_{out}[kpc]	47.87	-14.80	+23.96
V_0 [km/s]	263.10	-16.44	+25.93
e^{ν_0}	0.083	-0.014	+0.014

Table 2. Parameters of the MWC model.[11] θ, σ_θ^- and σ_θ^+ are the mean and the 1σ credible interval limits from the posteriors of the parameters.

MWC model	θ	σ_θ^-	σ_θ^+
$M_b[10^{10}\mathrm{M}_\odot]$	1.0	-0.4	+0.4
$M_{td}[10^{10}\mathrm{M}_\odot]$	3.9	-0.4	+0.4
$M_{Td}[10^{10}\mathrm{M}_\odot]$	4.0	-0.5	+0.5
a_{td}[kpc]	5.2	-0.5	+0.5
a_{Td}[kpc]	2.7	-0.4	+0.4
$\rho_0^{halo}[\mathrm{M}_\odot\mathrm{pc}^{-3}]$	0.009	-0.003	+0.004
A_h [kpc]	17	-3	+4

In figure 1, the red and blue curves show the best fit to the BG and MWC models, respectively. For the likelihood analysis reported in Crosta et al.[11] the two models appear almost identically consistent with the data, indicating that weak fields in GR can drive the MW rotation curve as the classical dark-matter-based analogue.

The fitted value r_{in}= 0.39 kpc, besides being quite close to the value adopted for the Plummer radius (b_b = 0.3 kpc), provides an independent measurements of the radial size of the MW bulge directly from the velocity data. The least constrained parameter of the BG model is the radial extension of the MW disk, as expected due to the limited radial coverage of the Gaia-only velocity data used.

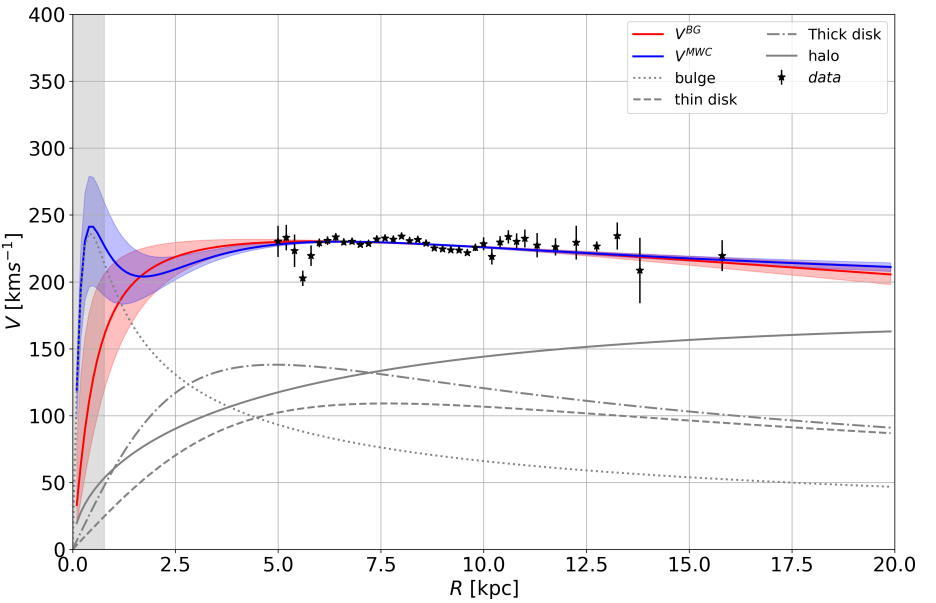

Fig. 1. From M. Crosta, M. Giammaria, M.G. Lattanzi and E. Poggio.[11] The azimuthal velocity profile of the MW as derived from the sample of disk tracers selected from the Gaia DR2. The black starred symbols represent the median values within a radial bin of about 0.2 kpc. The corresponding error bars are computed via bootstrapping. The other grey curves represent the kinematical substructures that contribute to the MWC model, in particular the grey solid line shows the contribution of the NFW halo. The coloured areas represent the reliability intervals of the fitted curves; note that for $R < 5$ kpc both the classical and the relativistic curves are very uncertain because of the lack of data in that region.The grey vertical band represents twice the value of r_{in} estimated with the BG model.

Differently form Balasin and Grummiller, in Crosta et al.[11] also the metric factor $e^{-\nu}$ was estimated via the Einstein equation for the density

$$\rho(R,z) = e^{-\nu(R,z)} \frac{1}{8\pi R^2} \left[(\partial_R N(R,z))^2 + (\partial_z N(R,z))^2 \right]. \tag{18}$$

Figure 2 two shows that the two models provide a similar baryonic mass distribution in the Galactic disk over the radial range explored by the Gaia data.

From the fit of the data the local relativistic baryonic matter density results $\rho(R = R_\odot, z = 0) \equiv \rho_\odot = 0.083 \pm 0.006\, \mathrm{M}_\odot \mathrm{pc}^{-3}$ that is in agreement with independent current estimates.[19–21] Note that, differently form the classical approach, the local mass density was used as the observed datum at Sun position in the likelihood function.

Finally, in order to disentangle the gravitational dragging component, which has not newtonian counterpart, we compared: i) the MWC baryonic-only contribution with the effective Newtonian profile V_{eN}^{BG}, which was calculated by implementing the BG density profile as described in Binney and Tremaine[22] and Almeida et al.[23];

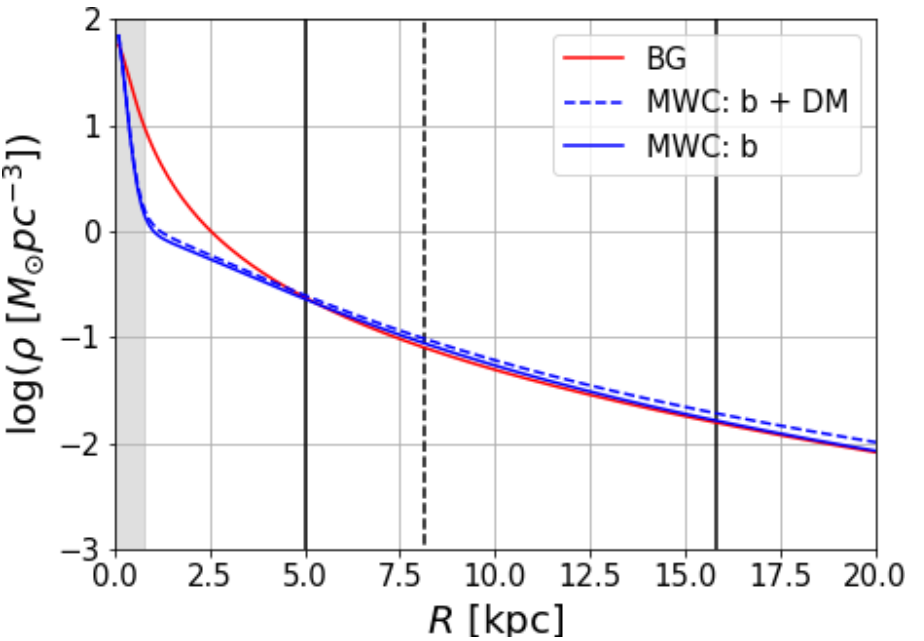

Fig. 2. From M. Crosta, M. Giammaria, M.G. Lattanzi and E. Poggio.[11] The density profile of the MW at $z = 0$ derived from 100 random draws from the posterior distribution of the fit. The red solid line is the BG model, while the blue dashed line represents the total matter contribution for the MWC model (i.e. the sum of the bulge and the two disks as the baryonic counterpart, plus the dark matter halo). The blue solid line shows the contribution of the sole baryonic matter. The vertical black solid lines limit the range of our data, while the vertical black dashed line indicates the Sun position in the Galaxy. Finally, the grey vertical band represents twice the value of r_{in} estimated with the BG model.

ii) the MWC dark matter-only contribution with the "dragging curve" traced by subtracting the effective component V_{eN}^{BG} to the total V^{BG}. More precisely, this last step implied a minimization procedure to get the effective BG disk half- thickness $|z|_{eff}$, that yields $|z|_{eff} = 0.215$ kpc (very close to the value of adopted for the classical thin disc), namely

$$(V_{drag}^{BG}(R_i; |z|_{eff}|) = \sqrt{(V^{BG}(R))^2 - (V_{eN}^{BG}(R; |z|_{eff}))^2}. \tag{19}$$

The results are illustrated in figure 3. Over the range covered by the Gaia data, the relativistic "dragging" component overlaps the one due to the halo in the MWC models. For R $\leq$ 5 kpc (the region we cannot constrain with the Gaia data at the moment), the two effective Newtonian velocities differ sharply. This could indicate the breaking point for the direct applicability of the BG model to the Milky Way, as it calls for a more suitable relativistic description of its central regions.

Despite the above limitations, the results points clearly to the possibility that a gravitational "dragging-like" effect due to the geometry background could sustain a flat RC.

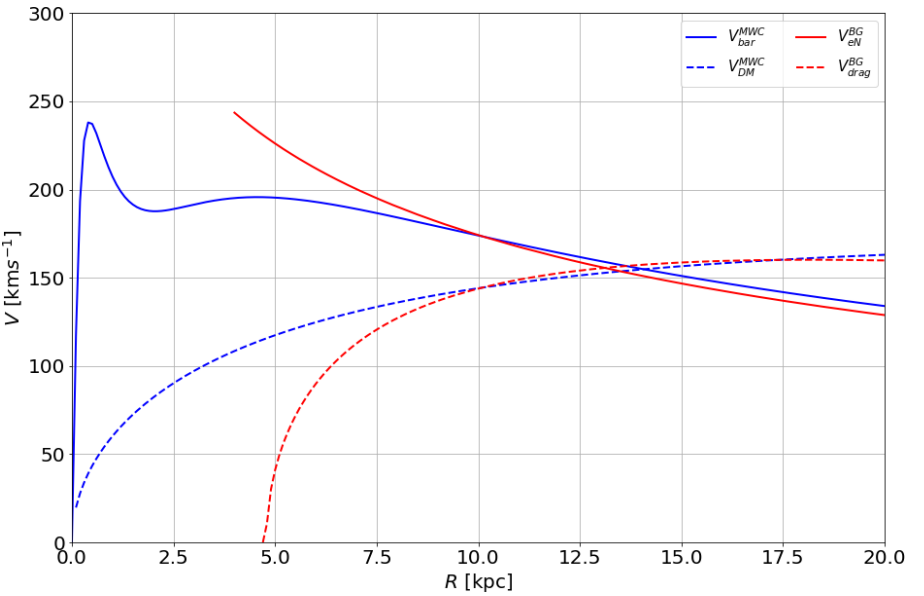

Fig. 3. From M. Crosta, M. Giammaria, M.G. Lattanzi and E. Poggio.[11] Red and blue colors refer to the BG and MWC model, respectively. Solid lines represent the relativistic effective Newtonian rotation curve, V^{BG}_{eN}, and its analogue for the MWC model, as contributed by the total of baryonic mass. The dashed lines show the MWC halo component alone, and the gravitational dragging contribution to V^{BG}, V^{BG}_{drag}, obtained by subtracting V^{BG}_{eN} from V^{BG} itself.

5. Concluding Remarks and Future Perspectives

By setting a coherent GR framework, one can effectively establish to what extent the MW structure is dictated by the standard theory of gravity. The paper Crosta et al.[11] explored the weak relativistic regime of Einstein's equation for the galactic dynamics and gives a possible interpretation of the MW RC as traced by the Gaia data by considering the background curvature, in some respects how space tells mass to move. If we look at DM proprieties, it does not absorb or emit light but it exerts and responds only to the gravity force; it enters the calculation as extra mass (halo) required to justify the flat galactic rotational curves. A gravitational dragging "DM-like" effect driving the MW velocity rotation curve could imply that geometry - unseen but perceived as manifestation of gravity according to Einstein's equation - is responsible of the flatness at large Galactic radii. In spite of some inadequacies, the simplified BG model adopted was proven also to be quite useful to estimate the (external) radial size of the Galactic bulge and the disc thickness at radial distances R $\geq$4 kpc. Obviously, more data and much improved mathematical models are necessary to confirm such a scenario.

For the observational side the sample size will increases from current 6000 to more than 100 thousands upper main sequence disc stars, with the addition of early-type B stars, in perspective of the full Gaia Data Release 3 expected in 2022.[24] Also

data from spectroscopic surveys (e.g. SDSS, APOGEE, LAMOST, RAVE, GES - Gaia ESO Survey, GALAH) will be merged.

For the theoretical side, the findings described in the previous section push on the fully use of Einstein's theory, point the lack of mathematical solutions for GR Galactic models and state the need to develop more complex background "geometries" to account for the MW multi-structures in concomitance of the incoming and increasingly accurate Gaia data releases along with other Galactic observations targeting the Galactic center. One attempt could be to study, e.g., the class of Lewis and Papapetrou metrics to encompass all the different MW structures and consider different conformal factors to be fitted with the Gaia data (as was done for the density in the BG model). Once a MW geometry is provided, one can extend it to other similar galaxies and include a fully GR kinematics.

With more physically appropriate metrics, along with adequate solution, the Galaxy can play a reference role for other galaxies, much like the Sun for stellar models.

In the main article [CQG **38** (2021) 055003], a new "canonical" form for the Lewis metrics of the Weyl class has been obtained, depending only on three parameters — Komar mass and angular momentum per unit length, plus the angle deficit — corresponding to a coordinate system fixed to the "distant stars" and an everywhere timelike Killing vector field. Such form evinces the local but non-global static character of the spacetime, and striking parallelisms with the electromagnetic analogue. We discuss here its generality, main physical features and important limits (the Levi-Civita static cylinder, and spinning cosmic strings). We contrast it on geometric and physical grounds with the Kerr spacetime — as an example of a metric which is locally non-static.

Keywords: Gravitomagnetism; 1+3 quasi-Maxwell formalism; Sagnac effect; gravitomagnetic clock effect; synchronization gap; local and global staticity; Levi-Civita solution; cosmic strings.

1. Introduction

The general stationary solution of the vacuum Einstein field equations with cylindrical symmetry are the Lewis metrics[1–4]

$$ds^2 = -f(dt^2 + Cd\varphi)^2 + r^{(n^2-1)/2}(dr^2 + dz^2) + \frac{r^2}{f}d\varphi^2 \ ; \tag{1}$$

$$f = ar^{1-n} - \frac{c^2 r^{n+1}}{n^2 a} \ ; \qquad C = \frac{cr^{n+1}}{naf} + b \ , \tag{2}$$

usually interpreted as describing the exterior gravitational field produced by infinitely long rotating cylinders. They divide into two classes: (i) the Weyl class, when all the constants n, a, b, and c are real; (ii) the Lewis class, for n imaginary [implying in turn c real and a and b complex, in order for the line element (1) to be real[3,4]].

In the main article, Ref. 5, we have shown that the Weyl class metrics can be written in the "canonical" form

$$ds^2 = -\frac{r^{4\lambda_{\rm m}}}{\alpha}\left(dt - \frac{j}{\lambda_{\rm m} - 1/4}d\phi\right)^2 + r^{4\lambda_{\rm m}(2\lambda_{\rm m}-1)}(dr^2 + dz^2) + \alpha r^{2(1-2\lambda_{\rm m})}d\phi^2 \ ,$$

depending only on three parameters with a clear physical significance: the Komar mass ($\lambda_{\rm m}$) and angular momentum (j) per unit z-length, plus the parameter α governing the angle deficit. This form allows for a transparent comparison with the Levi-Civita non-rotating cylinder — archetype of the contrast between local and global staticity — which Ref. 5 discusses in detail both on physical and geometrical grounds. Therein its matching to the van Stockum[6] cylinder in star fixed coordinates is also shown. Here we revise some main features of the solution, focusing on its generality [and redundancies of the more usual form (1)-(2)], notable limits, and physical properties, with special attention to those less developed in Ref. 5. Addressing the question posed to us in the discussion following the presentation of this work at MG16,[7] we focus here on its comparison with a non-static (globally and locally) stationary solution, exemplified by the Kerr spacetime.

2. Stationary spacetimes and levels of gravitomagnetism

The line element $ds^2 = g_{\alpha\beta}dx^\alpha dx^\beta$ of a stationary spacetime can generically be written as

$$ds^2 = -e^{2\Phi}(dt - \mathcal{A}_i dx^i)^2 + h_{ij}dx^i dx^j \ , \tag{3}$$

where $e^{2\Phi} = -g_{00}$, $\Phi \equiv \Phi(x^j)$, $\mathcal{A}_i \equiv \mathcal{A}_i(x^j) = -g_{0i}/g_{00}$, and $h_{ij} \equiv h_{ij}(x^k) = g_{ij} + e^{2\Phi}\mathcal{A}_i\mathcal{A}_j$. Observers of 4-velocity $u^\alpha = e^{-\Phi}\partial_t^\alpha \equiv e^{-\Phi}\delta_0^\alpha$, whose worldlines are tangent to the timelike Killing vector field ∂_t, are *at rest* in the coordinate system of (3). They are dubbed "static" or "laboratory" observers. The quotient of the spacetime by their worldlines yields a 3-D Riemannian manifold Σ with metric h_{ij} (called the "spatial metric"), which measures the spatial distances between neighboring laboratory observers.[8] It is identified in spacetime with the *space projector* with respect to u^α, $h_{\alpha\beta} \equiv u_\alpha u_\beta + g_{\alpha\beta}$. Let $U^\alpha = dx^\alpha/d\tau$ be the 4-velocity of a test point particle in geodesic motion. The space components of the geodesic equation $DU^\alpha/d\tau = 0$ yield[5,8–11]

$$\frac{\tilde{D}\vec{U}}{d\tau} = \gamma\left[\gamma\vec{G} + \vec{U}\times\vec{H}\right] \ ; \qquad \vec{G} = -\tilde{\nabla}\Phi \ ; \qquad \vec{H} = e^{\Phi}\tilde{\nabla}\times\vec{\mathcal{A}} \ , \tag{4}$$

where $\gamma = -U^\alpha u_\alpha$ is the Lorentz factor between U^α and u^α, $\tilde{\nabla}$ denotes covariant differentiation with respect to the spatial metric h_{ij} (i.e., the Levi-Civita connection of Σ, $\tilde{\nabla}_j X^i = X^i{}_{,j} + \Gamma(h)^i_{jk}X^k$, for some spatial vector $\vec{X}$), $\tilde{D}/d\tau \equiv U^i\tilde{\nabla}_i$, so that $\tilde{D}\vec{U}/d\tau$ describes the acceleration of the 3-D curve obtained by projecting the timelike geodesic onto the space manifold Σ, being $\vec{U}$ its tangent vector. The latter is identified in spacetime with the projection of U^α onto Σ: $(\vec{U})^\alpha = h^\alpha{}_\beta U^\beta$ [so its space

components equal those of U^α, $(\vec{U})^i = U^i$]. The spatial vectors $\vec{G}$ and $\vec{H}$ (living on Σ) are dubbed, respectively, "gravitoelectric" and "gravitomagnetic" fields [or, jointly, "gravitoelectromagnetic" (GEM) fields]. These play in Eq. (4) roles analogous to those of the electric ($\vec{E}$) and magnetic ($\vec{B}$) fields in the Lorentz force equation, $DU^i/d\tau = (q/m)[\gamma\vec{E} + \vec{U} \times \vec{B}]^i$, and are identified in spacetime, respectively, with minus the acceleration and twice the vorticity of the laboratory observers:

$$G^\alpha = -\nabla_{\mathbf{u}} u^\alpha \equiv -u^\alpha{}_{;\beta} u^\beta \; ; \qquad H^\alpha = \epsilon^{\alpha\beta\gamma\delta} u_{\gamma;\beta} u_\delta \; . \tag{5}$$

They motivate also dubbing the scalar Φ and the vector $\vec{\mathcal{A}}$ gravitoelectric and gravitomagnetic potentials, respectively.

Other realizations of the analogy arise in the equations of motion for a "gyroscope" (i.e., a spinning pole-dipole particle) in a gravitational field and a magnetic dipole in a electromagnetic field. According to the Mathisson-Papapetrou equations,[12,13] under the Mathisson-Pirani spin condition,[14] the spin vector S^α of a gyroscope of 4-velocity U^α is Fermi-Walker transported along its center of mass worldline, $DS^\alpha/d\tau = S^\mu a_\mu U^\alpha$, where $a^\alpha \equiv DU^\alpha/d\tau$. If the gyroscope's center of mass is at rest in the coordinate system of (3) ($U^\alpha = u^\alpha$) the space part of this equation yields[5]

$$\frac{d\vec{S}}{d\tau} = \frac{1}{2}\vec{S} \times \vec{H} \; , \tag{6}$$

which is analogous to the precession of a magnetic dipole in a magnetic field, $D\vec{S}/d\tau = \vec{\mu} \times \vec{B}$. When the electromagnetic field is non-homogeneous, a force is also exerted on the magnetic dipole, covariantly described by $DP^\alpha/d\tau = B^{\beta\alpha}\mu_\beta$,[14,15] where μ^β is the magnetic dipole moment 4-vector, and $B_{\alpha\beta} = \star F_{\alpha\mu;\beta} U^\mu$ ($F^{\alpha\beta} \equiv$ Faraday tensor, $\star \equiv$ Hodge dual) is the "magnetic tidal tensor" as measured by the particle. A covariant force is likewise exerted on a gyroscope in a gravitational field (the "spin-curvature" force[12–15]), which can be written in the remarkably similar form[14]

$$\frac{DP^\alpha}{d\tau} = -\mathbb{H}^{\beta\alpha} S_\beta; \qquad \mathbb{H}_{\alpha\beta} \equiv \star R_{\alpha\mu\beta\nu} U^\mu U^\nu = \frac{1}{2}\epsilon_{\alpha\mu}{}^{\lambda\tau} R_{\lambda\tau\beta\nu} U^\mu U^\nu. \tag{7}$$

Here $\mathbb{H}_{\alpha\beta}$ is the "gravitomagnetic tidal tensor" (or "magnetic part" of the Riemann tensor) as measured by the particle, playing a role analogous to that of $B_{\alpha\beta}$ in electromagnetism. For a particle at rest in a stationary field in the form (3), it is related to the gravitomagnetic field $\vec{H}$ by the expression[11]

$$\mathbb{H}_{ij} = -\frac{1}{2}\left[\tilde{\nabla}_j H_i + (\vec{G} \cdot \vec{H}) h_{ij} - 2G_j H_i\right] \; . \tag{8}$$

In the linear regime, $\mathbb{H}_{ij} \approx H_{i,j}$, and so one can say that (comparing to $\vec{H}$) $\mathbb{H}_{\alpha\beta}$ is essentially a quantity one order higher in differentiation of $\vec{\mathcal{A}}$.

2.1. *Sagnac effect*

By contrast with classical electromagnetism (where only the curl of the magnetic vector potential, $\nabla\times\vec{A}=\vec{B}$, manifests physically), and more like in quantum theory (where $\vec{A}$ manifests itself in the so-called Aharonov-Bohm effect[16]), in General Relativity there are also gravitational effects governed by the gravitomagnetic vector potential $\vec{\mathcal{A}}$ (or 1-form $\boldsymbol{\mathcal{A}}$). One of them is the Sagnac effect, consisting of the difference in arrival times of light-beams propagating around a spatially closed path in opposite directions. In flat spacetime, where the concept was first introduced (see e.g. Refs. 17, 18), the time difference is originated by the rotation of the apparatus with respect to global inertial frames (thus to the "distant stars"), see Fig. 1 in Ref. 5. In a gravitational field, however, it arises also in apparatuses which are fixed relative to the distant stars (i.e., to *asymptotically* inertial frames), Fig. 1(a) below, signaling frame-dragging.[5,18–22] In both cases the effect can be read off from the spacetime metric (3), encompassing the flat Minkowski metric written in a rotating coordinate system, as well as arbitrary stationary gravitational fields. Along a photon worldline, $ds^2=0$; by (3), this yields two solutions, the future-oriented one being $dt=\mathcal{A}_i dx^i+e^{-\Phi}dl$, where $dl=\sqrt{h_{ij}dx^i dx^j}$ is the spatial distance element. Consider photons constrained to move within a closed loop C in the space manifold Σ; for instance, an optical fiber loop, as depicted in Fig. 1 (a). Using the + (-) sign to denote the anti-clockwise (clockwise) directions, the coordinate time it takes for a full loop is, respectively, $t_\pm=\oint_{\pm C}dt=\oint_C e^{-\Phi}dl\pm\oint_C\mathcal{A}_i dx^i$; therefore, the Sagnac *coordinate* time delay $\Delta t_{\rm S}$ (Δt in the notation of Ref. 5) is

$$\Delta t_{\rm S}\equiv t_+-t_-=2\oint_C\mathcal{A}_i dx^i=2\oint_C\boldsymbol{\mathcal{A}}\,, \tag{9}$$

translating, in the observer's proper time, to $\Delta\tau_{\rm S}=e^{\Phi}\Delta t_{\rm S}$. We can thus cast gravitomagnetism into the three distinct levels in Table 1, corresponding to different orders of differentiation of $\boldsymbol{\mathcal{A}}$ (the first one being $\boldsymbol{\mathcal{A}}$ itself).

2.2. *Synchronization gap*

Another physical process where $\boldsymbol{\mathcal{A}}$ manifests is in the synchronization of the clocks carried by the "laboratory observers" (i.e., tangent to the Killing vector field ∂_t). Consider a curve $x^\alpha(\lambda)$ of tangent $dx^\alpha/d\lambda$ which is spatially closed (i.e., its projection onto Σ yields a closed curve C, so that after each loop it re-intersects the worldline of the original observer). Along $x^\alpha(\lambda)$, the synchronization through Einstein's light signaling procedure[8,21] amounts to the condition that the curve be orthogonal (at every point) to ∂_t^α, that is, $g_{0\beta}dx^\beta/d\lambda=0\Leftrightarrow dt=\mathcal{A}_i dx^i$. This curve will thus re-intersect the worldline of the original observer at a coordinate time $t_f=t_i+\Delta t_{\rm sync}$, where[8]

$$\Delta t_{\rm sync}=\oint_C\mathcal{A}_i dx^i=\oint_C\boldsymbol{\mathcal{A}}\quad(=\Delta t_{\rm S}/2)\,. \tag{10}$$

The observer will then find that his clock is not synchronized with his preceding neighbor's by a time gap (as measured in his proper time) $\Delta\tau_{\rm sync} = e^{\Phi}\Delta t_{\rm sync}$, corresponding, in coordinate time, to an interval $\Delta t_{\rm sync}$ [which is one half the Sagnac time delay $\Delta t_{\rm S}$ along such loop, Eq. (9)]. Only when $\Delta t_{\rm sync} = 0$ the observers are able to fully synchronize their clocks along a closed loop.

2.3. *Gravitomagnetic clock effect*

As is well known, in the field of a spinning body the periods of co- and counter-rotating circular geodesics differ; such an effect has been dubbed[23–26] gravitomagnetic "clock effect". The corresponding angular velocities read (see e.g. Sec. 3.1 of Ref. 5)

$$\Omega_{\rm geo\pm} = \frac{-g_{0\phi,r} \pm \sqrt{g_{0\phi,r}^2 - g_{\phi\phi,r}g_{00,r}}}{g_{\phi\phi,r}} \tag{11}$$

and thus the difference between their periods, $\Delta t_{\rm geo} = 2\pi(\Omega_{\rm geo+}^{-1} + \Omega_{\rm geo-}^{-1}) = -4\pi g_{0\phi,r}/g_{00,r}$, is[5,27]

$$\Delta t_{\rm geo} = \Delta t_{\rm S} + \Delta t_H; \qquad \Delta t_{\rm S} = 4\pi\mathcal{A}_\phi; \qquad \Delta t_H = -2\pi\frac{\star H_{r\phi}}{G_r e^{\Phi}} \ , \tag{12}$$

where $\star H_{jk} \equiv \epsilon_{ijk}H^i$ is the 2-form dual to the gravitomagnetic field $\vec{H}$, such that $\star H_{r\phi} = \sqrt{h}H^z$ in cylindrical coordinates, and $\star H_{r\phi} = -\sqrt{h}H^\theta$ in spherical coordinates. Here h is the determinant of the space metric h_{ij} in (3). Hence, the effect consists of the sum of two contributions of different origin, corresponding to two distinct levels of gravitomagnetism in Table (1): the Sagnac time delay $\Delta t_{\rm S}$ around the circular loop, governed by $\boldsymbol{\mathcal{A}}$, cf. Eq. (9), plus the term Δt_H due to the gravitomagnetic force $\gamma\vec{U}\times\vec{H}$ in Eq. (4) (which has a direct electromagnetic counterpart, see Sec. 3.1 in Ref. 5; cf. also Ref. 26).

The delay (12) corresponds to orbital periods (in coordinate time) as seen by the "laboratory" observers, at rest in the coordinates of (3). Other observers (e.g. rotating with respect to the former) will measure different periods since, from their point of view, the closing of the orbits occurs at different points. An *observer-independent* akin effect[25,28] can however be derived, based on the proper times (τ_+ and τ_-) measured by each orbiting particle between the events where they meet, see Fig. 1 (b). Set a starting meeting point at $\phi_+ = \phi_- = 0$, $t = 0$; the next meeting point is defined by $\phi_+ = 2\pi + \phi_-$. Since $\phi_\pm = \Omega_{\rm geo\pm}t$, the meeting point occurs at a coordinate time $t = 2\pi/(\Omega_{\rm geo+} - \Omega_{\rm geo-})$. Hence,

$$\tau_\pm = \frac{t}{U_\pm^0} = \frac{2\pi(U_\pm^0)^{-1}}{\Omega_{\rm geo+} - \Omega_{\rm geo-}} \ ; \qquad \Delta\tau \equiv \tau_+ - \tau_- = 2\pi\frac{(U_+^0)^{-1} - (U_-^0)^{-1}}{\Omega_{\rm geo+} - \Omega_{\rm geo-}} \ . \tag{13}$$

3. Artificial features of the usual form of the Weyl class metric

In the case of the static Levi-Civita cylinder, which follows from (1)-(2), with n and a real, by making[a] $b = 0 = c$, we have[b] $\Phi = 2\lambda_{\rm m} \ln(r) + const.$, $\mathbf{G} = -2\lambda_{\rm m}/r\mathbf{d}r$, $\boldsymbol{\mathcal{A}} = 0 = \vec{H}$, where $\lambda_{\rm m} = (1-n)/4$. This exactly matches the electromagnetic counterparts for an infinite static charged cylinder, if ones identifies $\lambda_{\rm m}$ with minus the charge per unit z-length. ($\lambda_{\rm m}$ being actually the Komar mass per unit z- length, as we shall see in Sec. 4.3). However, in the general case $b \neq 0 \neq c$, we have

- Φ, $\boldsymbol{\mathcal{A}}$, and $\vec{G}$ complicated [Eqs. (43) of Ref. 5], and very different from the electromagnetic counterparts for a infinitely long spinning charged cylinder (in the inertial rest frame);
- $\vec{H}$ and $\mathbb{H}_{\alpha\beta}$ both *non-zero* [and complicated, Eqs. (43) and (45) of Ref. 5], at odds with the electromagnetic analogue.

These features are somewhat unexpected given the similarities with the electromagnetic analogue in the static case, and given that this metric is known to be *locally static*. The situation resembles more the electromagnetic analogue as seen from a rotating frame. Moreover,

- ∂_t ceases to be time-like for $r^{2n} > a^2n^2/c^2 \Rightarrow$ no observers at rest are possible past this radius

which is, again, reminiscent of a rigidly rotating frame in flat spacetime where, past a certain value of r, the observers would be superluminal. The question then arises, can the metric, in the usual form (1)-(2) given in the literature, be actually written in some trivially rotating coordinate system? We will next show this to be the case.

4. The "canonical" form of the Weyl class metric

4.1. *"Star-fixed" coordinates: the metric with only three parameters*

An analysis of the curvature invariants [cubic and quadratic, Eqs. (39)-(41) and (50) of Ref. 5] reveals that the Weyl class metric (i.e., with n real) is a "purely electric" Petrov type I spacetime.[5,29,30] This means that, at each point, there is an (unique) observer for which the gravitomagnetic tidal tensor vanishes, $\mathbb{H}_{\alpha\beta} = 0$. These observers have 4-velocity of the form $U^\alpha = U^t(\partial_t^\alpha + \Omega\partial_\phi^\alpha)$, with *constant* angular velocity Ω given by

$$\Omega = \frac{c}{n - bc} \qquad \text{or} \qquad \Omega = -\frac{1}{b} \ , \tag{14}$$

the first (second) value yielding a time-like U^α if $a > 0$ ($a < 0$). Thus, by performing a coordinate rotation at constant angular velocity

$$\phi = \varphi - \Omega t \ , \tag{15}$$

[a] We shall see that the condition $c = 0$ is actually not necessary, cf. Eqs. (16)-(18).
[b] Taking $a > 0$, so that t is the temporal coordinate.

one switches to a coordinate system where these observers are at rest, and the metric takes the form

$$ds^2 = -\frac{r^{1-s}}{\alpha}(dt + \bar{C}d\phi)^2 + r^{(s^2-1)/2}(dr^2 + dz^2) + \alpha r^{1+s} d\phi^2 \ , \qquad (16)$$

with, for $\Omega = c/(n - bc)$,

$$s = n \ ; \qquad \alpha = \frac{\bar{C}^2}{ab^2} \ ; \qquad \bar{C} = b\frac{n - bc}{n} = b\frac{s - bc}{s} \ , \qquad (17)$$

and, for $\Omega = -1/b$,

$$s = -n \ ; \qquad \alpha = -ab^2 \ ; \qquad \bar{C} = -b\frac{n - bc}{n} = b\frac{s - bc}{s} \qquad (18)$$

Equation (16) shows that the metric depends only on three effective parameters: α, s, and $\bar{C}$, manifesting a redundancy in the original four parameters [different values of (n, a, b, c) yielding the same values of $(s, \alpha, \bar{C})$ correspond to the same physical solution]. The two values (14) for the angular velocity Ω are two equivalent paths of reaching (16), and manifest a particular case of the redundancy: two sets of parameters (a_1, b_1, c_1, n_1) and (a_2, b_2, c_2, n_2), with $a_1 > 0$ and $a_2 < 0$, such that the values of $(s, \alpha, \bar{C})$ are the same. There is one special case excluded from each of the transformations (14)-(15); namely, $bc = n$ for the first value of Ω, and $b = 0$ for the second; they are however redundant, as both lead to the Levi-Civita line-element[c] (26).

Observe that the Killing vector field ∂_t is, in (16), *everywhere time-like* ($g_{00} < 0$ for all r). Therefore, observers of 4-velocity $u^\alpha = (-g_{00})^{1/2}\partial_t^\alpha$, at rest in the coordinates of (16), exist everywhere (even for arbitrarily large r). As we shall see in Sec. (4.4) below, ∂_t is actually tangent to inertial observers at infinity, hence the reference frame associated to the coordinate system in (16) is asymptotically inertial, and thus fixed to the "distant stars".

4.2. *Symmetry under swap of time and angular coordinates*

In the transformation (15) one assumes, as is usual practice, that φ is an angular coordinate, ranging $[0, 2\pi]$, and t the time coordinate [which in turn implies $\alpha > 0$ and thus $a > 0$ in case (17), and $a < 0$ in case (18)]. Such assumption is however not necessary to reach (16). Indeed, swapping $t \leftrightarrow \varphi$ in (1), again leads to (16), as we shall now show. Substituting, in (1), $\varphi \to t'$, $t \to \varphi'$, the time-like observers measuring vanishing gravitomagnetic tidal tensor have now angular velocity $\Omega' = 1/\Omega$, where Ω is given by (14), and $\Omega' = (n - bc)/c$ yields a time-like U^α if $a > 0$, and likewise $\Omega' = -b$ for $a < 0$. Applying the transformation $\phi' = \varphi' - \Omega' t' = \varphi' - t'/\Omega$ to such line element leads to a primed version of (16),

$$ds^2 = -\frac{r^{1-s}}{\alpha}(dt' + \bar{C}d\phi')^2 + r^{(s^2-1)/2}(dr^2 + dz^2) + \alpha r^{1+s} d\phi'^2 \qquad (19)$$

[c] That it is so for $b = 0$ can be immediately seen by substituting in (16)-(17), yielding (26); likewise, that it is so for $n = bc$ can be seen by substituting $n \to bc$ in the expression for $\bar{C}$ in (18).

with, for $\Omega' = (n - bc)/c$, the identifications $s = n$, $\alpha = c^2/(an^2)$, $\bar{C} = c/n$; and, for $\Omega' = -b$, the identifications $s = -n$, $\alpha = -a$, $\bar{C} = -c/n$. This is a natural result. Equations (1)-(2) are just a general solution of the vacuum Einstein field equations with three commuting Killing vector fields, one time-like and two spacelike,[4,31] having no information on global aspects of the coordinates; it is thus natural that one be free to choose the angular coordinate rendering the axial symmetry.

One must note, however, that the metric in star fixed coordinates (16) does not preserve such symmetry. The coordinate rotation (15), with the identification $\varphi = \varphi + 2\pi$, breaks that symmetry by implicitly choosing ϕ (and φ) as a periodic coordinate, and t non-periodic. Indeed, substituting in (16) $\phi \to t'$, $t \to \phi'$, leads to (19) with $\phi' \leftrightarrow t'$ swapped:

$$ds^2 = -\frac{r^{1-s}}{\alpha}(\bar{C}dt' + d\phi')^2 + r^{(s^2-1)/2}(dr^2 + dz^2) + \alpha r^{1+s}dt'^2 \; ; \qquad (20)$$

forcing now on it the identification $(t', \phi') = (t', \phi' + 2\pi)$ (i.e, taking ϕ' to be periodic), makes it become the Levi-Civita metric in a rotating coordinate system, immediately diagonalizable through the coordinate rotation $\phi'' = \phi' + \bar{C}t$. This occurs because, by overriding the original identifications $(t, \phi) = (t, \phi + 2\pi)$, the geometry was *globally* (albeit not locally) changed. Indeed such transformation (with such identifications) is not a global diffeomorphism, as can be seen e.g. from the fact the ordered pairs $\mathcal{P}_1$: (t, ϕ) and $\mathcal{P}_2$: $(t, \phi + 2\pi)$, which represented the same event in the original metric (16), are mapped into the two different events $\mathcal{P}'_1$: (t', ϕ') and $\mathcal{P}'_2$: $(t' + 2\pi, \phi')$ in the metric (20). The transformation $(t', \phi') = (\phi, t)$, followed by $\phi'' = \phi' + \bar{C}t$, actually amounts to (76) of Ref. 5 which, as shown therein, corresponds to the "famous"[2,4] transformation that takes the Weyl class metric into the static Levi-Civita one.

4.3. *The metric in terms of physical parameters — "canonical" form*

The fact that in Eq. (16) the Killing vector field $\xi^\alpha = \partial_t^\alpha$ is everywhere time-like, tangent to inertial observers at infinity, and appropriately normalized,[5] allows for defining a corresponding Komar integral on simply connected tubes $\mathcal{V}$ of unit z-length parallel to the z-axis, having a physical interpretation of "active" gravitational mass per unit z-length, as discussed in Secs. 5.2.1 and 2.4 of Ref. 5 (cf. also Refs. 32–35). It is given by

$$\lambda_{\rm m} = \frac{1}{8\pi}\int_{\partial\mathcal{V}} \star\mathbf{d\xi} = \frac{1}{8\pi}\int_{\mathcal{S}} (\star d\xi)_{\phi z} d\phi dz = \frac{1-s}{4} \; ,$$

where $\partial\mathcal{V} = \mathcal{S} \cup \mathcal{B}_1 \cup \mathcal{B}_2$ is the tube's boundary, $\mathcal{S}$ its lateral surface, parameterized by $\{\phi, z\}$, and $\mathcal{B}_1$ and $\mathcal{B}_2$ its bases, lying on the planes orthogonal to the z-axis and parameterized by $\{r, \phi\}$, and in the second and third equalities we noticed that $(\star d\xi)_{r\phi} = 0$ and $(\star d\xi)_{\phi z} = 1 - s$. Likewise, the Komar integral associated with the

axial symmetry Killing vector field $\zeta^\alpha = \partial^\alpha_\phi$ has the interpretation of the spacetime's angular momentum per unit z-length,

$$j = -\frac{1}{16\pi}\int_{\partial\mathcal{V}} \star\mathbf{d}\boldsymbol{\zeta} = -\frac{1}{16\pi}\int_{\mathcal{S}} (\star d\zeta)_{\phi z} d\phi dz = \frac{s\bar{C}}{4}$$

where we in the second equality we noticed that $(\star\zeta)_{r\phi} = 0$. It follows that (16) can be re-written as

$$\boxed{ds^2 = -\frac{r^{4\lambda_{\rm m}}}{\alpha}\left(dt - \frac{j}{\lambda_{\rm m} - 1/4}d\phi\right)^2 + r^{4\lambda_{\rm m}(2\lambda_{\rm m}-1)}(dr^2+dz^2) + \alpha r^{2(1-2\lambda_{\rm m})}d\phi^2 \ .} \tag{21}$$

4.4. *Physical properties; gravitomagnetism*

For $\alpha > 0$ [so that t in Eq. (21) is a temporal coordinate], the metric can be put in the form (3), with

$$e^{2\Phi} = \frac{r^{4\lambda_{\rm m}}}{\alpha} \quad \Rightarrow \quad \Phi = 2\lambda_{\rm m}\ln(r) + K \ ; \qquad \boldsymbol{\mathcal{A}} = -\frac{4j}{1-4\lambda_{\rm m}}\mathbf{d}\phi \ ; \tag{22}$$

$$h_{ij}dx^i dx^j = r^{4\lambda_{\rm m}(2\lambda_{\rm m}-1)}(dr^2+dz^2) + \alpha r^{2(1-2\lambda_{\rm m})}d\phi^2 \tag{23}$$

[with $K \equiv -\ln(\alpha)/2$]. The gravitoelectric and gravitomagnetic 1-forms/fields read, cf. Eqs. (4),

$$\mathbf{G} = -\frac{2\lambda_{\rm m}}{r}\mathbf{d}r \ ; \qquad \vec{H} = \mathbf{H} = 0 \ . \tag{24}$$

Thus Φ, $\mathbf{G}$ and $\mathbf{H} = 0$ match their electromagnetic counterparts for a spinning charged cylinder (as viewed from the inertial rest frame, see e.g. Sec. 4 in Ref. 5) identifying the Komar mass with *minus* the charge, $\lambda_{\rm m} \leftrightarrow -\lambda$; the gravitomagnetic potential 1-form $\boldsymbol{\mathcal{A}} = \mathcal{A}_\phi\mathbf{d}\phi$ also resembles the magnetic potential 1-form $\mathbf{A} = \mathfrak{m}\mathbf{d}\phi$. The cylinder's rotation does not manifest in the inertial forces (nor in the tidal forces, as shown in Sec. 5.2.3 of Ref. 5); the only inertial force acting on test particles is the gravitoelectric (Newtonian-like) force $m\vec{G}$, independent of j. Thus, particles dropped from rest or in initial radial motion move along radial straight lines, cf. Eq. (4); and circular geodesics have a *constant* speed given by $v_{\rm geo} = \sqrt{\lambda_{\rm m}/(1/2-\lambda_{\rm m})}$, being thus possible when $0 \leq \lambda_{\rm m} < 1/4$ (it is when $\lambda_{\rm m} > 0$ that $\vec{G}$ is attractive, and they become null for $\lambda_{\rm m} = 1/4$). The vanishing of $\vec{H}$ means also that gyroscopes at rest in the coordinates of (21) do not precess, the components of their spin vector $\vec{S}$ remaining constant, cf. Eq. (6). Since $\vec{G} \overset{r\to\infty}{\to} \vec{0}$, it follows moreover that the reference frame associated to the coordinate system in (21) is *asymptotically* inertial, thus one can take it as the rest frame of the "distant stars" ("star-fixed" frame).

The only surviving gravitomagnetic object is thus the gravitomagnetic 1-form $\boldsymbol{\mathcal{A}}$, corresponding to the first level in Table 1. One of its physical manifestations is the

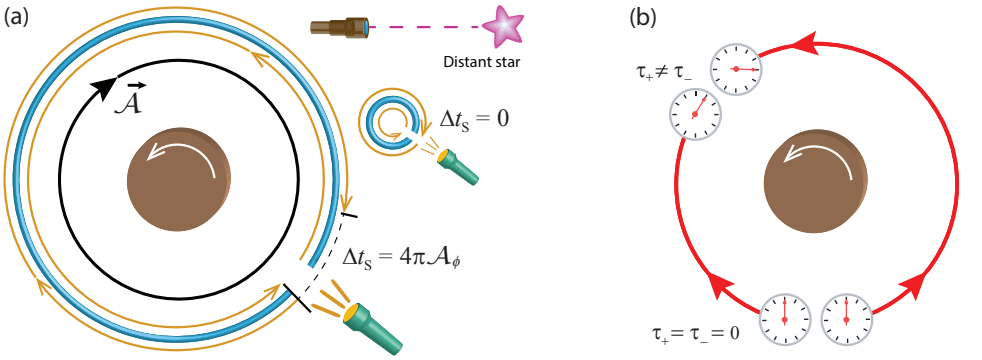

Fig. 1. (a) Sagnac effect around spinning cylinders: a flashlight sends light beams propagating in opposite directions along optical fiber loops fixed with respect to the "distant stars" (i.e., to the asymptotic inertial frame at infinity). In each loop C, the difference in beam arrival times is $\Delta t_S = 2\oint_C \boldsymbol{\mathcal{A}}$; since $\boldsymbol{\mathcal{A}}$ is a *closed* form ($\mathbf{d}\boldsymbol{\mathcal{A}} = 0$), the effect vanishes for all loops not enclosing the cylinder, and has the same value (25) for all loops enclosing it (the co-rotating beam arriving first). (b) Frame independent gravitomagnetic clock effect: a pair of clocks in oppositely rotating circular geodesics around a cylinder; when the cylinder spins ($j \neq 0$) the clocks measure different proper times between the events where they meet, $\tau_+ > \tau_-$.

Sagnac effect: consider, as depicted in Fig. 1(a) optical fiber loops fixed with respect to the distant stars, i.e., at rest in the coordinate system of (21). The difference in arrival times for light beams propagating in opposite directions along any of such loops is given by the circulation of $\boldsymbol{\mathcal{A}}$ along the loop, c.f. Eq. (9). Observe that $\boldsymbol{\mathcal{A}}$ is a closed form, $\mathbf{d}\boldsymbol{\mathcal{A}} = 0$ (since $\mathcal{A}_\phi$ is constant), defined in a space manifold Σ homeomorphic to $\mathbb{R}^3\backslash\{r = 0\}$. By the Stokes theorem, this means[5] that the effect vanishes along any loop which does not enclose the central cylinder (or the axis $r = 0$), such as the small loop in Fig. 1 (a), and has the *same* nonzero value

$$\Delta t_S = 4\pi\mathcal{A}_\phi = -\frac{4\pi j}{1/4 - \lambda_m} \tag{25}$$

along any loop enclosing the cylinder, regardless of its shape; for instance, the large circular loop depicted in Fig. 1(a). It is worth noticing that this mirrors the situation for the Aharonov-Bohm effect around spinning charged cylinders, which is likewise independent of the shape of the paths; the two effects are actually described by formally analogous equations[d].

The apparatus above makes use of a star-fixed reference frame, which is physically realized by aiming telescopes at the distant stars.[36,37] It is possible, however (still based on the Sagnac effect) to detect the cylinder's rotation in a more local way, without the need for setting up a specific frame; only not with a single loop, as along a single loop the effect can always be made to vanish by spinning it with some angular velocity. In particular, for a concentric circular loop, the effect

[d]Re-writing (9) in terms of the half-loop phase delay $\Delta\varphi = (E/\hbar)\Delta t_S/2 = (2\pi E/\hbar)\mathcal{A}_\phi$ and identifying $\{E, \mathcal{A}_\phi\} \leftrightarrow \{q, A_\phi\}$, where $E \equiv$ photon's energy, see Sec. 4.1 in Ref. 5.

vanishes if it has zero angular momentum, i.e., if it comoves with the zero angular momentum observers (ZAMOs) of the same radius. The angular velocity of such observers, Eq. (69) of Ref. 5, is however r-dependent; hence, considering instead a "coil" of optical loops, as depicted in Fig. 4 of Ref. 5, provides a frame-independent (thought) experiment to detect the cylinder's rotation, since it is impossible to make the effect vanish simultaneously in every loop when $j \neq 0 \Leftrightarrow \boldsymbol{\mathcal{A}} \neq 0$.

4.4.1. *Observer-independent gravitomagnetic clock effect*

Another consequence of the vanishing of $\vec{H}$ is that the gravitomagnetic clock effect in Eq. (12) reduces to the Sagnac time delay, $\Delta t_{\rm geo} = \Delta t_{\rm S} = 4\pi \mathcal{A}_\phi$; hence, all that was said above about beams in optical loops around the cylinder, applies as well to pairs of particles in oppositely rotating circular geodesics (the co-rotating geodesics having thus shorter periods). It is however actually possible to detect the cylinder's rotation using only *one pair* of particles (i.e., a pair of clocks), through the difference in the proper times (τ_+ and τ_-) measured by each of them between the events where they meet, see Fig. 1 (b). From Eqs. (13) and (11), with $U^0_\pm = (-g_{00} - 2\Omega_{{\rm geo}\pm} g_{0\phi} - \Omega^2_{{\rm geo}\pm} g_{\phi\phi})^{-1/2}$, we have

$$\Delta\tau \equiv \tau_+ - \tau_- = \frac{8\pi j r^{2\lambda_{\rm m}}}{\sqrt{\alpha(1-4\lambda_{\rm m})(1-2\lambda_{\rm m}) + 8\lambda_{\rm m} j^2 r^{8\lambda_{\rm m}-2}\alpha^{-1}(1/4-\lambda_{\rm m})^{-1}}} \quad (>0)$$

(this result is mentioned in main paper,[5] though without presenting it explicitly). Hence, when $j \neq 0$, the proper times measured by each clock differ when they meet, the co-rotating clock measuring a longer time.

4.5. *Important limits: Levi-Civita static cylinder and cosmic strings*

It is immediate to obtain important limits from the canonical form (21). Taking the limit $j \to 0$ yields the Levi-Civita metric[2–4]

$$ds^2 = -\frac{r^{4\lambda_{\rm m}}}{\alpha} dt^2 + r^{4\lambda_{\rm m}(2\lambda_{\rm m}-1)}(dr^2 + dz^2) + \alpha r^{2(1-2\lambda_{\rm m})} d\phi^2 \ . \tag{26}$$

The inertial fields $\vec{G}$ and $\vec{H} = 0$, as well as the spatial metric h_{ij}, remain the same as in (21) (the same applying to the tidal fields/forces, see Sec. 5.2.3 in Ref. 5). They differ only in the gravitomagnetic potential 1-form $\boldsymbol{\mathcal{A}} = -4j/(1-4\lambda_{\rm m})\mathbf{d}\phi$, governing global physical effects such as the Sagnac effect and synchronization gap (10) in loops around the cylinder, and the gravitomagnetic clock effect, which are all zero for the static metric (26), see Figs. 1-2.

The limit $\lambda_{\rm m} \to 0$ yields

$$ds^2 = -\frac{1}{\alpha}\left[dt + 4j d\phi\right]^2 + dr^2 + dz^2 + \alpha r^2 d\phi^2 \tag{27}$$

which is the metric of a spinning cosmic string[2,38,39] of *Komar* angular momentum per unit length j and angle deficit $2\pi(1-\alpha^{1/2}) \equiv 2\pi\delta$. In this case the spacetime

is locally flat ($R_{\alpha\beta\gamma\delta} = 0$) for $r \neq 0$. All the GEM inertial fields vanish, $\vec{G} = \vec{H} = 0$ (and the same for the tidal fields), thus there are no gravitational forces of any kind. Global gravitational effects however subsist, governed by $\boldsymbol{\mathcal{A}} = -4j\mathbf{d}\phi$ and α. The non-vanishing gravitomagnetic potential 1-form $\boldsymbol{\mathcal{A}}$ means that a Sagnac effect remains, thus the apparatuses manifesting the source's rotation discussed in Sec. 4.4 apply here as well. The same applies to the synchronization of clocks: observers at rest in the coordinates of (27) (which are in this case inertial observers) can synchronize their clocks along closed loops not enclosing the string (i.e., the axis $r = 0$), but are unable to do so for loops enclosing it. As for the gravitomagnetic clock effect, it does not apply here, as circular geodesics do not exist (since there is no gravitational attraction, $\vec{G} = 0$). The angle deficit generates double images of objects located behind the string,[40,41] and a holonomy[41,42] along closed (in spacetime or only spatially) loops around the string. Namely, vectors parallel transported along such loops turn out rotated by an angle $-2\pi\alpha^{1/2}$ (i.e, $2\pi\delta$) about the z-axis when they return to the initial position — an effect which is independent of the shape of the loop and of j; see Sec. 5.2.4 of Ref. 5. One thus can say that the metric (27) possesses two holonomies: a spatial holonomy governed by α, which is the same for spinning or non-spinning strings, plus a synchronization holonomy (Sec. 5.3.3 of Ref. 5) that arises in the spinning case.

4.6. *Summary of "canonical" features*

We argue Eq. (21) to be the most natural, or *canonical*, form for the metric of a Weyl class rotating cylinder for the following reasons:

- the Killing vector field ∂_t is (for $\alpha > 0$) everywhere time-like (i.e., $g_{00} < 0$ for all r), therefore physical observers $u^\alpha = (-g_{00})^{-1/2}\partial_t^\alpha$, at rest in the coordinates of (21), exist everywhere.
- The associated reference frame is *asymptotically* inertial, and thus fixed with respect to the "distant stars" (Sec. 4.4).
- A conserved Komar mass per unit length ($\lambda_{\rm m}$) can be defined from ∂_t which matches its expected value from the gravitational field $\vec{G}$ and potential Φ in Sec. 4.4 (see also Sec. 5.2.1 of Ref. 5), and also that of the Levi-Civita static cylinder (26).
- It is irreducibly given in terms of three parameters with a clear physical interpretation: the Komar mass ($\lambda_{\rm m}$) and angular momentum (j) per unit length, plus the parameter α governing the angle deficit of the spatial metric h_{ij}.
- The GEM fields are strikingly similar to the electromagnetic analogues — the electromagnetic fields of a rotating cylinder as measured in the inertial rest frame (namely $\boldsymbol{\mathcal{A}} = \mathcal{A}_\phi\mathbf{d}\phi$; $\mathcal{A}_\phi \equiv$constant, $\vec{H} = \mathbb{H}_{\alpha\beta} = 0$, and Φ and $G_{,i}$ match the electromagnetic counterparts identifying the Komar mass per unit length $\lambda_{\rm m}$ with the minus charge per unit length λ, cf. Sec. 4 of Ref. 5).

- It is immediate from it to obtain the two important limits: spinning cosmic string ($\lambda_{\rm m} = 0$), and Levi-Civita static solution (evincing that $j = 0$ is the necessary and *sufficient* condition).
- The GEM inertial fields and tidal tensors are the *same* as those of the Levi-Civita static cylinder (just like the electromagnetic forces produced by a charged spinning cylinder are the same as by a static one).
- It is obtained from a simple rigid rotation of coordinates, Eq. (15), which is a well-defined *global* coordinate transformation (Sec. 4.1).
- It makes immediately transparent the locally static but globally stationary nature of the metric (see Sec. 5 below).
- It has a smooth matching to the van Stockum interior solution (corresponding to a cylinder of rigidly rotating dust) *written in star-fixed coordinates* (Sec. 5.4.2 of Ref. 5).

We conclude that the Lewis metric in its usual form (1)-(2) indeed possesses a trivial coordinate rotation [of angular velocity $-\Omega$, equivalently given by either of Eqs. (14)], which has apparently gone unnoticed in the literature, and causes the artificial features listed in Sec. 3. As shown in Sec. 5.4 of Ref. 5, such rotation has a simple interpretation when the solution is matched to the van Stockum interior solution (corresponding to a rigidly rotating cylinder of dust): the coordinate system in (1)-(2) is *rigidly comoving* with the cylinder.

5. Contrast with a locally (and globally) *non-static* solution — the Kerr spacetime

Question by O. Semerák: *you were comparing the results for the (rotating) Weyl class Lewis metric with the static case; how about the comparison with Kerr, which is different because there the vorticity should contribute to the gravitomagnetic field?*

The contrast with the Kerr spacetime is indeed instructive. In what pertains to gravitomagnetism, it fundamentally differs from the Weyl class cylindrical metrics (rotating or non-rotating) in two mains aspects: it is not locally static, and its Riemann tensor is not (except at the equatorial plane) "purely electric".[29]

Staticity.— a spacetime is static[43] within some region *iff* a time-like Killing vector field ξ^α exists which is proportional to the gradient of some (single-valued) function ψ, $\xi_\alpha = \eta\partial_\alpha\psi$. Locally, this condition is equivalent to the integral lines of ξ^α having no vorticity, i.e., being hypersurface orthogonal (globally, however, the vorticity-free condition is not sufficient[43,44]). One can show (Proposition 5.1 in Ref. 5) that, in the GEM framework, local staticity amounts to the existence of a coordinate system where the metric takes the stationary form (3) with $\boldsymbol{\mathcal{A}}$ closed ($\mathbf{d}\boldsymbol{\mathcal{A}} = 0$); and global staticity to $\boldsymbol{\mathcal{A}}$ being moreover an *exact* form (in a globally well defined coordinate system).

The Weyl class Lewis metric (21) is locally static since $\mathbf{d}\boldsymbol{\mathcal{A}} = 0$; but, unless $j = 0 \Rightarrow \boldsymbol{\mathcal{A}} = 0$ (Levi-Civita static cylinder), *not globally* static, since $\boldsymbol{\mathcal{A}} = \mathcal{A}_\phi \mathbf{d}\phi$ is not an exact form. This means that the Killing vector field ∂_t is hypersurface

orthogonal but (unless $j = 0$) such hypersurfaces are not of global simultaneity, see Fig. 2 (a)-(b). In the case of the Kerr spacetime, $\mathbf{d}\boldsymbol{\mathcal{A}} \neq 0$, so it is not globally static; no hypersurface orthogonal time-like Killing vector field exists, the only Killing vector field which is time-like at infinity being ∂_t in Boyer-Lindquist coordinates, whose integral lines are well known to have vorticity. Geometrically, this means that the distribution of hyperplanes orthogonal to ∂_t (i.e., the hyperplanes of *local* simultaneity,[21] or local rest spaces of the "laboratory" observers) is not integrable, see Fig. 2 (c). On top of this, outside the equatorial plane, $R_{\alpha\beta\gamma\delta}$ is not purely electric (see Sec. V.C of Ref. 29), thus no observers exist measuring a vanishing gravitomagnetic tidal tensor $\mathbb{H}_{\alpha\beta}$.

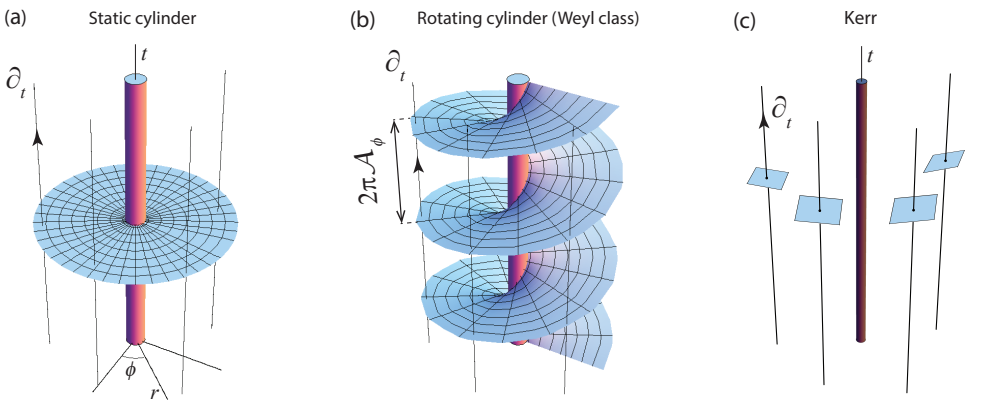

Fig. 2. (a)-(b): In the Weyl class Lewis metrics (21) the Killing vector field ∂_t is hypersurface orthogonal; such hypersurface is of global simultaneity (a plane, in a t, r, ϕ plot) for a non-spinning (Levi-Civita) cylinder, and of local but *non-global* simultaneity (the helicoid $t - \mathcal{A}_\phi \phi = const.$) in the spinning case. (c) In the Kerr spacetime ∂_t is not hypersurface orthogonal, i.e., the distribution of hyperplanes orthogonal to ∂_t (hyperplanes of *local* simultaneity) is not integrable. In (a) observers of worldlines tangent to ∂_t ("laboratory observers") are able to globally synchronize their clocks. In (b) they are unable to synchronize their clocks *around* the cylinder: each 2π turn along the helicoid leads to a different event in time, the jump between turns being the synchronization gap $\Delta t_{\text{sync}} = 2\pi\mathcal{A}_\phi$. In (c) the laboratory observers are (generically) unable to synchronize their clocks along any spatially closed loop, $\Delta t_{\text{sync}} = \oint \boldsymbol{\mathcal{A}} \neq 0$.

Physically, this means that whereas for the Weyl class spinning cylinder (21) only the first level of gravitomagnetism in Table 1 is non-zero, in the Kerr spacetime all the three levels are non-zero. Therein it is thus possible to detect the source's rotation in a more local way (i.e., not needing experiments on loops around the source): in a reference frame fixed to the distant stars, due to the non-zero gravitomagnetic field $\vec{H}$, test particles in geodesic motion will appear to be deflected by a gravitomagnetic (or Coriolis) force $\gamma\vec{U} \times \vec{H}$, cf. Eq. (4), causing e.g. their orbits to precess (Lense-Thirring precession[36]), and gyroscopes will as well be seen to precess, cf. Eq. (6). The non-vanishing $\mathbb{H}_{\alpha\beta}$ means moreover that gyroscopes at rest (or generically moving) will be acted by a force (7).

Table 1. Gravitomagnetic effects present in the Weyl class Lewis metrics and in the Kerr spacetime, as measured in star-fixed reference frames (canonical and Boyer-Lindquist coordinate systems, respectively), split by levels of gravitomagnetism, corresponding to orders of differentiation of $\boldsymbol{\mathcal{A}}$.

Level of Gravitomagnetism		Lewis-Weyl	Kerr
Governing object	Physical effect		
$\vec{\mathcal{A}}$ (gravitomagnetic vector potential)	• Sagnac effect • Synchronization gap	✓ (global effects)	✓ (global *and* local)
$\vec{H}$ (gravitomagnetic field $= e^{\phi}\nabla\times\vec{\mathcal{A}}$)	• gravitomagnetic force $m\gamma\vec{U}\times\vec{H}$ • gyroscope precession $d\vec{S}/d\tau=\vec{S}\times\vec{H}/2$ • local Sagnac effect in light gyroscope	×	✓
$\vec{H}+\vec{\mathcal{A}}$	• Gravitomagnetic "clock" effect	• co-rotating geodesic has *shorter* period	• co-rotating geodesic has *longer* period
$\mathbb{H}_{\alpha\beta}$ (gravitomag. tidal tensor $\sim\partial_i\partial_j\mathcal{A}_k$)	• Force on gyroscope $DP^{\alpha}/d\tau=-\mathbb{H}^{\beta\alpha}S_{\beta}$	×	✓

Even in what pertains to the first level of gravitomagnetism (governed by $\boldsymbol{\mathcal{A}}$), present in both, they substantially differ. The fact that $\mathbf{d}\boldsymbol{\mathcal{A}}=0$ in the Lewis-Weyl metric means that a Sagnac effect (9) arises only on loops enclosing the cylinder (as discussed in Sec. 4.4), and is independent of the shape of the loop; and similarly for the synchronization of clocks: the laboratory observers are able to synchronize their clocks along spatially closed loops that do not enclose the cylinder [in other words, closed in spacetime synchronization curves exist along the helicoid of Fig. 2 (b)]; it is only on loops around the cylinder that a synchronization gap (10) arises, see Fig. 2 (b). In the Kerr spacetime, by contrast, since $\mathbf{d}\boldsymbol{\mathcal{A}}\neq 0$, the Sagnac effect depends on the shape of the loop, and is generically non-zero (regardless of the loop enclosing or not the axis). The laboratory observers are likewise unable to synchronize their clocks around generic closed loops.

Another interesting contrast is in the gravitomagnetic clock effect (12). Around the spinning cylinder (21), since $\vec{H}=0$, it reduces to the Sagnac time-delay (25), and thus the co-rotating geodesic has a shorter period. In the case of the Kerr spacetime, by contrast, the term Δt_H of (12) is not zero,

$$\Delta t_{\rm geo}=\Delta t_{\rm S}+\Delta t_H=4\pi\frac{J}{M};\quad \Delta t_{\rm S}=-\frac{8\pi J}{r-2M}\,(<0);\quad \Delta t_H=\frac{4\pi Jr}{M(r-2M)}\,(>0),$$

and is actually dominant,[27] so it is the other way around: the co-rotating orbit has a longer period, $\Delta t_{\rm geo}=4\pi J/M>0$. The physical interpretation of $\Delta t_H>0$ is that the gravitomagnetic force $\gamma\vec{U}\times\vec{H}$ in Eq. (4) is repulsive (attractive) for co- (counter-) rotating geodesics, see Fig. 1(b) of Ref. 27.

Magnetized black holes: The role of rotation, boost, and accretion in twisting the field lines and accelerating particles*

Combined influence of rotation of a black hole and ambient magnetic fields creates conditions for powerful astrophysical processes of accretion and outflow of matter which are observed in many systems across the range of masses; from stellar-mass black holes in binary systems to supermassive black holes in active galactic nuclei. We study a simplified model of outflow of electrically charged particles from the inner region of an accretion disk around a spinning (Kerr) black hole immersed in a large-scale magnetic field. In particular, we consider a non-axisymmetric magnetosphere where the field is misaligned with the rotation axis. In this contribution we extend our previous analysis of acceleration of jet-like trajectories of particles escaping from bound circular orbits around a black hole. While we have previously assumed the initial setup of prograde (co-rotating) orbits, here we relax this assumption and we also consider retrograde (counter-rotating) motion. We show that the effect of *counter-rotation may considerably increase the probability of escape from the system, and it allows more efficient acceleration of escaping particles to slightly higher energies compared to the co-rotating disk.*

Keywords: Black holes, magnetosphere, non-axisymmetry, dynamics of ionized matter, acceleration of particles

1. Introduction

In this contribution we further study astrophysically relevant class of escaping (jet-like accelerated) trajectories in a dynamical system of a magnetized rotating black hole. Electrically charged particles following such orbits may escape the attraction of the black hole in a collimated outflow and they may be accelerated to very high energies. In Paper I[1] we adopted a simple axisymmetric model consisting of a rotating black hole in an asymptotically uniform magnetic field aligned with the rotation axis. Initially neutral particles are supposed to follow circular orbits in the equatorial plane (and freely fall below ISCO). At a particular ionization radius, these particles obtain electric charge and their dynamics changes due to the presence of electromagnetic field, and escape from the accretion disk along high-velocity jet-like trajectories becomes possible. However, the efficiency of the acceleration process remains only moderate in the axisymmetric setup.[1]

*Based on an invited contribution at 16th Marcel Grossmann Meeting, Session PT5 "Dragging is never draggy: MAss and CHarge flows in GR" (id. #393), 5–10 July 2021.

In Paper II[2] we relax the assumption of the perfect spin-magnetic alignment and consider a generalized non-axisymmetric model. The effect of non-axisymmetry in electro-vacuum magnetospheres of compact objects is known to introduce dynamically relevant features like magnetic null-points,[3] and breaking the axial symmetry also appears to strongly affect the acceleration process in the current model. In particular, the number of escaping orbits generally increases and acceleration to ultrarelativistic energies becomes possible in the oblique magnetosphere.[2,4] Furthermore,[5] by employing a boost transformation of the system into a frame in translation motion, we explored the electromagnetic aspects of the linear (kick) velocity of the black hole. Refer to enlightening discussions by various authors[6,7] and see also the relevant context of these solutions.[8]

In the above-mentioned previous papers, we numerically studied escaping orbits and we assessed in detail the role of a broad variety of parameters of the model. Nevertheless, the assumption that initially neutral matter co-rotates with the central black hole, was adopted in all previous analyses. Here we relax this assumption and we also consider counter-rotating (retrograde) circular orbits as an initial setup of neutral particles. We compare the both cases (of co-rotating vs. counter-rotating) in terms of the efficiency of the formation and acceleration of the individual trajectories and the emerging outflow.

The role of counter-rotation in processes of accretion and outflow near compact objects has been only partially explored in the literature and various relevant aspects of accretion of counter-rotating matter has been studied. In particular, high-resolution hydrodynamic simulations suggest that counter-rotating structure may largely increase the accretion rate.[9] Moreover, general relativistic magnetohydrodynamic (GRMHD) simulations show that accretion of counter-rotating matter may produce conditions for highly efficient jet launching.[10] We also note that counter-rotating high-velocity outflows are indeed reported in various systems, such as the spiral galaxy NGC 1068.[11]

The paper is organized as follows. In Section 2 we specify the employed model of oblique black hole magnetosphere, we review the equations of motion and describe the charging process of initially neutral matter. Jet-like trajectories of charged particles escaping from counter-rotating orbits are discussed in Section 3 with the focus on the direct comparison with the co-rotating analogues. Results are summarized and briefly discussed in Section 4. As the initial setup of the model investigated in the present paper is analogous to that of Papers I and II, we refer to the more complete introduction and references presented therein.

2. Model specification

We consider a spacetime around a rotating, axially-symmetric, uncharged black hole of mass M and spin a described by the Kerr metric, which may be expressed in Boyer–Lindquist coordinates $x^\mu = (t,\, r,\, \theta,\, \varphi)$ as follows:[12,13]

$$ds^2 = -\frac{\Delta}{\Sigma}\,[dt - a\sin\theta\, d\varphi]^2 + \frac{\sin^2\theta}{\Sigma}\,[(r^2+a^2)d\varphi - a\, dt]^2 + \frac{\Sigma}{\Delta}\, dr^2 + \Sigma d\theta^2, \quad (1)$$

where $\Delta(r) \equiv r^2 - 2Mr + a^2$ and $\Sigma(r,\theta) \equiv r^2 + a^2\cos^2\theta$. Roots of $\Delta(r)$ locate the outer (+) and the inner (-) horizons as: $r_\pm = M \pm \sqrt{M^2 - a^2}$. Geometrized units are used throughout the paper; values of basic constants (gravitational constant G, speed of light c, Boltzmann constant k, and Coulomb constant k_C) therefore equal unity, $G = c = k = k_C = 1$.

The black hole is supposed to be weakly magnetized by an external, asymptotically uniform magnetic field with an asymptotic strength B which has an arbitrary inclination (angle α) with respect to the rotation axis. Vector potential $A_\mu = (A_t, A_r, A_\theta, A_\varphi)$ of a corresponding test-field solution is given as:[14]

$$A_t = \frac{B_z a M r}{\Sigma}\left(1 + \cos^2\theta\right) - B_z a + \frac{B_x a M \sin\theta\cos\theta}{\Sigma}\left(r\cos\psi - a\sin\psi\right), \quad (2)$$

$$A_r = -B_x(r - M)\cos\theta\sin\theta\sin\psi, \quad (3)$$

$$A_\theta = -B_x a(r\sin^2\theta + M\cos^2\theta)\cos\psi - B_x(r^2\cos^2\theta - Mr\cos 2\theta + a^2\cos 2\theta)\sin\psi, \quad (4)$$

$$A_\varphi = B_z\sin^2\theta\left[\frac{1}{2}(r^2 + a^2) - \frac{a^2 M r}{\Sigma}(1 + \cos^2\theta)\right] - B_x\sin\theta\cos\theta\left[\Delta\cos\psi + \frac{(r^2 + a^2)M}{\Sigma}\left(r\cos\psi - a\sin\psi\right)\right], \quad (5)$$

where B_z denotes the component parallel to the rotation axis, while B_x corresponds to the perpendicular component, i.e., $B_z = B\cos\alpha$ and $B_x = B\sin\alpha$. Setting $B_x = 0$ reduces the above vector potential A_μ to the axisymmetric solution[15] employed in Paper I. Azimuthal coordinate ψ of Kerr ingoing coordinates is expressed in Boyer–Lindquist coordinates as follows:

$$\psi = \varphi + \frac{a}{r_+ - r_-}\ln\frac{r - r_+}{r - r_-}. \quad (6)$$

The Hamiltonian $\mathcal{H}$ of a particle of electric charge q and rest mass m in the field A_μ and metric $g^{\mu\nu}$ is defined as:[12]

$$\mathcal{H} = \tfrac{1}{2}g^{\mu\nu}(\pi_\mu - qA_\mu)(\pi_\nu - qA_\nu), \quad (7)$$

where π_μ is the generalized (canonical) momentum. The equations of motion are expressed as:

$$\frac{\mathrm{d}x^\mu}{\mathrm{d}\lambda} \equiv p^\mu = \frac{\partial\mathcal{H}}{\partial\pi_\mu}, \quad \frac{d\pi_\mu}{d\lambda} = -\frac{\partial\mathcal{H}}{\partial x^\mu}, \quad (8)$$

where $\lambda \equiv \tau/m$ is dimensionless affine parameter (τ denotes the proper time). Employing the first equation we obtain the kinematical four-momentum as: $p^\mu = \pi^\mu - qA^\mu$, and the conserved value of the Hamiltonian is therefore given as: $\mathcal{H} = -m^2/2$. System is stationary and the time component of canonical momentum π_t is therefore an integral of motion which equals (negatively taken) energy of the test particle $\pi_t \equiv -E$. In the rest of paper we switch to specific quantities $E/m \to E$,

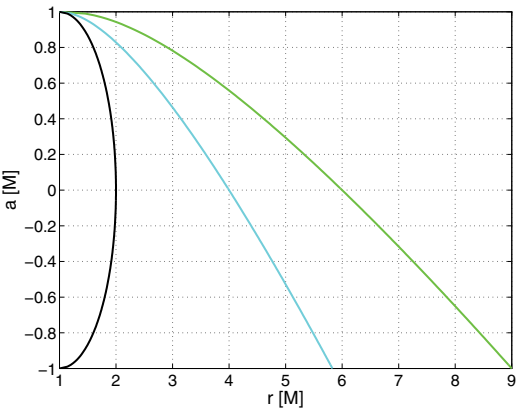

Fig. 1. Position of the black hole's outer horizon (black), marginally bound circular orbit (cyan) and ISCO (green). Negative spin values correspond to the counter-rotating orbits.

$q/m \to q$ which corresponds to setting the rest mass of the particle $m = 1$ in the formulas.

As an initial configuration of electrically neutral particles, we consider circular Keplerian orbits specified by the values of constants of motion, i.e., by specific energy $E_{\rm Kep}$ and specific angular momentum $L_{\rm Kep}$ given as follows:[16]

$$E_{\rm Kep} = \frac{r^2 - 2Mr \pm a\sqrt{Mr}}{r\sqrt{r^2 - 3Mr \pm 2a\sqrt{Mr}}}, \quad L_{\rm Kep} = \frac{\pm\sqrt{M}(r^2 + a^2 \mp 2a\sqrt{Mr})}{\sqrt{r(r^2 - 3Mr \pm 2a\sqrt{Mr})}}, \tag{9}$$

where the upper signs are valid for the prograde (co-rotating) orbits and the lower ones for the retrograde (counter-rotating) orbits. Circular geodesics remain stable only above the innermost stable circular orbit (ISCO):

$$r_{\rm ISCO} = M\left(3 + Z_2 \mp \sqrt{(3 - Z_1)(3 + Z_1 + 2Z_2)}\right), \tag{10}$$

where $Z_1 \equiv 1 + \left(1 - \frac{a^2}{M^2}\right)^{1/3}\left[\left(1 + \frac{a}{M}\right)^{1/3} + \left(1 - \frac{a}{M}\right)^{1/3}\right]$ and $Z_2 \equiv \sqrt{\frac{3a^2}{M^2} + Z_1^2}$. Positions of the ISCO and marginally bound circular orbit[16] are plotted in Fig. 1.

Below ISCO the geodesics are supposed to turn into freely falling inspirals maintaining the energy and angular momentum corresponding to the ISCO radius, i.e., the particles keep $E = E_{\rm Kep}(r_{\rm ISCO})$ and $L = L_{\rm Kep}(r_{\rm ISCO})$ during their infall while the radial velocity u^r is obtained from the normalization condition $u^\mu u_\mu = -1$.

In our model, we suppose that initially neutral elements undergo a sudden charging process (e.g., due to photoionization) at a given radius r_0 and obtain specific electric charge q. While the change of the rest mass m is considered as negligible, the particle dynamics changes due to the presence of the electromagnetic field.[17]

In particular, the conserved value of energy is modified as:

$$E = E_{\rm Kep} - qA_t, \tag{11}$$

while the values of spatial components of canonical momentum are changed as:

$$\pi_r = \pi_r^0 + qA_r, \quad \pi_\theta = qA_\theta, \quad \pi_\varphi = L_{\rm Kep} + qA_\varphi, \tag{12}$$

where π_r^0 is zero for particles ionized above/at ISCO and for infalling particles with ionization radius $r_0 < r_{\rm ISCO}$ the value is calculated from the normalization condition.

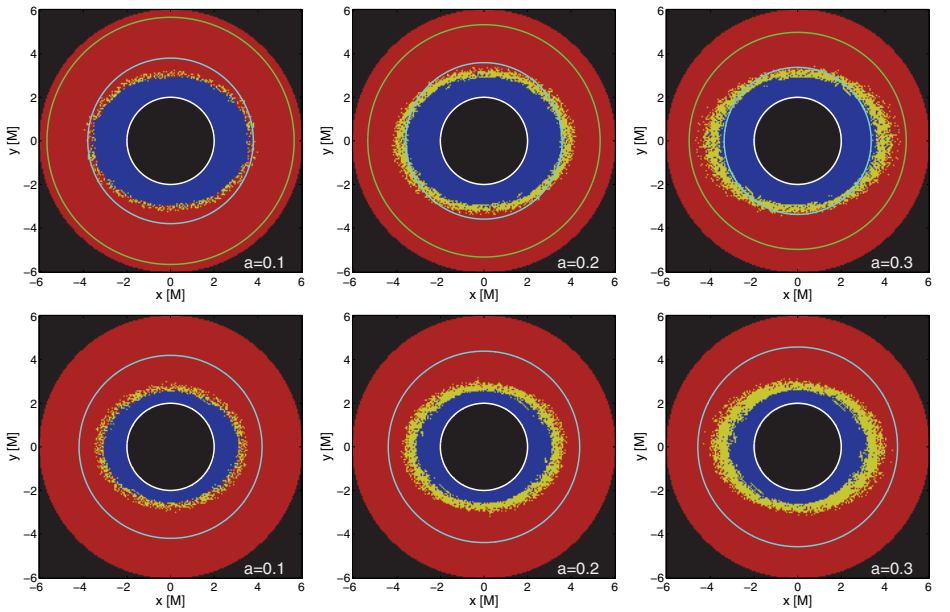

Fig. 2. Comparison of initially co-rotating orbits (upper row) with counter-rotating orbits (lower row). Color-coding: blue for plunging orbits, red for stable ones, and yellow for escaping trajectories. The green circle denotes the ISCO, the cyan circle marks the radius of the marginally bound orbit and the white one shows the ergosphere. The inner black region marks the horizon of the black hole. The parameters of the system are $\alpha = 35^\circ$ and $qB = -5\,M^{-1}$. The magnetic field is inclined in the positive x-direction.

3. Escape zones

The dynamics of initially neutral particles on stable circular orbits (above ISCO) or on a plunging trajectory (below ISCO) changes abruptly as they obtain the electric charge and become affected by the electromagnetic field given by Eqs. (2)-(5). As a result, some stable particles may become plunging, while some plunging trajectories are stabilized by the field. Moreover, it appears that particles may also become unbound and escape to infinity in jet-like trajectories.

We have previously analyzed escaping particles in this model and, in particular, in Paper I[1] we considered the axisymmetric system ($B_x = 0$), while in the Paper II[2] the general non-axisymmetric configuration was studied. We have used the method of effective potential to find the necessary conditions for the escape of particles. It appears that for the parallel orientation of the spin axis z and magnetic field component B_z, only negatively charged particles may escape (while positively charged escape for the anti-parallel orientation). Non-zero spin a and B_z are required for the escape and final Lorentz factor γ is found to be an increasing function of the spin, specific charge $|q|$ and $|B_z|$ while it decreases with the ionization radius r_0.

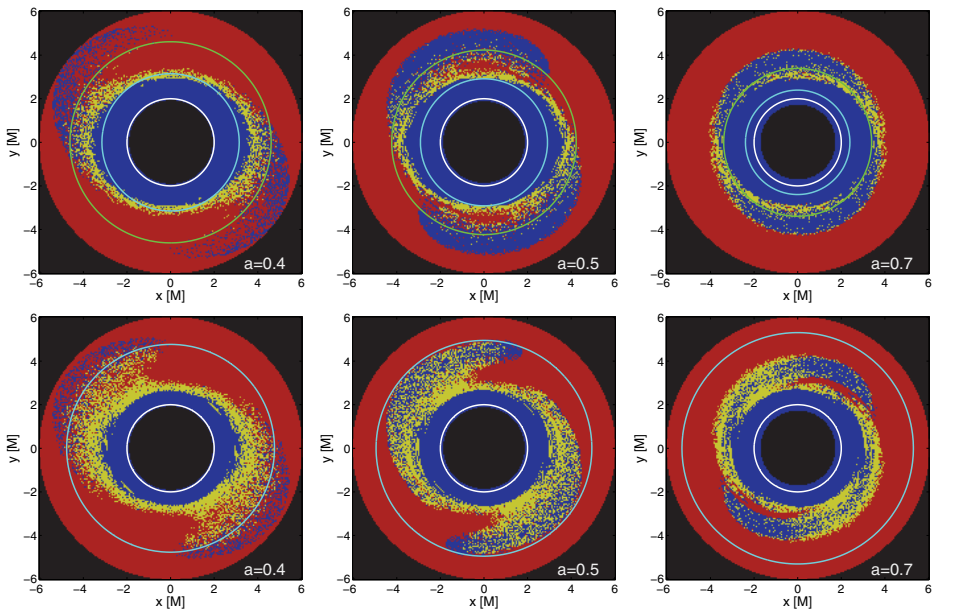

Fig. 3. Comparison of initially co-rotating orbits (upper row) with counter-rotating orbits (lower row). The color-coding and parameters as in Fig. 2.

However, as the above conditions are necessary but not sufficient, we need to investigate the dynamic system numerically in order to determine which particles actually follow the escaping trajectories. Initial locations of escaping particles form *escape zones* whose emergence and evolution with respect to the parameters of the system was discussed in our previous papers.[1,2,4] Efficiency of the acceleration mechanism was quantified by the final Lorentz factor of escaping particles leading to the conclusion that also ultrarelativistic velocities with very high energies may be achieved within the non-axisymmetric model.

In this contribution, we extend the previous discussion and consider a modified setup. In particular, here we suppose that the initially neutral matter may follow counter-rotating geodesics, i.e., unlike the previous papers, here we also consider

the lower signs in Eqs. (9) and (10). The ISCO of counter-rotating orbits is located generally farther from the horizon compared to the co-rotating ones (see Fig. 1). In particular, no stable retrograde circular orbits around rotating black hole are allowed for $r \leq 6\,M$ and the ISCO location grows with the spin up to $r_{\rm ISCO} = 9\,M$ for the maximally rotating black hole with $a = M$.

We assume that below ISCO the initially neutral particle falls freely towards the horizon keeping the energy and angular momentum corresponding to the ISCO radius, while the radial velocity is computed from the normalization condition. At the ionization radius r_0 the particle obtains the electric charge and its dynamics changes due to magnetic field. Three main scenarios may occur then; the particle plunges into the horizon, follows the stable orbit around the black hole or escapes to infinity.

Analogously to our previous studies, we adopt the visual representation of resulting orbits in escape boundary plots in which we assign blue dots to plunging orbits, red dots to stable orbits and yellow dots to escaping ones. In Figs. 2-4 we compare the co-rotating setup (upper rows) with the counter-rotating case (bottom rows) in a series of escape boundary plots for a particular set of parameters ($qB = -5\,M^{-1}$ and $\alpha = 35^\circ$) with varying values of spin. In Fig. 2 we observe that for low spins the both cases do not differ significantly. Corresponding escape zones have comparable shapes and sizes regardless the sense of revolution. However, if we consider moderate values of spin, the situation changes and significant differences between the escape zones in co-rotating and counter-rotating disks arise as shown in Fig. 3. Most importantly, we observe that the number of escaping trajectories is substantially higher for counter-rotating orbits forming considerably larger escape zones. The tendency of more rapid rotation to favorize the escape from counter-rotating orbits is confirmed in Fig. 4, where we notice that high spin allows only narrow escape zones in the co-rotating disk while counter-rotating zones become significantly wider. Also, these plots exhibit clear signatures of a transition from the regular to chaotic system in agreement with previous studies of similarly perturbed black hole systems.[2, 18–20]

Another convenient way to visualize the escape zones is to fix the initial value of the azimuthal angle φ_0 and plot the trajectories in the $r_0 \times a$ plane (ionization radius vs. spin) using the same color-coding of trajectories as in Figs. 2-4. The angle φ is measured anticlockwise from the positive direction of x-axis (which is the direction of the field inclination). In particular, we choose the value $\varphi_0 = 135^\circ$ for which the structure of the escape zone seems especially complex. In Fig. 5 we present the resulting plots for several values of magnetization parameter qB and compare co-rotating escape zones (left column) with the counter-rotating zones (right column). It confirms that counter-rotating orbits are generally more prone to escape regardless the value of qB while the both cases differ most significantly for rapidly rotating black holes.

Previous analysis in Papers I and II shows that spin parameter is an important factor for the acceleration of escaping particles. In particular, it appears that final

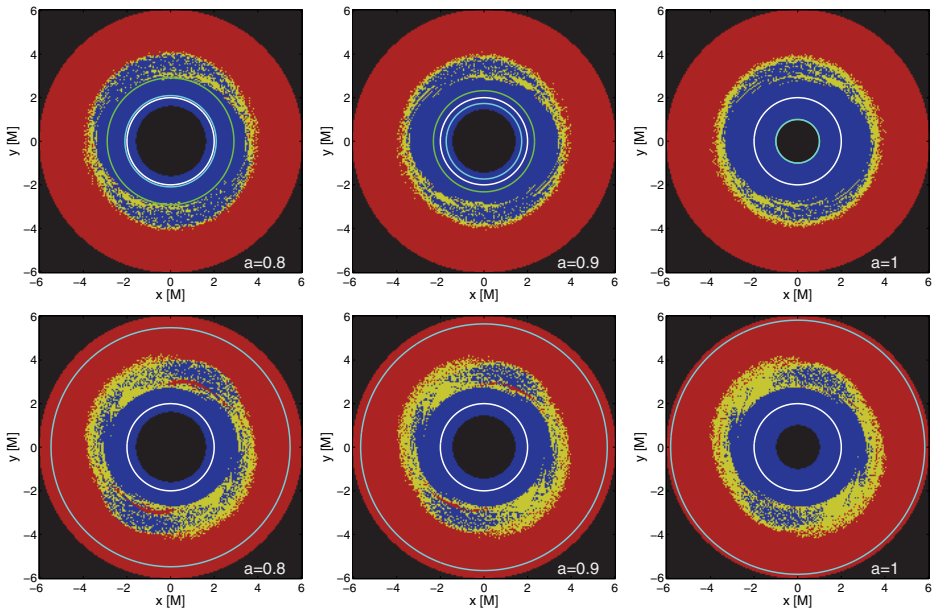

Fig. 4. Comparison of initially co-rotating orbits (upper row) with counter-rotating orbits (lower row). The color-coding and parameters as in Fig. 2.

value of γ for the fixed qB grows with the spin and decreases with the ionization radius r_0. Maximally accelerated particles are thus expected to originate from the inner edge of the escape zone near maximally rotating black hole with spin $a = M$.

In Fig. 5 we observe that counter-rotating escape zones for high spins are considerably wider compared to co-rotating ones and, moreover, we notice that counter-rotating zones are located closer to the horizon. We thus expect that particles escaping from counter-rotating orbits could reach slightly higher energies. This is indeed the case as shown in Fig. 6 where the final values of the Lorentz factor are encoded with the color-scale. For this particular set of parameters ($qB = -20\,M^{-1}$, $\varphi_0 = 135°$) we find that maximally accelerated counter-rotating particle reaches $\gamma_{\max} = 8.1$ being launched from $r_0 = 2.3\,M$ while for the co-rotating disk we find $\gamma_{\max} = 7.3$ for the particle escaping from $r_0 = 2.5\,M$.

4. Conclusions

We have numerically analyzed a simplified model of the outflow of electrically charged particles from the inner region of the accretion disk near a weakly magnetized rotating black hole. Stable circular orbits (freely falling below ISCO) of initially neutral particles were perturbed by the ionization process occuring in the non-axisymmetric magnetosphere. As a result, the escaping jet-like trajectories may be realized for some range of parameters and acceleration to high energies becomes

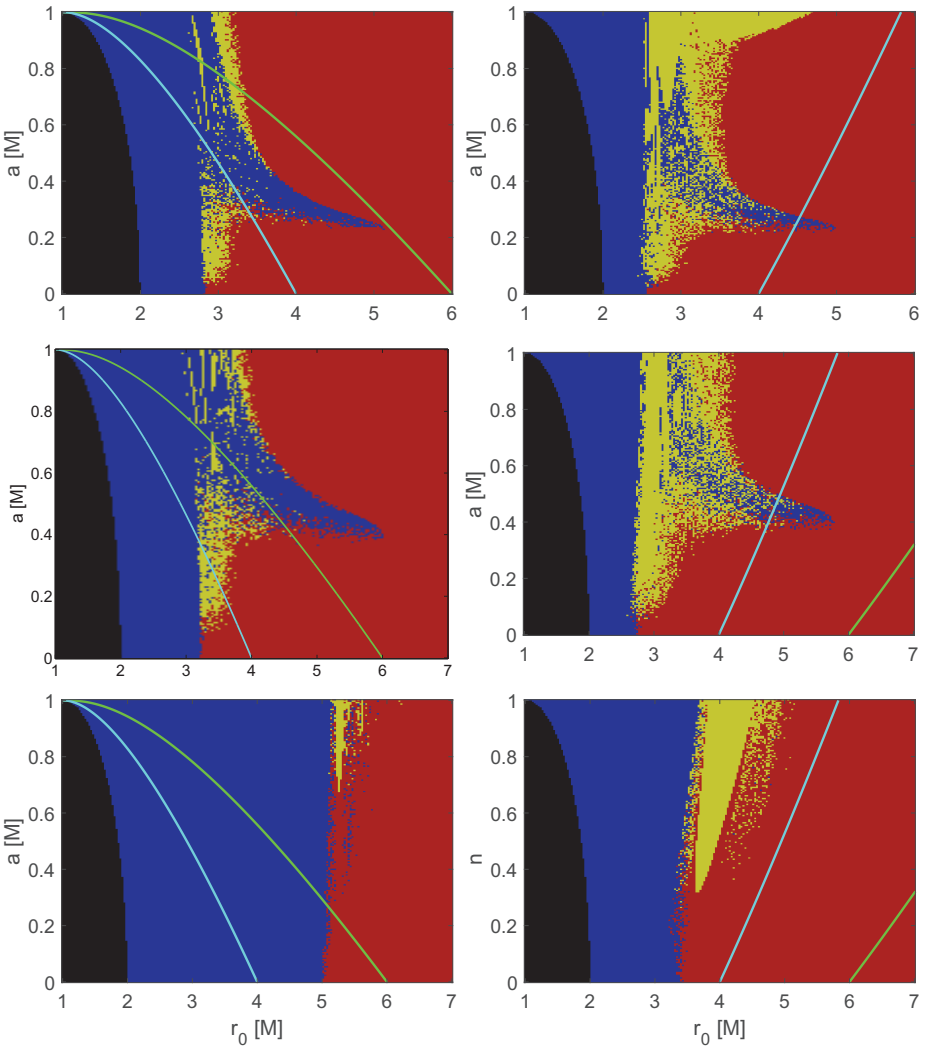

Fig. 5. Comparison of escape zones in co-rotating (left panels) and counter-rotating disks (right panels) for several values of magnetization parameter: $qB = -M^{-1}$ (bottom panels), $qB = -5\,M^{-1}$ (middle panels) and $qB = -10\,M^{-1}$ (upper panels). The inclination of the field is $\alpha = 35^\circ$ and $\varphi_0 = 135^\circ$. The color-coding as in Fig. 2.

possible. While we have previously studied various aspects of given model and investigated the formation of escape zones in detail,[1,2] we have assumed the initial setup of co-rotating accretion disk. In particular, the neutral particles above ISCO were supposed to follow prograde circular orbits and freely fall below ISCO.

In this contribution we have generalized the previous analysis by considering also counter-rotating (retrograde) Keplerian orbits as an initial setup of neutral

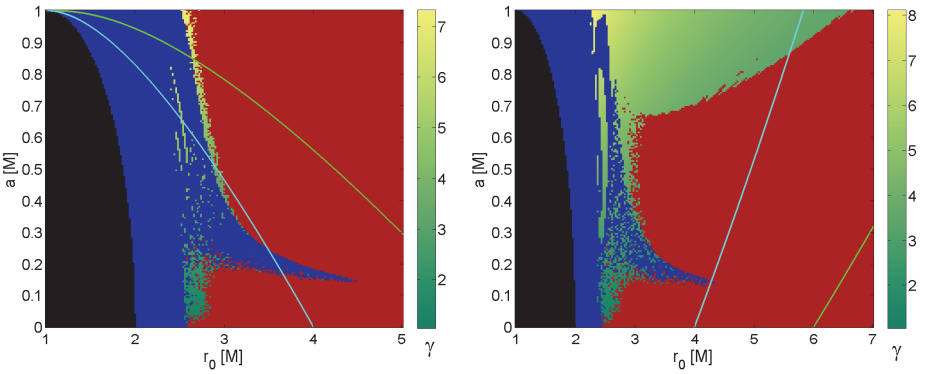

Fig. 6. Final Lorentz factor γ of escaping particles is encoded with the colorscale comparing the co-rotating (left) and the counter-rotating disks (right) while other parameters remain fixed as: $\alpha = 35°$ and $qB = -20\,M^{-1}$.

matter. We have studied the escape zones emerging in the counter-rotating disks which were directly compared with the corresponding co-rotating versions. Based on the analyzed set of escape zones we may conclude that counter-rotation tends to increase the efficiency of the outflow. While its effect becomes negligible for low spins, for moderate to high spin values we observe that counter-rotating disks allow the formation of significantly wider escape zones compared to their co-rotating analogues. The position of the zone is also affected as counter-rotating zones are shifted towards the horizon which makes the acceleration process more efficient. Although the difference is rather small, we observe that counter-rotating particles may be accelerated to higher energies.

A rapidly spinning compact object couples to an ambient curved background via the so-called spin-curvature coupling. In expressing this, one has to deal with the ambiguity of the definition of the center of mass of the body. What is worse, in a Hamiltonian formalism, this choice corresponds to an unphysical "parasitic" degree of freedom in the dynamical system. A solution to this is to apply a Hamiltonian constraint on the system and to obtain a set of brackets where the center-of-mass degree of freedom is erased from the algebra. I report on my progress in this procedure in the case of the so-called Tulczyjew-Dixon (or "covariant") supplementary spin condition and in my effort to cover the resulting phase space with canonical coordinates.

Keywords: Equations of motion – Classical relativity – Spinning bodies – Two-body problem – Gravitational waves

1. Introduction: Motion of spinning particle

Notation and convention: I use the $G = c = 1$ geometrized units and a $(-+++)$ metric signature. Greek indices $\mu, \nu, ...$ run from 0 to 3, and Einstein summation convention is assumed.

When the surface of a given body is rotating at relativistic speeds, it will couple to any curved space-time background by the so-called *spin-curvature coupling*. This effect is an important ingredient for the relativistic two-body problem and, in particular, for the modelling of gravitational waves from compact binaries.

To understand how the spin-curvature coupling arises, imagine a compact object such as a neutron star moving in an ambient curved space-time background where, in order to treat the problem step by step, we will for now understand the compact object exclusively as a "test" object. When the variability length, or the curvature scale of the background is much longer than the size of the body, it is meaningful to construct a set of Riemann normal coordinates X^μ with respect to the background geometry centred on the body. The coordinate acceleration of individual elements of the body caused by the background gravitational field then is $\sim \Gamma^\mu{}_{\nu\kappa} U^\nu U^\kappa$, where $\Gamma^\mu{}_{\nu\kappa}$ are Christoffel symbols of the background and U^ν the four-velocity of the body elements, both expressed in the local frame.

Let us now assume that the body is approximately rigidly rotating with respect to the time-foliation by the Riemann normal coordinates $X^0 = \text{const}$.. We can then

formally write $U^i = (\vec{\omega} \times \vec{X})^i$ $(i = 1, 2, 3)$ where $\vec{\omega}$ is some angular velocity vector. Then let us further assume that we are comparing relative accelerations on the constant-time slice $X^0 = 0$ in the Riemann normal frame so that we obtain

$$\delta a^\mu \sim \Gamma^\mu{}_{\nu\kappa} U^\nu U^\kappa \sim R^\mu{}_{0j0} X^j + R^\mu{}_{0ji} X^j (\vec{\omega} \times \vec{X})^i + \dots , \tag{1}$$

where $R_{\mu\nu\kappa\lambda}$ is the Riemann tensor along the wordline of the particle and the three dots denote higher-order terms in the size of the body. Now by averaging over $\vec{X}$, we see that we are able to choose a centre of coordinates such that the first, dipole-type term vanishes. However, the second term cannot be reduced by any coordinate shift. If we then take any system of particles, be it dust or a body held together by some force, we always see that the centre of mass of this system is subject to a residual *spin-curvature force*.

1.1. *Mathisson-Papapetrou-Dixon equations*

Procedures such as the one sketched above were carried out in various degrees of generality by Mathisson,[1] Papapetrou[2] and Dixon[3] to derive the equations of motion of extended bodies in curved space-time

$$\frac{\mathrm{D}P_\mu}{\mathrm{d}\tau} = -\frac{1}{2} R_{\mu\nu\kappa\lambda} \dot{x}^\nu S^{\kappa\lambda} + \dots , \tag{2}$$

$$\frac{\mathrm{D}S^{\mu\nu}}{\mathrm{d}\tau} = 2P^{[\mu} \dot{x}^{\nu]} + \dots , \tag{3}$$

where $x^\nu(\tau)$ is a referential position within the body, P_μ its momentum, and $S^{\kappa\lambda}$ has the general meaning of an angular momentum or "gravitomagnetic dipole" about its own center of mass. The parameter chosen here is proper time τ, but the equations can be parametrized by any other parameter. It should be noted that even though P_μ has the meaning of the overall linear momentum of the system, it may not be strictly true that the word-line is chosen so that $\dot{x}^\nu \propto P^\nu$.[4]

The three dots in the equation above denote higher-order terms corresponding to the interactions of the higher-order multipoles with the background curvature. The ability to discard higher-order terms is possible only for compact objects, for many astrophysical bodies the spin-curvature term is vastly sub-dominant. However, one can also easily show that even for compact objects, the spin-curvature coupling is suppressed to the 1.5 post-Newtonian order on the level of the equations of motion of binaries, and to linear order in the mass ratio. Thus, there is a limit to the applicability of the discussion of the strictly "test-particle" motion and at some point cross-reaction with other "non-test" effects cannot be ignored any more.

1.2. *The ambiguity of x^ν and $S^{\kappa\lambda}$*

As discussed at length in the literature the procedure of finding a center of mass for a rotating body is ambiguous.[4,5] In particular, the result depends on the slicing

(the frame) we choose for the worldtube of the body. This is an issue even in flat space-time, where one is free to transform to another center of mass and angular-momentum tensor by the shifts[6]

$$x'^{\mu} = x^{\mu} + \delta x^{\mu}\,, \quad S'^{\nu\kappa} = S^{\nu\kappa} + P^{\nu}\delta x^{\kappa} - P^{\kappa}\delta x^{\nu}\,, \tag{4}$$

where δx^{μ} is some shift vector. This worldline shifting has a natural covariant extension to curved space-time by using Synge's world functions, but the overall physical content of the ambiguity is the same in both cases.[7]

A way to fix this "gauge freedom" of the worldline and the angular-momentum tensor is to choose a so-called *supplementary spin condition* of the form $S^{\mu\nu}V_{\nu} = 0$ with V_{ν} some time-like vector. The vector V^{μ} then has the meaning of the frame in which the center of mass and angular momentum are measured. When chosen judiciously, the supplementary condition eliminates all the nonphysical degrees of freedom from the system and one is left with only the physical ones to be evolved. Sometimes the choice of V^{ν} is implicit; the vector V^{ν} refers to the quantities it is supposed to fix (such as $x^{\nu}, S^{\kappa\lambda}$). In such cases one often ends up in a system where the non-physical degrees of freedom are not entirely constrained.[4,5,8,9]

2. Hamiltonian formalism

There is a range of reasons to use the Hamiltonian formalism, for the spinning-particle motion, from efficient numerical methods,[9] through perturbation theory,[10] to the use of the results in the so-called Effective-one-body model for relativistic binaries.[7,11] Let us now briefly summarize the Hamiltonians introduced by Witzany *et al.* in a previous work.[9] Consider the three covariant Hamiltonians corresponding to different choice of the frame V^{ν}:

$$V^{\nu} \text{ parallel transported along } x^{\nu}(\tau): \tag{5}$$

$$H_{\mathrm{KS}} = \frac{1}{2m} g^{\mu\nu} P_{\mu} P_{\nu}\,, \tag{6}$$

$$V^{\nu} \propto P^{\nu}: \tag{7}$$

$$H_{\mathrm{TD}} = \frac{1}{2\mathcal{M}} \left(g^{\mu\nu} - \frac{4 S^{\nu\gamma} R^{\mu}{}_{\gamma\kappa\lambda} S^{\kappa\lambda}}{4\mathcal{M}^2 + R_{\chi\eta\omega\xi} S^{\chi\eta} S^{\omega\eta}} \right) P_{\mu} P_{\nu}\,, \tag{8}$$

$$V^{\nu} = \dot{x}^{\nu}: \tag{9}$$

$$H_{\mathrm{MP}} = \frac{1}{2m} g^{\mu\nu} P_{\mu} P_{\nu}\,, \tag{10}$$

where $m = -\dot{x}^{\nu} P_{\nu}$, $\mathcal{M} = \sqrt{-P^{\nu} P_{\nu}}$ are mass parameters with slightly different meanings but all corresponding roughly to the mass of the spinning body.[9,12]

The equations of motion are obtained with the use of the Poisson bracket

$$\{x^\mu, P_\nu\} = \delta^\mu_\nu\,,\ \{x^\mu, S^{\kappa\lambda}\} = 0\,,\ \{x^\mu, x^\nu\} = 0\,, \tag{11}$$

$$\{P_\mu, P_\nu\} = -\frac{1}{2} R_{\mu\nu\kappa\lambda} S^{\kappa\lambda}\,, \tag{12}$$

$$\{S^{\mu\nu}, P_\kappa\} = -\Gamma^\mu{}_{\lambda\kappa} S^{\lambda\nu} - \Gamma^\nu{}_{\lambda\kappa} S^{\mu\lambda}\,, \tag{13}$$

$$\{S^{\mu\nu}, S^{\kappa\lambda}\} = g^{\mu\kappa} S^{\nu\lambda} - g^{\mu\lambda} S^{\nu\kappa} + g^{\nu\lambda} S^{\mu\kappa} - g^{\nu\kappa} S^{\mu\lambda}\,, \tag{14}$$

There is a set of canonical coordinates that reduce the Poisson brackets to the simple canonical form, these were also discussed by Witzany *et al.*[9]

2.1. *Hunting down degrees of freedom*

Amongst the choices for the supplementary conditions discussed above, only the so-called Tulczyjew-Dixon or "covariant" supplementary spin condition $V^\nu \propto P^\nu$ constrains the gauge freedom fully. This can be seen, in particular, by counting the degrees of freedom in phase space within the Hamiltonian formalism. A covariant formalism for a spinning particle parametrized by proper time τ should then not have more than 4 orbital degrees of freedom (corresponding to the 4 space-time coordinates), and a *single* degree of freedom corresponding to the spin sector (recall that each degree of freedom corresponds to a pair of canonically conjugate coordinates). If a larger number degrees of freedom crops up in the system of evolution equations, there are necessarily nonphysical or gauge-type degrees of freedom left in the system.

This being said, the issue with the Hamiltonian $H_{\rm TD}$ presented in equation (8) is the following. The supplementary spin condition $S^{\mu\nu}P_\nu = 0$ is only an *integral of motion* of $H_{\rm TD}$ when used along with the brackets (11)-(14). This means that in a numerical evolution one finds initial data such that $S^{\mu\nu}P_\nu = 0$ initially and then evolves them – the system consequently conserves the supplementary condition up to numerical noise.

Nevertheless, what one *cannot* do is to assume $S^{\mu\nu}P_\nu = 0$ as an identity to reduce the number of degrees of freedom that are evolved numerically while respecting the geometric structure of the problem.[9] That, is the system still keeps an additional gauge degree of freedom in the numerical evolution, even though it stays zero up to numerical error. Is there perhaps a way to obtain just the minimal Hamiltonian system without this redundant degree of freedom?

Efforts of this type have actually been carried out perturbatively with the use of the so-called Newton-Wigner supplementary spin condition $V^\mu \propto P^\mu/\mathcal{M} + \xi^\mu(x^\nu)$, where $\xi^\mu(x^\nu)$ is a fixed time-like vector field.[7,8] As such, this supplementary spin condition is necessarily non-covariant and refers to an additional fixed structure on the background. In other words, the vector $\xi^\mu(x^\nu)$ defines a privileged observer frame and the dynamics are in some sense defined with respect to this privileged frame. This impression is even more strengthened by the fact that the constraint procedure of the algebra (11)-(14) by the Newton-Wigner condition seems to be necessarily

coupled to a constraint procedure on the time parameter. To rephrase this, the Newton-Wigner condition forces one's hand into an explicit 3+1 formalism – and covariance is lost.

2.2. *Dirac constraint procedure*

Let me now sketch the Dirac constraint procedure for the Tulczyjew-Dixon constraint $S^{\mu\nu}P_\nu = 0$ applied to the Poisson bracket (11)-(14). This should serve as a covariant counter-example to the procedures using the Newton-Wigner condition.

It was already shown in the paper by Witzany *et al.*[9] that one can add the Tulczyjew-Dixon Lagrangian-constraint term to the "minimal" Hamiltonian (6), solve for the Lagrange multiplier, and the resulting Hamiltonian gives the correct Mathisson-Papapetrou-Dixon equations for the motion of the body under the Tulczyjew-Dixon supplementary spin condition. The resulting Hamiltonian is actually H_{TD} presented in eq. (8). That is, we already *know* that applying the constraint $S^{\mu\nu}P_\nu = 0$ as a Lagrangian constraint to the system will lead to the correct dynamics, one only needs to figure out the correct *Dirac bracket* corresponding to this constraint.

Let me now briefly summarize the Dirac constraint procedure.[13,14] One starts with a set of n independent constraints $\Phi_a = 0$, $a = 1...n$ with a Poisson bracket $\{\Phi_a, \Phi_b\} = C_{ab}$, where one assumes the matrix C to be invertible, $\exists (C^{-1})^{bc}$: $C_{ab}(C^{-1})^{bc} = \delta_a^c$. Then we define the Dirac bracket $[,]$ for any phase-space functions A, B as

$$[A, B] = \{A, B\} - \{A, \Phi_a\}(C^{-1})^{ab}\{\Phi_b, B\}\,. \tag{15}$$

Now it is easy to see that this bracket fulfils the Jacobi identity and that $[\Phi_c, A] = 0$ for any A when evaluated on the $\Phi_a = 0$ hypersurface in phase space. As a result, the set of constraints $\Phi_a = 0$ can then be used as an *identity* on phase space in the sense that its use will commute with the Dirac bracket. In particular, it can be shown that the system with a given Hamiltonian and a Dirac bracket is equivalent to the system with the same Hamiltonian and a Lagrangian-constraint term.[13,14]

Now to the specific case of the constraint $S^{\mu\nu}P_\nu = 0$. Even though there are 4 components to this equation, not all of them are linearly independent. For instance, independently on whether the constrain is fulfilled or not, it holds that $P_\mu(S^{\mu\nu}P_\nu) = 0$, and $w_\mu(S^{\mu\nu}P_\nu) = 0$, where $w_\mu = \epsilon_{\mu\rho\sigma\chi}S^{\rho\sigma}P^\chi$ and $\epsilon_{\mu\rho\sigma\chi}$ is the Levi-Civita pseudo-tensor. As such, there are only *two* non-trivial constraints on the system hidden in the formula $S^{\mu\nu}P_\nu = 0$. Nevertheless, as already shown partially by Witzany *et al.*,[9] one can proceed in a covariant fashion by defining

$$C^{\mu\nu} = \{S^{\mu\kappa}P_\kappa, S^{\nu\lambda}P_\lambda\} = -\tilde{\mathcal{M}}^2 S^{\mu\nu}\,, \tag{16}$$

$$\tilde{\mathcal{M}}^2 \equiv -P_\lambda P^\lambda + \frac{1}{4}R_{\gamma\rho\sigma\chi}S^{\gamma\rho}S^{\sigma\chi}\,, \tag{17}$$

$$C^\dagger_{\kappa\lambda} = -\frac{1}{\tilde{\mathcal{M}}^2 S^2}S_{\kappa\lambda}\,, \tag{18}$$

where $S^2 \equiv S^{\mu\nu}S_{\mu\nu}/2$. The matrix $C^\dagger_{\kappa\lambda}$ is then a pseudo-inverse of $C^{\mu\nu}$ on the non-trivial sub-spaces of the constraint (specifically, $C^{\mu\nu}C^\dagger_{\nu\lambda}$ projects out the sub-spaces $\sim P_\mu, w_\mu$ discussed above). One can then covariantly define the Dirac bracket using the original Poisson bracket (11)-(14) as

$$[A,B] = \{A,B\} - \{A, S^{\mu\nu}P_\nu\}C^\dagger_{\mu\kappa}\{S^{\kappa\lambda}P_\lambda, B\}\,. \tag{19}$$

The resulting brackets for $P_\mu, x^\nu, S^{\kappa\lambda}$ are now straightforward to compute and they contain various orders of new spin and curvature terms as compared to the original brackets. (The full expressions and simplified bases will be reported on elsewhere.)

2.3. *The zeroth-order problem*

The bracket (19) is essentially what we have been looking for: only a minimal number of degrees of freedom is left in the phase space and one can happily evolve them in the Hamiltonian formalism defined by the Dirac bracket and the minimal Hamiltonian (6). In particular, it is advantageous to define the spin vector

$$s^\lambda \equiv \frac{1}{2\mathcal{M}}\epsilon^{\lambda\gamma\rho\sigma}S_{\gamma\rho}P_\sigma\,, \tag{20}$$

$$\Rightarrow S^{\mu\nu} = \frac{1}{\mathcal{M}}\epsilon^{\mu\nu\kappa\lambda}P_\kappa s_\lambda\,, \tag{21}$$

where the second equality applies on the $S^{\mu\nu}P_\nu = 0$ hypersurface. This vector partially reduces the number of the many dependent components of the tensor $S^{\mu\nu}$, but not fully, since it also holds that $s^\mu P_\mu = 0$.

Now one would like to transform to canonical coordinates so that the bracket (19) reduces to a simple form. One soon realizes that one of the biggest obstacles is the *zeroth-order problem*. That is, even in flat space-time $R_{\mu\nu\kappa\lambda} = 0$ and Minkowski coordinates, the bracket is quite non-trivial. Specifically, it reduces in the pure Minkowski case to

$$[x^\mu, P_\nu] = \delta^\mu_\nu\,,\ [P_\mu, P_\nu] = 0\,,\ [P_\mu, s^\lambda] = 0\,, \tag{22}$$

$$[x^\mu, x^\nu] = \frac{1}{\mathcal{M}^3}\epsilon^{\mu\nu\kappa\lambda}P_\kappa s_\lambda\,, \tag{23}$$

$$[x^\mu, s^\nu] = \frac{P^\mu s^\nu - s^\mu P^\nu}{\mathcal{M}}\,, \tag{24}$$

$$[s^\mu, s^\nu] = -\frac{1}{\mathcal{M}}\epsilon^{\mu\nu\kappa\lambda}P_\kappa s_\lambda\,. \tag{25}$$

There is no obvious and/or elegant way to cover this Dirac algebra with canonical coordinates.

2.4. *Is Newton-Wigner the only way?*

The difficulty with Poisson brackets of spinning systems in flat space-time was already the concern of the works of Newton and Wigner,[15] even though there the

motivation was the quantum analogue of this problem for the commutation relations of operators. Jordan[16] proved that the Newton-Wigner basis of positions and spins is the only basis such that the position "transforms as a position should". (For a review and a classical rederivation, see the recent paper by Schwartz and Giulini.[17])

The results on the Newton-Wigner basis can be rephrased in the context of this work as follows. Consider any physical Dirac-constraint procedure that 1) reduces the unphysical spin degrees of freedom, 2) forces the time parametrization to be coordinate time $t = x^0$ (by using the $P^\mu P_\mu = -\mathcal{M}^2$ on-shell constraint[13,18]), and 3) parametrizes the phase-space in terms of variables $X^i, P_j, \tilde{S}^k$ such that P_j are spatial components of P_μ and such that the final bracket is

$$[X^i, X^j]' = 0\,, \tag{26}$$
$$[X^i, P_j]' = \delta^i_j\,, \tag{27}$$
$$[X^i, \tilde{S}^j]' = 0\,, \tag{28}$$
$$[\tilde{S}^j, P_i]' = 0\,, \tag{29}$$
$$[\tilde{S}^i, \tilde{S}^j]' = \epsilon^{ijk}\tilde{S}^k\,, \tag{30}$$

where ϵ^{ijk} is the permutation symbol. Then (up to singular systems), the variables $X^i, P_j, \tilde{S}^k$ are *necessarily* the Newton-Wigner variables with $\xi^\mu = \delta^\mu_0$.

One conclusion of this theorem is that if one was to cover the algebra (22)-(25) with coordinates X^μ canonically conjugate to P_μ and two other canonically conjugate coordinates on the spin sector of the phase space, then these would necessarily be Newton-Wigner variables when reduced to spatial sections. Even this result would be interesting, since it would "covariantize" the Newton-Wigner prescription. Of course, it is also possible to construct canonical coordinates that do not have $\sim P_\mu$ as canonical variables, but these seem to almost always violate manifest rotational and/or translational invariance of the dynamics.

3. Summary and Outlooks

I have shown that capturing the spin-curvature coupling of a test body on a curved background in a covariant Hamiltonian formalism – while eliminating redundant degrees of freedom – is a non-trivial matter. This matter is also far from closed. In the future, I hope to find a set of "covariant Newton-Wigner variables" for the brackets (22)-(25) and formulate a (possibly implicit) iteration problem to canonicalize the full curved-spacetime brackets (19). These should provide a first, truly general basis for the canonical treatment of spinning test particles in general relativity (but see also the work of Steinhoff in the ADM formalism[19]).

This result should then have obvious pay-offs for the relativistic two-body problem and gravitational-wave modelling. For example, the procedure of Vines *et al.*[7] suggests that the minimally coupled spinning particle (that is, with no additional multipoles) under the Tulczyjew-Dixon condition represents a "test Kerr black hole"

on the curved background, since its effective quadrupole in the Newton-Wigner variables matches the Hansen multipole of a Kerr black hole.[20] Does this apply at all orders? A more general and robust formalism is needed for an answer. The question of the minimally coupled particle is all the more interesting due to the fact that the motion of a spining test particle under the Tulzcyjew-Dixon condition is integrable at $O(S)$ in Kerr space-time,[10,21,22] but apparently non-integrable at $O(S^2)$.[23] This then naturally ties-in to the important question of the integrability and smoothness of gravitational-wave inspirals and our ability to efficiently generate predictions for them.[24,25]

Acknowledgements

I would like to thank to thank Oldřich Semerák for organizing this interesting parallel session. This work was supported by European Union's Horizon 2020 research and innovation programme under grant agreement No 894881.

Gravitomagnetic resonance and gravitational waves

Matteo Luca Ruggiero

Antonello Ortolan
INFN, Laboratori Nazionali di Legnaro, Legnaro - Italy

We show that using Fermi coordinates it is possible to describe the gravitational field of a wave using a gravitoelectromagnetic analogy. In particular, we show that using this approach, a new phenomenon, called gravitomagnetic resonance, may appear. We describe it both from classical and quantum viewpoints, and suggest that it could in principle be used as the basis for a new type of gravitational wave detectors.

Keywords: Gravitomagnetism; gravitational waves; gravitomagnetic resonance

1. Introduction

General Relativity (GR) is the best model that we have to understand gravitational interactions, and its predictions were verified with great accuracy during last century, even though we know that there are difficulties to explain, in the general relativistic framework, observations on galactic and cosmological scales, without claiming the existence of *dark components*.[1,2] Remarkably, GR not only predicts corrections to known Newtonian effects such as in the case of perihelion advance, but there are general relativistic effects without Newtonian counterparts: for instance, this is the case of gravitational waves and the so-called gravitomagnetic effects produced by mass currents.

As for gravitational waves, the first indirect evidence of their existence came from the observation of the binary pulsar B1913+16, whose orbital parameters are modified by the emission of gravitational waves.[3,4] It took about 100 years after the publication of Einstein's theory of gravity to obtain, in 2015, the first direct detection of gravitational waves,[5] which was the beginning of gravitational wave astronomy.

It is well known[6] that Einstein equations, in weak-field approximation (small masses, low velocities), can be written in analogy with Maxwell equations for the electromagnetic field, where the mass density and current play the role of the charge density and current, respectively; more in general, both the inertial and curvature effects in the vicinity of a given world-line, can be dealt with using a gravitoelectromagnetic formalism.[7,8] These gravitomagnetic effects are very small if compared to the gravitoelectric ones, originating from mass density and, consequently, it is very difficult to measure them. Nonetheless, there have been various attempts and proposals: we remember the LAGEOS tests around the Earth,[9,10] the subsequent

LARES mission,[11,12] and the recent measurements performed with laser-tracked satellites.[13] A comprehensive analysis of the Lense-Thirring effect in the solar system can be found in Ref. 14. The mission Gravity Probe B[15] was launched to measure the precession of orbiting gyroscopes.[16] There have been other proposals, such as LAGRANGE, which exploit spacecrafts located in the Lagrangian points of the Sun-Earth system,[17] or the use of satellites around the Earth.[18] In addition, we mention the GINGER experiment, which aims to measure gravitomagnetic effects in a terrestrial laboratory by using an array of ring lasers.[19–22]

Recently, the gravitomagnetic effects connected with the passage of a gravitational wave were analyzed:[23] this should not be surprising, since a gravitational wave transports angular momentum. In particular, these effects can be easily understood by using Fermi coordinates on the basis of a gravitoelectromagnetic analogy.[8] Here, we review this approach and suggest how it could be possible to detect the effects due to the magnetic-like part of a plane gravitational wave. The plan of the paper is as follows: in Section 2 we review Fermi coordinates and the definition of local spacetime metric, then we use this approach to study the effect of a plane gravitational wave in Section 3. Conclusions are in Section 4.

2. Local spacetime metric in Fermi coordinates

If we consider the world-line of a given observer, which ideally constitutes our laboratory frame, it is possible to write the expression of the local spacetime metric in its vicinity, using Fermi coordinates. This expression depends both on the background spacetime and on the properties of the world-line. Fermi coordinates in the vicinity of an arbitrary accelerated world-line with rotating tetrads were studied in Refs. 24–26, and the general expression of the line element, up to quadratic displacements $|X^i|$ from the reference world-line, turns out to be

$$ds^2 = -\left[\left(1+\frac{\mathbf{a}\cdot\mathbf{X}}{c^2}\right)^2 - \frac{1}{c^2}\left(\mathbf{\Omega}\wedge\mathbf{X}\right)^2 + R_{0i0j}X^iX^j\right]c^2dT^2 + \\ + \left[\frac{1}{c}\left(\mathbf{\Omega}\wedge\mathbf{X}\right)_i - \frac{4}{3}R_{0jik}X^jX^k\right]cdTdX^i + \left(\delta_{ij} - \frac{1}{3}R_{ikjl}X^kX^l\right)dX^idX^j. \quad (1)$$

Here, $\mathbf{X}$ is the position vector in the Fermi frame. We see that in the line element (1) there are both the gravitational effects, deriving from the curvature tensor, and the inertial effects, due to world-line acceleration $\mathbf{a}$ and the tetrad rotation $\mathbf{\Omega}$.

The metric (1) can be written in terms of the gravitoelectromagntic potentials $(\Phi, \mathbf{A})$ (see Refs. 7, 8), neglecting the terms g_{ij} related to the spatial curvature:

$$ds^2 = -\left(1-2\frac{\Phi}{c^2}\right)c^2dT^2 - \frac{4}{c}(\mathbf{A}\cdot d\mathbf{X})dt + \delta_{ij}dX^idX^j, \quad (2)$$

where

$$\Phi(T,\mathbf{X}) = \Phi^I(\mathbf{X}) + \Phi^C(T,\mathbf{X}), \quad \mathbf{A}(T,\mathbf{X}) = \mathbf{A}^I(\mathbf{X}) + \mathbf{A}^C(T,\mathbf{X}), \quad (3)$$

In particular, in the gravitoelectric potential $\Phi(T, \mathbf{X})$

$$\Phi^I(\mathbf{X}) = -\mathbf{a}\cdot\mathbf{X} - \frac{1}{2}\frac{(\mathbf{a}\cdot\mathbf{X})^2}{c^2} + \frac{1}{2}\left[|\mathbf{\Omega}|^2|\mathbf{X}|^2 - (\mathbf{\Omega}\cdot\mathbf{X})^2\right] \tag{4}$$

is the *inertial* contribution, while

$$\Phi^C(T, \mathbf{X}) = -\frac{1}{2}R_{0i0j}(T)X^iX^j \tag{5}$$

is the *curvature* contribution. As for the gravitomagnetic potential $\mathbf{A}(T, \mathbf{X})$, we may distinguish the *inertial* contribution

$$A^I_i(\mathbf{X}) = -\left(\frac{\mathbf{\Omega}c}{2}\wedge\mathbf{X}\right)_i, \tag{6}$$

and the *curvature* contribution:

$$A^C_i(T, \mathbf{X}) = \frac{1}{3}R_{0jik}(T)X^jX^k. \tag{7}$$

The gravitoelectric and gravitomagnetic fields $\mathbf{E}$ and $\mathbf{B}$ are defined in terms of the potentials by

$$\mathbf{E} = -\nabla\Phi - \frac{1}{c}\frac{\partial}{\partial T}\left(\frac{1}{2}\mathbf{A}\right), \quad \mathbf{B} = \nabla\times\mathbf{A}. \tag{8}$$

which, up to up to linear order in $|X^i|$, can be written as

$$\mathbf{E}^I = \mathbf{a}\left(1 + \frac{\mathbf{a}\cdot\mathbf{X}}{c^2}\right) + \mathbf{\Omega}\wedge(\mathbf{\Omega}\wedge\mathbf{X}), \quad E^C_i(T, \mathbf{X}) = c^2R_{0i0j}(T)X^j. \tag{9}$$

and

$$\mathbf{B}^I = -\mathbf{\Omega}c, \quad B^C_i(T, \mathbf{R}) = -\frac{c^2}{2}\epsilon_{ijk}R^{jk}{}_{0l}(T)X^l. \tag{10}$$

In summary, the gravitoelectricmagnetic fields are written in the form

$$\mathbf{E} = \mathbf{E}^I + \mathbf{E}^C, \quad \mathbf{B} = \mathbf{B}^I + \mathbf{B}^C. \tag{11}$$

In addition, the analogy with electromagnetism can be exploited to describe the motion of free test masses; in particular, the motion of free test masses *relative* to a reference mass, at rest at origin of the Fermi frame, is determined by the geodesics of the metric (1). The latter can be written in the form of a Lorentz-like force equation[7]

$$m\frac{\mathrm{d}^2\mathbf{X}}{\mathrm{d}T^2} = -m\mathbf{E} - 2m\frac{\mathbf{V}}{c}\times\mathbf{B} \tag{12}$$

up to linear order in the particle velocity $\mathbf{V} = \frac{\mathrm{d}\mathbf{X}}{\mathrm{d}T}$ (which is the *relative velocity* with respect to the reference mass). Moreover, the evolution equation of classical spinning particle with spin $\mathbf{S}$ in an external gravitomagnetic field $\mathbf{B}$ is

$$\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}T} = \frac{1}{c}\mathbf{B}\times\mathbf{S}, \tag{13}$$

in analogy with the corresponding equation for a charged spinning test particle in a magnetic field.[7]

In the following Section we will apply this formalism to plane gravitational waves.

3. Gravitomagnetic resonance due to the passage of a gravitational wave

Gravitomagnetic effects deriving from the passage of the gravitational wave can be in principle detected by using devices such as the heterodyne antenna (see e.g. Ref. 8) or studying the perturbations of planetary motion.[27] Here, we focus on a different approach, that is based on the fulfilment of a *resonance condition*.[28]

We consider a spinning particle interacting with the gravitatomagnetic field a plane wave. In the Fermi frame, where the spacetime metric is written in the form (1), we consider coordinates T, X, Y, Z with a set of unit vectors $\{\mathbf{u}_X, \mathbf{u}_Y, \mathbf{u}_Z\}$; the direction of propagation of the wave is the X axis. In this case, for a circularly polarized wave, the components of the gravitomagnetic field deriving from the spacetime curvature (and, hence, connected to the passage of the wave) can be written in the form[8]

$$B_X^C = 0, \quad B_Y^C = -\frac{A\omega^2}{2}\left[-\cos(\omega T)\, Y + \sin(\omega T)\, Z\right],$$
$$B_Z^C = -\frac{A\omega^2}{2}\left[\sin(\omega T)\, Y + \cos(\omega T)\, Z\right], \tag{14}$$

where A is the amplitude and ω the frequency of the wave. In order to study the interaction with a spinning particle, we consider a frame clockwise rotating in the YZ plane with the wave frequency ω; then, the corresponding basis vectors are $\mathbf{u}_{X'} = \mathbf{u}_X$, $\mathbf{u}_{Y'}(T) = \cos(\omega T)\,\mathbf{u}_Y - \sin(\omega T)\,\mathbf{u}_Z$ and $\mathbf{u}_{Z'}(T) = \sin(\omega T)\,\mathbf{u}_Y + \cos(\omega T)\,\mathbf{u}_Z$. As a consequence, the gravitomagnetic field is written as

$$\mathbf{B}^C(T) = \frac{A\omega^2}{2}\left[Y\,\mathbf{u}_{Y'}(T) - Z\,\mathbf{u}_{Z'}(T)\right] \tag{15}$$

Notice that $\mathbf{B}^C$ is a *static field* in the rotating frame that we have considered.

Let us consider the spin evolution equation (13); the total gravitomagnetic field is $\mathbf{B} = \mathbf{B}^I + \mathbf{B}^C$, where $\mathbf{B}^I = -\boldsymbol{\Omega} c$ and it is simply proportional to the rotation rate $\boldsymbol{\Omega}$ of the frame. We suppose that $\boldsymbol{\Omega}$ is constant and it is in the direction of propagation of the wave: then, we may write $\mathbf{B}^I = -B^I \mathbf{u}_X$ where $B^I = \Omega c$. As a consequence, the spin evolution equation turns out to be

$$\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}T} = \frac{1}{c}\left[\mathbf{B}^C(T) + \mathbf{B}^I\right] \times \mathbf{S}. \tag{16}$$

If we consider the frame co-rotating with $\mathbf{B}^C(T)$, since $\boldsymbol{\omega} = -\omega \mathbf{u}_X$ is the rotation rate, the time derivatives in the two frames are related by

$$\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}T} = \left(\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}T}\right)_{\mathrm{rot}} + \boldsymbol{\omega} \times \mathbf{S} = \left(\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}T}\right)_{\mathrm{rot}} - \omega \mathbf{u}_{X'} \times \mathbf{S}. \tag{17}$$

Then, from Eqs. (16) and (17) we get

$$\left(\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}T}\right)_{\mathrm{rot}} = \left[\Delta\omega\mathbf{u}_{X'} + \frac{1}{c}\mathbf{B}^C\right] \times \mathbf{S} = \frac{1}{c}\mathbf{B}_{eff} \times \mathbf{S}, \tag{18}$$

where we set $\omega - \frac{1}{c}B^I = \omega - \Omega = \Delta\omega$ and $\frac{1}{c}B^C = \omega^*$ (see below).

Then, according to Eq. (18), we may say that the spinning particle undergoes a precession determined by the static effective gravitomagnetic field $\mathbf{B}_{eff} = c\left[\Delta\omega\mathbf{u}_{X'} + \frac{1}{c}\mathbf{B}^C\right]$. Accordingly, we see that when $\Delta\omega \simeq 0$, i.e. in *resonance* condition, the spin precession is around the direction of $\mathbf{B}^C$, which is in any case in the YZ plane, so the precession may flip the spin completely. In summary, the *gravitomagnetic resonance* is obtained when the rotation rate of the frame is equal to the frequency of the gravitational wave. It is important to remember that all precessions are referred to a reference spinning particle,[23] at the origin of the Fermi frame so, in any case, we are talking about a *relative precession.*

Actually, the above description, which is analogous to the classical dynamics of a magnetic moment in a magnetic field, can be translated into quantum terms for a two-level system,[28] taking into account the Hamiltonian description of the interaction of the spin of intrinsic particles in a gravitational field.[7, 29–31] As a consequence, we may introduce a probability transition for spinning particles in the field of a gravitational wave. Let us suppose that $|g>$ and $|e>$ are the two eigenvectors, respectively of the ground and excited states, of the projection of the spinning particle along the X axis. If we suppose that a spin is, at $t = 0$, in the ground state $|g>$, the probability of transition to the excited state $|e>$ at time t is given by Rabi's formula

$$P_{g\to e}(T) = \frac{(\omega^*)^2}{(\omega^*)^2 + \Delta\omega^2}\sin^2\left(\sqrt{(\omega^*)^2 + \Delta\omega^2}\frac{T}{2}\right). \tag{19}$$

Again, at resonance, i.e. when $\Delta\omega = 0$, or $\omega = \Omega$, even a weak gravitational field can reverse the direction of the spin: the probability of transition is equal to 1 *independently of the strength of the gravitomagnetic field*, for $T = \frac{2n+1}{(\omega^*)}\pi$.

Let us add a comment on how the resonance condition could be achieved without requiring the physical rotation of our reference frame. In fact, if we consider charged spinning particles, we may get an equivalent situation by using a true magnetic field, on the basis of Larmor theorem, which states the equivalence between a system of electric charges in a magnetic field and the same system rotating with the Larmor frequency. So a magnetic field can be used to produce the gravitomagnetic field $\mathbf{B}^I$.

4. Conclusions

We have seen that, using Fermi coordinates, it is possible to emphasize the gravitomagnetic effects connected to the passage of a gravitational wave. Current detectors such as LIGO and VIRGO can detect only the interaction of a system of masses

with the electric-like component of the field, so we discussed the possibility of detecting the interaction of a suitable probe with the magnetic-like component of the wave field. In particular, we considered the interaction of the wave with a spinning particle, both using a classical and a quantum approach, and we showed that in analogy with what happens in electromagnetism, a gravitational magnetic resonance phenomenon may appear when the reference frame rotates along the direction of propagation of the wave and the rotation rate is equal to the wave frequency. Actually, since it is not possible to have physical rotations for arbitrary frequencies, we pointed out that an equivalent situation can be obtained by using a true magnetic field, on the basis of the Larmor theorem. As for the detection of this effect, we imagine not to detect the modification of a single spinning particle, rather to consider a great number of identical particles. For instance, the precession induced by the gravitational wave can modify the magnetization of a macroscopical sample which, in turn, can be detected by measuring the differences in the magnetic field produced.

Studying the EPRL spinfoam self-energy

Pietropaolo Frisoni
Department of Physics and Astronomy, Western University, London, Ontario, Canada
E-mail: pfrisoni@uwo.ca

I present some recent progresses in the study of the EPRL self-energy amplitude.[1] New numerical methods allow to analyze how the divergence scales, for which previous works only provided bounds spanning more than 9 orders of magnitude. I discuss the role that the Immirzi parameter plays in the asymptotic behavior, and the dependence of the scaling on some boundary data. Finally, I discuss the dynamical expectation values of some relevant geometric boundary observables.

Keywords: Spinfoam; self energy; infrared divergences; HPC; LQG.

1. Introduction

The spinfoam formalism is an attempt to define the dynamics of loop quantum gravity in an explicitly Lorentz covariant way.[2,3] It defines transition amplitudes for spinnetwork states of the canonical theory in a form of a sum (or equivalently a refinement[4]) over all the possible two-complexes having the chosen spinnetwork as boundary. This is equivalent to a sum over histories of quantum geometries providing in this way a regularised version of the quantum gravity path integral.

The state of the art of the spinfoam approach to LQG is currently the model proposed by Engle, Pereira, Rovelli and Livine (EPRL),[5,6] independently developed by Freidel and Krasnov[7] and extended to arbitrary spinnetwork states.[8,9] I assume that the reader is familiar with the EPRL-FK[a] model, and refer to the original literature[10–13] and existing reviews (e.g.[2,14–16]) for the details on how it encodes the covariant dynamics of Loop Quantum Gravity.

The EPRL model presents infrared divergences, which have a similar structure to the UV divergences in the Feynman expansion of a standard quantum field theory. The presence of divergences require a renormalization procedure. This is an important open direction of investigation in the theory, since their study and understanding is important in the definition of the continuum limit. A number of questions are still open, for example regarding the proper normalisation of the n point functions and similar.[14] Divergences have been the subject of many studies following different investigation strategies: via refining of the 2-complex as proposed in,[17–19] or via a resummation, defined for instance using group field theory/random tensor models as proposed in.[20–23] The properties of these divergences have been studied

[a]From now on I will call it just EPRL for notation convenience.

in the context of the Ponzano-Regge model of 3d quantum gravity and discrete BF theory,[24,25] group field theory[26] and EPRL model: with both Euclidean[27,28] and Lorentzian signature.[29]

Analytic estimates of divergences in the Lorentzian EPRL model[29] and[30] are based on two different methods. In[29] the "self-energy" amplitude is considered, finding a logarithmic divergence $\log K$ as a *lower bound*, where K is an artificial cut-off on the internal $SU(2)$ spins associated with the faces of the diagrams (the need to introduce a cut-off is justified by the fact that the sum on the internal spins is unbounded). The computation is rather involved and relies on the techniques developed for the asymptotic analysis of the vertex amplitude of the model.[31] This approach requires an independent study of each geometrical sector and the logarithmic divergence is obtained by looking at the non-degenerate geometries. On the other hand, in[30] is proposed an algorithm to systematically determine the potential infrared divergence for all spinfoam diagrams. The approach is based on the hypothesis that the dominant contribution to the divergence scaling of the amplitude comes from the uniform scaling of all the spins and that there is no interference between various terms of the sum. This leads to an *upper bound* on the divergence proportional to K^9.

These two bounds are therefore remarkably different, leading a window of possibilities which spans several orders of magnitude, and it is necessary to find methods of investigation that can help clarify the question. Here I report the results of a numerical study[1] regarding the scaling of the self-energy amplitude, which also investigates the dependence on the Immirzi parameter and some other boundary data. In particular, the numerical estimates confirm both the two bounds previously found.

For the numerical calculation of the EPRL vertex amplitudes, the "sl2cfoam-next" library was used.[32] All computations were performed on Compute Canada's Cedar and Graham clusters (www.computecanada.ca). The plots were made with julia[33] and Mathematica.[34] Here I present a summary of the results obtained. The interested reader can find further details and analysis, including explicit formulas for the $SU(2)$ invariant symbols and the booster functions, in the full analysis.[1]

The paper is organized as follows. In section 2 I describe the triangulation used to study the self-energy amplitude. In section 3 the amplitude is derived in the purely $SU(2)$ BF model. This intermediate step allows to compare the numerical results with the analytical ones present in the literature. In section 4 the EPRL amplitude is derived from the BF model. In section 5 I perform the numerical analysis of the EPRL self-energy amplitude. Finally, in section 6, I report the results of the dynamical expectation value of the boundary angle operators.

2. Self-energy diagram

I consider bubbles, studying one of the most elementary diagrams appearing in the self-energy amplitude.[29,30] Since the associated divergence can be viewed as the one

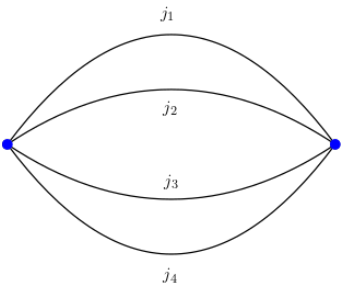

Fig. 1. Boundary graph of the spinfoam associated with the self-energy amplitude. In blue are highlighted the two four valent nodes, corresponding to the two tetrahedra in the dual triangulation. The nodes are joined by all the links. The boundary spins are denoted with j_f, where $f = 1, ..., 4$.

related to a particularly simple triangulation, from a computational point of view it turns out to be the one of the simplest divergence to deal with. The triangulation is formed by two 4-simplices joined by four tetrahedra. The associated two-complex turns out to be composed by two vertices, four edges, six internal faces (one per couple of edges) and four external faces (one per edge). The boundary of the dual triangulation is formed by two tetrahedra joined by all the faces, therefore the boundary graph consists in two four valent nodes connected by all the links (see Fig. 1).

The kinematical Hilbert space of LQG at fixed graph Γ, with L links and N nodes, is:

$$\mathcal{H}_\Gamma = L_2 \left[SU(2)^L / SU(2)^N \right] \tag{1}$$

For the self-energy diagram, we have $L = 4$, $N = 2$ and the corresponding graph[b] Γ is represented in Figure 1. Since the self-energy spinfoam graph is entirely symmetrical and has two nodes, I shall use the $+$ and $-$ symbols as labels for the latter. I use the same symbols to distinguish the corresponding intertwiners $i_\pm$, i.e. the invariant $SU(2)$ tensors associated with each node. The intertwiner space of a 4-valent node is denoted as:

$$\mathcal{I}_4 = Inv \left[V^{j_1} \otimes V^{j_2} \otimes V^{j_3} \otimes V^{j_4} \right] \tag{2}$$

where V^{j_i} is the irreducible representation of spin j_i. I consider the recoupling base (j_1, j_2) for the intertwiner space (2). That is, I fix a pairing of the links at each node and I choose the basis that diagonalises the modulus square of the sum of the $SU(2)$ generators in the pair (j_1, j_2). A basis for the Hilbert space (1) is given by the spin-network states $|j_l, i_\pm\rangle$, where the j_l's are the spin associated with each link of the graph, $l = 1...4$, and the $i_\pm$'s are a basis in the corresponding intertwiners space (2) according to the recoupling scheme. The spin-network states are interpreted

[b] From now on, I will drop the explicit dependence on Γ.

as quantum tetrahedra or, if the node have valence higher than 4, as quantum polyhedra.[c, 35,36] The corresponding discrete geometry, in which the shared faces between the tetrahedra must have the same area but nor necessarily the same shape or orientation, is called *twisted geometry*.[37]

I shall focus on the subspaces $\mathcal{H}_j$ of (1) such that all spins are the same $j_l = j$, for which the basis states are denoted as

$$|j, i_\pm\rangle \equiv \bigotimes_\pm |i_\pm\rangle = |i_+\rangle \otimes |i_-\rangle \tag{3}$$

The explicit dependence on j can be dropped in the notation, since all the spins have the same value.

3. Derivation of the BF spinfoam amplitude

I start deriving the formula for the spinfoam transition amplitude associated to the triangulation described in section 2. The strategy chosen to derive the self-energy EPRL amplitude consists in starting from the corresponding amplitude for the BF model, for which it is possible to compare our numerical computations with the exact estimate of the amplitude's divergence,[30] since in the pure $SU(2)$ model one can isolate the divergent factor. Then, I include the contribution of the booster functions (see[38]), as they encode all the details of the EPRL model. This process serves to facilitate the derivation and, at the same time, make sure that the phases and normalization factors are correct.

3.1. *Numerical scaling of the BF amplitude*

The BF self-energy amplitude is written as:

$$W_{BF}\left(j, S_+, S_-\right) = \sum_{j_{ab}} \prod_{(a,b)} \left(2j_{ab}+1\right) \{15j\}^2 \tag{4}$$

where the algebric notation $\{15j\}^2$ refers to the spinfoam in Figure 2. For the algebraic expression of the $SU(2)$ $\{15j\}$ invariant quantities, I refer to.[1,39] In (4), $(a,b) = (23, 24, 25, 35, 45, 34)$ are the labels which denote the spins attached to the 6 internal faces of the spinfoam, while the dependence on the 4 boundary spins is denoted with $j \equiv j_f$ with $f = 1...4$. In (4), the parameters specifying the boundary tetrahedra are generically denoted with S. The sums over the internal faces (explicitly highlighted in red) are unbounded: this is precisely the way in which the bubble's divergence manifests itself. Strictly speaking, the dimensional factor of the boundary faces should be taken into account in the expression for the amplitude, but this is a constant overall factor that can be ignored in the analysis, since it does not affect the scaling of the divergence. The 4-simplices are labeled in the following

[c] At least to some extent, since the Heisenberg uncertainty principle prevent us from determining the full geometry of the polyhedra. Thus, the interpretation of a spinnetwork state as a sharp polyhedron fails.

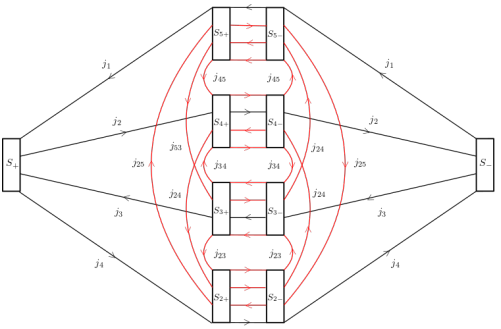

Fig. 2. Spinfoam corresponding to the BF self-energy amplitude. The two $\{15j\}$ symbols are graphically represented in order to highlight the bulk contractions.

way. The subscripts + and − distinguish the tetrahedra belonging to one vertex amplitude from those of the other, while the numeric subscripts distinguish the ones belonging to the same vertex. The two boundary tetrahedra, on the "opposite sides" of the spinfoam, are only labeled with + and − subscripts according the notation introduced in 2. The internal faces, dual to triangles, are labeled by two points indicating the tetrahedra attached to them, while the spins attached to the boundary links are labeled according to Figure 1.

In order to study numerically the scaling behavior of the amplitude, I impose an arbitrary cutoff K on the spin's values of the 6 internal faces. This allows to estimate the divergence scaling without performing an infinite number of sums. By doing so, the amplitude acquires an *artificial* dependence also on K. From now on, I refer to K as the "bulk spins cut-off".

I perform the integration over $SU(2)$ and obtain:

$$W_{BF}\left(j,i;K\right) =(-1)^{2(i_+ + i_-)} \sum_{j_{ab}} \prod_{(a,b)} (2j_{ab}+1) \sum_{i_e} \prod_{e} (2i_e+1) \{15j\}^2 \qquad (5)$$

I denoted with $i \equiv (i_+, i_-)$ the dependence on the intertwiners at the two nodes in the recoupling base (j_1, j_2), and the phase $(-1)^{2(i_+ + i_-)}$ comes from the fact that I changed the orientation of the line represented by the boundary intertwiners, according to our convention for the $\{15j\}$ symbol, following the rules of the $SU(2)$ graphical calculus.[40]

In passing from (4) to (5), I attached an intertwiner i_e with $e = 2, ..., 5$ to each edge. Therefore, each edge carries a boundary spin, three face spins and an intertwiner. Triangular inequalities constrain the intertwiner to assume values in an interval centered on a face spin, implying that, for a fixed value of the spins on the faces, the sums over these intertwiners are bounded. I choose the spinnetwork boundary state with fixed spins and intertwiners and analyze the bubble's divergence with it, since the contraction of the amplitude with less trivial boundary states (for example, coherent states) requires to compute all the possible amplitudes

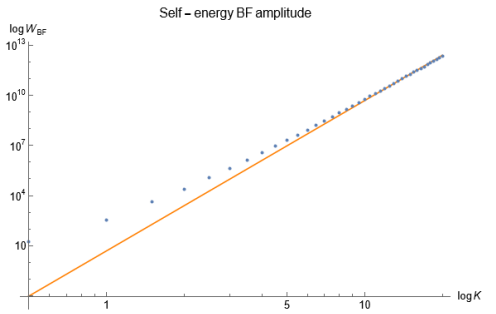

Fig. 3. Logarithmic plot of the BF self-energy amplitude scaling. The points computed with (5) are fitted with the curve $W_{BF} = 4.8 * K^9$, and the latter is shifted so that the last point coincides with the end of the curve. Notice that the divergence scaling is reached for very low values of the bulk spins cutoff K.

obtained by varying independently the intertwinwers i_+, i_-, thus increasing the computational complexity. The computation with other choices of boundary states are considered in.[1]

As previously stated, I only consider equilateral boundary spins configuration, that is, the spins $j \equiv j_f = j_1 ... j_4$ have all the same value[d]. In fixing the boundary state entirely, that is, both the boundary spins and the intertwiners, the amplitude turns out to depend only on 6 parameters, namely the 4 spins $j \equiv j_f$ and the 2 intertwinwers $i \equiv (i_+, i_-)$. To further minimize the computational time, I fix the spins of the boundary faces to their minimum non-trivial value $j = \frac{1}{2}$. Notice that the value of the boundary spins j and intertwiners i is not relevant, since in the BF model the amplitude must be independent of the values of the latter. Computing the amplitude (5) numerically, for different values of K, I verify that it correctly reproduces the divergent scaling derived in,[30] as shown in Figure 3:

$$W_{BF}(j, i, K) \propto K^9. \tag{6}$$

4. From BF to EPRL

In the BF model it is possible to isolate the divergent factor, but the aim is to use the numerical tools to study the EPRL model, where only analytical estimates of the lower[29] and upper bounds[30] on the scaling of the bubble's divergence are available in the literature. The picture is therefore not clear, especially considering that these two limits differ greatly. In fact, while the lower bound is logarithmically divergent in the cutoff K over the $SU(2)$ representation spins, the upper bound turns out to be K^9.

[d]Notice that, by doing so, each boundary intertwiner assumes a range of possible integer values ranging from 0 to $2j + 1$, so the overall phase of the amplitude is always unitary.

The crucial point of the passage from BF to EPRL model lies in the expression of the EPRL vertex amplitude. Since the reader may be unfamiliar with such amplitude form, I briefly underline the essential ideas, referring to the original paper[38] for an accurate description.

4.1. *EPRL vertex amplitude*

The EPRL vertex amplitude is built from the topological $SL(2,\mathbb{C})$ spinfoam vertex amplitude by imposing, weakly, the simplicity constraints. This results in a restriction of the unitary irreducible representations in the principal series.[10,41] In order to evaluate it in its original form, one should perform four group integrals (one of the original five integrals is redundant and has to be removed to guarantee finiteness[42]). Each group integral is, in general, a six dimensional unbounded highly oscillating integral for which numerical integration methods are not easy to implement efficiently. To get around this computational hurdle, an alternative form for the amplitude has been derived, resulting in a superposition of $SU(2)$ $\{15j\}$ symbols weighted by one booster functions $B4$ per edge in the considered vertex.

$$A_v\,(j_f,\,i_e,\gamma) = \lim_{\Delta l\to\infty} \sum_{l_f=j_f}^{j_f+\Delta l} \sum_{k_e} \prod_e (2k_e+1)\, B_4(j_f,l_f;i_e,k_e;\gamma)\{15j\}_{j_f,i_1}(l_f,k_e) \tag{7}$$

For the explicit formulas of the booster functions B_4, I refer to.[1,38,43] In[1] it is also introduced a convenient graphical notation which combines the $SU(2)$ graphical calculus with algebraic formulas to define the quantities involved. Notice that in (7) the dimensional factors attached to the boundary intertwiners i_e and to the boundary spins j_f are neglected, since I assume the latter to be determined by the boundary spinnetwork state, so that they turn out to be constant. In less trivial spinfoams, as in the self-energy case, there are typically more vertex amplitudes glued together. This implies that dimensional factors of bulk spins and intertwiners must be taken into account, as did for the BF self-energy amplitude (5), in which the elementary vertex amplitude is represented by a single $SU(2)$ invariant $\{15j\}$ symbol. The key conceptual step to obtain the expression (7), starting from the integral representation over $SL(2,C)$, is to decompose each $SL(2,C)$ integral h according to the Cartan decomposition:

$$h = ue^{(\frac{r\sigma_3}{2})}v^{-1}, \tag{8}$$

where u and v are $SU(2)$ arbitrary rotations and $r\in[0,\infty)$ is the rapidity parameter of a boost along the z axis. The compact integrals, resulting from the above parameterization, are then evaluated exactly composing the $SU(2)$ invariants in the amplitude (7). This decomposition introduces a summation over a set of auxiliary spins l_f for each face involving the vertex (excluding the gauge fixed one), for a total

of 6 distinct l_f, with lower bound $l_f \geq j_f$, and a set of auxiliary intertwiners k_e for each edge in the vertex (excluding the gauge fixed one) for a total of 4, which can assume all the values compatible with triangular inequalities. Finally, the "Y-map" imposes that the polyhedron shared by two adjacent polytopes lives in the same space-like hyperplane.[16, 44, 45]

The Y-map is present only on one side of each booster function, namely the one reaching out to the next vertex: the group elements joining at the vertex are instead multiplied together without the latter. Because of this, an infinite sum appears on the auxiliary spins l_f and the EPRL model is, in principle, recovered only in the limit in which this sum becomes infinite. The full EPRL amplitude is well defined,[42] as the summations over the l_f are convergent. Nevertheless, in order to perform a numerical evaluation of the amplitude, we need to introduce a homogeneous cut-off [e] Δl on the auxiliary spins l_f. In the following, I will refer to the cutoff Δl as the number of *shell*.

Beside the numerical precision with which the single terms that contribute to the vertex amplitude are computed, notice that this is the only approximation on which this method is based. If the convergence in the sum over the auxiliary spins l_f is sufficiently good, then we obtain a reasonable estimate of the EPRL model. As originally shown in,[38] the largest contributions to the booster functions come from configurations with $l_f = j_f$, namely the minimal admissible values for the l_f spins. The EPRL model defined with the approximation $l_f = j_f$ is usually called "simplified model". Even if the convergence of the amplitude (7) as a function of Δl is assured,[46, 47] it is not possible to have a unique prescription to set the optimal Δl to get an acceptable convergence, since it depends on the details of data such as the face spins j_f and the Immirzi parameter. Furthermore, the convergence strongly depends on the structure of the 2-complex, and there is still no method that allows to estimate the error made in truncating the sum over the auxiliary spins. In section 5.1, I describe a numerical property of the convergence that allows extrapolating the limit $\Delta l \to \infty$ for the self-energy.

4.2. *EPRL self-energy amplitude*

According the procedure described above, starting from the BF amplitude (5), I attach a booster function between the bulk intertwiners, choosing the boundary intertwiners $i \equiv (i_+.i_-)$ as the gauge fixed ones in the two vertex amplitudes which form the self-energy spinfoam, which is the most convenient choice from a computational point of view. Here I consider the case[1] in which the two boundary intertwiners have the same value. When this happens, the fully algebraic compact

[e] The nature of this cut-off is obviously completely different from the K cutoff on the internal faces of self-energy amplitude introduced in section 3.1 for the BF amplitude.

expression of amplitude becomes[f]:

$$W(j,i,\gamma;K,\Delta l)=\sum_{j_{ab}}^{K}\prod_{(a,b)}(2j_{ab}+1)\sum_{i_e}A_v(j,j_{ab},i,i_e,\gamma;\Delta l)^2 \tag{9}$$

where $q = 2,...5$, and the EPRL vertex amplitude is defined in (7). The EPRL self-energy amplitude (9) is the main object of our analysis. The dependence on the Immirzi parameter γ is "hidden" inside the booster functions, which appear in the definition of the single vertex amplitude (7). In the EPRL self-energy amplitude (9) I explicitly emphasized the *artificial* dependence on the two cut-off K and Δl. I shall always consider the two boundary intertinwers $i \equiv (i_+.i_-)$ to have the same value. When this is the case, the asymptotic divergence scaling remains essentially[g] unchanged by modifying the value of the intertwiners. Since it is necessary to choose a specific value of i for the computations, in the following I use $i = (0, 0)$ by default. This completes the derivation of amplitude we considered in,[1] and now I describe the numerical results obtained.

5. Divergence analysis

The amplitude (9) has been studied numerically. Recalling that the analysis must be limited to a small number of parameters' configurations, the goal of the latter consists in answering the following question (for further numerical studies I refer again to,[1] which addresses more questions), for which there are currently no analytical methods of investigation: what is the exact asymptotic scaling of the EPRL divergence, and is there a dependence on the Immirzi parameter?

The logical step is to proceed in the same way as we did with the BF amplitude (5), that is, fix the boundary state entirely to the lowest value $j = 0.5$, and compute the amplitude as a function of the cut-off K on the internal faces. It is reasonable to do so using several different values of the Immirzi parameter γ. However, compared to the purely $SU(2)$ case, the EPRL amplitude (9) has an additional cut-off Δl necessary to truncate the sum on the auxiliary spins l_f in the single vertex amplitudes (7) which constitute self-energy. This fact makes the EPRL analysis much more complicated due to the reasons explained in section 4. In section 5.1 I present a property of the convergence which allows to extrapolate the limit $\Delta l \to \infty$. Since for computations it is necessary to select a specific value of the Immirzi parameter, I first illustrate the divergence scaling extrapolation algorithm by selecting a specific value for the latter. The analysis for different γ values is similar.

The result of the computation of the amplitude (9), for increasing values of Δl and K, is shown in Figure 4. From a simple qualitative analysis we infer that the convergence is faster for a reduced bulk spins cutoff, while it becomes slower

[f] In the following omit the EPRL subscript for the amplitude, since every time I write W (without the BF subscript) I always implicitly refer to the EPRL model.
[g] A part from irrelevant numerical fluctuations.

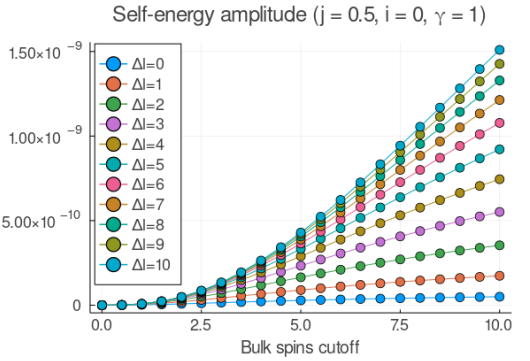

Fig. 4. Divergence of the EPRL self-energy amplitude (9) computed numerically. All boundary spins $j \equiv j_f$, where $f = 1...4$, are equal to $\frac{1}{2}$, while boundary intertwiners i_+, i_- are both set to zero. The plots with i_+, i_- equal to 1 are identical.

as K increases. Strictly speaking, the numerically computed curves turn out to be a *lower bound* to the EPRL divergence, since the latter is recovered only in the limit $\Delta l \to \infty$. Since further increasing numerically the parameter Δl requires exponentially increasing the computation times, it is necessary to introduce an algorithm for extrapolating the above limit.

5.1. *Extrapolation algorithm for the amplitude*

In order to derive the full EPRL amplitude, we study the convergence of (9) in the parameter Δl based on the data of Figure 4, and we extrapolate infinite shell limit based on this trend. In order to do so, we plot the ratios of the differences between adjacent curves of Figure 4, at fixed K, as a function of Δl. That is, we study the function:

$$f(K, \Delta l, \gamma) \equiv \frac{W(K, \Delta l + 2, \gamma) - W(K, \Delta l + 1, \gamma)}{W(K, \Delta l + 1, \gamma) - W(K, \Delta l, \gamma)}. \tag{10}$$

The result is shown in Figure 5. Numerical data shows that the convergence of (9) in the shell parameter Δl, for each bulk spins cut-off K, is such that the function (10) is first a decreasing function of Δl, then it remains constant in the convergence phase. Therefore, it exists an integer N such that:

$$W(K, \Delta l + 1, \gamma) - W(K, \Delta l, \gamma) \approx (c_{K,\gamma})^{\Delta l} \quad \text{for} \quad \Delta l \geq N \tag{11}$$

where the coefficient $c_{K,\gamma}$ is roughly equal to function (10) for the highest number of shells computed numerically. So, if the amplitude has been calculated up to N shells, we approximate the coefficient $c_{K,\gamma}$ as:

$$c_{K,\gamma} \equiv f\left(K, N - 2, \gamma\right). \tag{12}$$

For the extrapolation of the EPRL amplitude we used $N = 10$, even if Figure 5 shows that property (11) becomes evident even for lower values. Once the convergence is

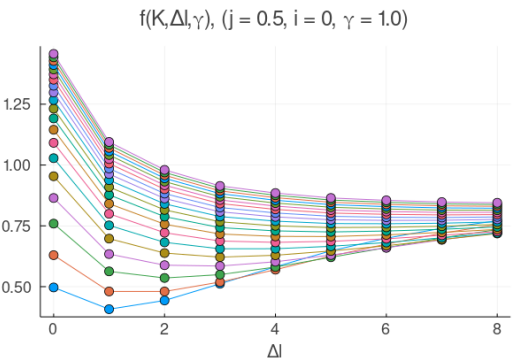

Fig. 5. Plot of the function $f(K, \Delta l, \gamma)$ defined as in (10). I plot the values of K between $\frac{1}{2}$ and 10 in ascending order from bottom to top.

reached, that is, when $\frac{W(K,\Delta l+1,\gamma)}{W(K,\Delta l,\gamma)} \approx 1$, function (10) shows some slight fluctuations by further increasing the shells[h]. This is evident for low bulk spins cut-off values, where convergence in Δl is extremely fast, as shown in Figure 5. Property (11) allows to obtain a good estimate of the EPRL curve by using the equation:

$$W(K,\gamma) \equiv \lim_{\Delta l \to \infty} W(K, \Delta l, \gamma) \approx W(K, N-1, \gamma) + \frac{W(K,N,\gamma) - W(K,N-1,\gamma)}{1 - c_{K,\gamma}} \tag{13}$$

Equation (13) is obtained by using the known limit of the geometric series:

$$\sum_{l=N}^{\infty} (c_{K,\gamma})^l = \frac{(c_{K,\gamma})^N}{1 - c_{K,\gamma}} \approx \frac{W(K,N,\gamma) - W(K,N-1,\gamma)}{1 - c_{K,\gamma}} \tag{14}$$

where in the second passage we used the property (11). In Figure 7 we plot the EPRL amplitude extrapolated with equation (13) along with the curves in Figure 4.

Let's discuss the above extrapolation scheme:

- Extrapolating the limit $\Delta l \to \infty$ of (9) for low values of the bulk spins cut-off K, for which a good convergence in the auxiliary spin sum has already been reached numerically, equation (13) provides a value which essentially coincides with the last computed point. This happens because, despite the fluctuations of function (10) for low K, the difference $W(K,N,\gamma) - W(K,N-1,\gamma)$ is extremely small. Therefore, the only relevant contribution to the extrapolated amplitude comes from the computed one, which is a good approximation of the EPRL model.
- For each bulk spins cut-off value K, the corresponding EPRL amplitude is extrapolated *independently* from the other values the latter. By doing so,

[h] As we shall see, this fluctuations are not relevant.

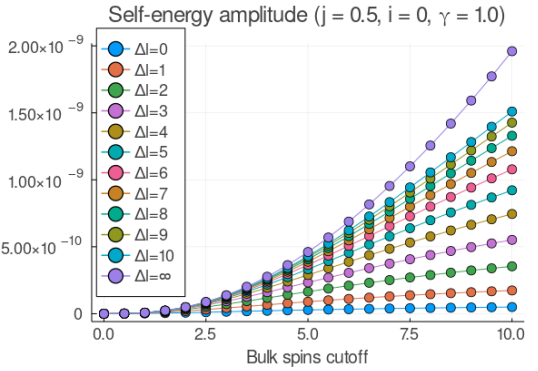

Fig. 6. EPRL asymptotic scaling curve extrapolated with the equation (13), plotted together with those computed numerically, that is, the curves of Figure 4. Notice that for $K \leq 4$, where the convergence is reached numerically, the extrapolated point essentially coincides with the last computed one.

we actually see that the resulting amplitude can be approximated extremely well by a polynomial fit $W(K,\gamma) = a + bK^c$ as a function of the bulk spins cut-off K.

- The specific properties of the convergence in the auxiliary spins sum of the single vertex amplitude (7) are still unexplored. It is possible that property (11) also manifests for spinfoam amplitudes defined on a more elaborate 2-complex with respect to the triangulation described in section 2. If this would be the case, the above extrapolation scheme could allow to obtain a good estimate of the EPRL model by using a negligible amount of computational resources compared to that necessary to reach a good approximation by using solely numerical techniques.
- In order to apply equation (13) it is necessary to know $W(K,N,\gamma)$, $W(K,N-1,\gamma)$, $W(K,N-2,\gamma)$. That is, only three amplitudes must be computed numerically (for N sufficiently high). Despite this, we still opted to compute all the amplitudes $W(K,\Delta l,\gamma)$ for $\Delta l = 0,1...N$. This was done both to test property (11) and, on the other hand, to estimate the effectiveness of the extrapolation with a qualitative comparison between all the numerically calculated amplitudes and the extrapolated one. Furthermore, since the curves in Figure 5 are not exactly constant, that is, they start to increase when $\frac{W(K,\Delta l+1,\gamma)}{W(K,\Delta l,\gamma)} \approx 1$, the extrapolated curve is an approximation, which improves by increasing N in equation (13). Therefore, the higher is the number of shells computed numerically, the better is the approximation represented by the extrapolated amplitude. In[1] we discuss this in more detail and we also provide further numerical confirmation of the effectiveness of this extrapolation algorithm.

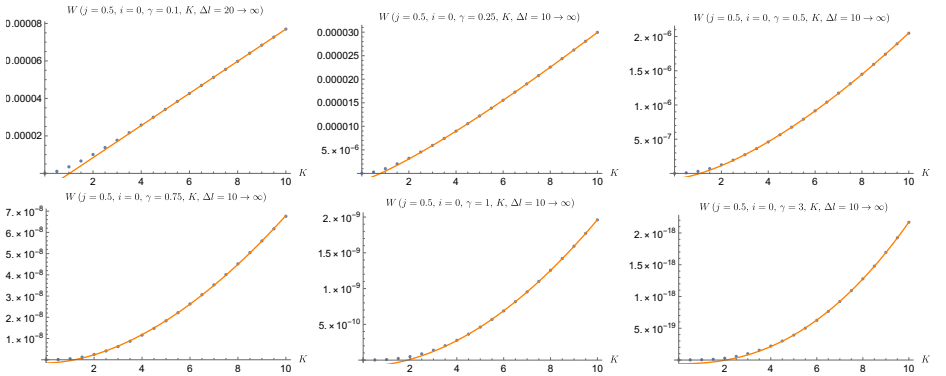

Fig. 7. EPRL asymptotic scaling curve extrapolated with the equation (13), plotted together with those computed numerically, that is, the curves of Figure 4. Notice that for $K \leq 4$, where the convergence is reached numerically, the extrapolated point essentially coincides with the last computed one.

5.2. *Scaling of the divergence and role of the Immirzi parameter*

Using the above scheme in,[1] we study the scaling of the asymptotic divergence of the EPRL self-energy amplitude for 9 different values of the Immirzi parameter. We choose an approximately uniform sampling of γ between 0.1 and 10, arguing that a significant effect of the latter in the scaling should occur in a range which spans two orders of magnitude. We fit the curves with a function:

$$W(K,\gamma) = a + bK^c \tag{15}$$

where a, b, c are real coefficients. The values[i] of $W(K,\gamma)$ are shown in table 1.

Table 1. Fit coefficients table

$W(K,\gamma) = a + bK^c \quad (j = 0.5, i = 0),\ K \in [0,10]$			
Immirzi parameter	a	b	c
$\gamma = 0.1$	$-3.0884 * 10^{-6}$	$6.0304 * 10^{-6}$	1.1
$\gamma = 0.25$	$-1.58614 * 10^{-6}$	$1.9783 * 10^{-6}$	1.2
$\gamma = 0.5$	$-7.5523 * 10^{-8}$	$6.7306 * 10^{-8}$	1.5
$\gamma = 0.75$	$-1.7153 * 10^{-9}$	$1.10779 * 10^{-9}$	1.8
$\gamma = 1$	$-8.6894 * 10^{-11}$	$2.5801 * 10^{-11}$	1.9
$\gamma = 3$	$-6.0026 * 10^{-20}$	$1.1186 * 10^{-20}$	2.3
$\gamma = 5$	$-4.5405 * 10^{-25}$	$1.0642 * 10^{-25}$	2.3
$\gamma = 7.5$	$-2.35075 * 10^{-29}$	$8.25374 * 10^{-30}$	2.3
$\gamma = 10$	$-1.7872 * 10^{-32}$	$9.2770 * 10^{-33}$	2.3

[i]Recall that we neglected all the dimensional factors which, in the amplitude (9), are constant as a function of K.

The analysis of the scaling shows that the amplitude is strongly suppressed as γ increases. Moreover, the divergence turns out to be well fitted by a linear scaling when the Immirzi parameter is small enough, while for $\gamma \geq 1$ the curve is approximated by a quadratic function in the range $K \in [0, 10]$. Unfortunately, the huge computation cost required by increasing the bulk spins cut-off in the divergence analysis prevents us from testing the divergence for $K > 10$. It is possible that the divergence scaling is actually independent of the Immirzi parameter, and that the different asymptotic trends, as γ varies, are only an effect of the fact that the range of the bulk spins cut-off K is too small. On the other hand, it is also possible that the Immirzi parameter plays an effective role in modifying the asymptotic scaling of self-energy amplitude. This deserves future investigations.

In any case, the numerically observed scaling in the range $K \in [0, 10]$, with boundary parameters $j = 0.5, i = 0$ falls within the upper and lower bounds present in the literature. In particular, unlike the BF self-energy divergence (see equation (3)), the role of the destructive interference between the oscillations of the booster functions $B_4(j_f, l_f; i, k)$ and the $\{15j\}$ symbols in the sum over the bulk spins j_{ab} implies that the divergence is considerably dumped. This was not expected, since it has been shown that in the three-dimensional EPRL model, the upper bound provided by the algorithm proposed in[30] provides an excellent estimate of the divergence.

6. Boundary observables

In this section we compute some spinfoam boundary observables. We focus on the normalized dynamical expectation value of geometrical operators, that is:

$$\langle O \rangle = \frac{\langle W|O|\Psi\rangle}{\langle W|\Psi\rangle} \tag{16}$$

where the bra W contains the propagator, namely the dynamics, while the ket Ψ turns out to be the tensor product of the *in* and *out* states of the LQG Hilbert space. With the term "propagator" we refer to the square matrices (they are such since the self-energy triangulation has two boundary tetrahedra) in which the element a, b corresponds to the EPRL self-energy amplitude with $a = i_+, b = i_-$. The observable O therefore contains the dynamic correlations.

The booster function $B_4(j_f, l_f; i, k)$ are interpreted as a quantum tetrahedron being boosted among adjacent frames: the two sets j_f and l_f describe the four areas of the tetrahedron in the two frames connected by a boost, and the two intertwiners i and k describe the quantum intrinsic shape of the tetrahedron.[48] Therefore, the expectation values (16) of geometric operators describing boundary tetrahedra should be equivalent with respect to the $SU(2)$ model. From a numerical point of view it is an excellent check, especially considering that numerical calculations carried out with the EPRL model are still in their primordial stages,[30, 43, 47] and, as far as we know, there are no such numerical computations (ie dynamic expectation value of

geometric operators) with spinfoams more complicated than those consisting of a single vertex amplitude[49] which used these specific techniques.

In[1] we find that the boundary observables are not affected in any way by the presence of the spinfoam divergence in the bulk. Furthermore, while in the divergence analysis we see an important contribution due to the number of shells Δl of the amplitude (9), for the observables there is no trace of a dependence in that sense[j]. In fact, an excellent approximation of the correct geometric value is obtained with the approximation $\Delta l = 0$. The fact that the number of shells is completely irrelevant in the computation of geometric boundary observables allows them to be computed very fast.

6.1. *Angles*

The shape of the tetrahedra in twisted geometry is measured by the angle operator:

$$A_{ab}|i_\pm\rangle = \cos(\theta_{ab})|i_\pm\rangle \tag{17}$$

which is interpreted as the cosine of the external dihedral angle between the faces a and b of the tetrahedron defined on the nodes $\pm$. The spinnetwork basis states diagonalize the dihedral angle θ_{ab} between faces a and b. The equation for measuring the dihedral angle $\cos(\theta_{ab})$ of $|i_\pm\rangle$ in terms of intertwiner spin $i_\pm$ was derived in[49] and it reads:

$$\cos(\theta_{ab}) = \frac{i_+(i_+ + 1) - j_a(j_a + 1) - j_b(j_b + 1)}{2\sqrt{j_a(j_a + 1)j_b(j_b + 1)}}. \tag{18}$$

We consider the expectation value (16) of the angle operator (17) in any of the two (equal) boundary regular tetrahedra of the triangulation using the spinnetwork state. According to the recoupling basis (j_1, j_2), we focus on the angle between faces 1 and 2. The expectation value can be computed as:

$$\frac{\langle W|A_{12}|W\rangle}{\langle W|W\rangle} = \frac{\sum\limits_{i_\pm} [W(j, i, K)]^2 \cos(\theta_{12})}{\sum\limits_{i_\pm} [W(j, i, K)]^2}. \tag{19}$$

Carrying out the numerical computation of (19), we obtain a value that is in agreement with the geometric value of the external angle of a regular tetrahedron up to the tenth significant digit, as shown in Figure 8. This is consistent with the fact that we are looking at the only angle which is completely sharp, while the others turn out to be spread. In fact, according to the Heisenberg uncertainty principle, since different angle operators do not commute, only one of the dihedral angles can be determined. We also analyzed the boundary states of the self-energy amplitude by using the Livine-Speziale coherent intertwiners, which allow to define a superposition of spin-network states peaked on a classical geometry with minimal

[j] At least for the ones that we computed.

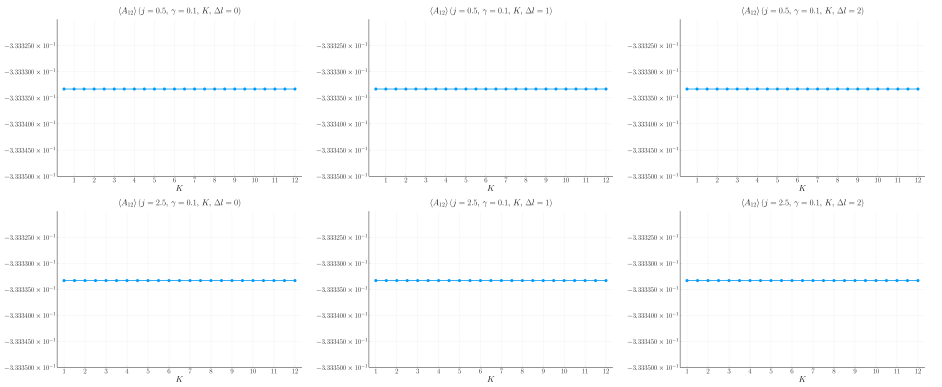

Fig. 8. Dynamic expectation value of the cosine of the external dihedral angle operator (19). We plot the angle for different values of Δl, showing that an excellent agreement with the value $-0.\bar{3}$ is obtained with the approximation $\Delta l = 0$. We used $\gamma = 0.1$.

spread. A wave packet peaked on a classical triangulated geometry, that can be viewed as a coherent state in the Hilbert space (1), is obtained by combining coherent intertwiners at each node. In this case, all the dihedral angles are minimally spread around the classical values, and this is exactly what we verify numerically. The plots obtained are qualitatively identical to those in Figure 8, except that the computed value of the angle is approximately[k] that of the external dihedral angle of a regular tetrahedron. This is due to the fact that the square modulus of the coefficients of the coherent states, in the spin-intertwiner basis, turns out to be a a distribution centered around the value of the intertwiner which determines the semiclassical value of the dihedral angle, and the width of the distribution is much higher as the spins are low. For the computation of the volumes, we refer to.[1]

7. Conclusions

I have presented the application[1] of new computational techniques applied to the study of the infrared divergence represented by the self-energy EPRL amplitude. The divergence scaling obtained falls within the upper and lower bounds in the literature. Particular emphasis was placed on the role of the Immirzi parameter in the asymptotic divergence. I presented the extrapolation method introduced to overcome the computational cost represented by the convergence in the shell parameter Δl, which can potentially be used in other contexts. The analysis of the boundary angles shows that the latter are finite and consistent with classical geometry, despite the divergence in the bulk, and that the approximation represented by the shells does not play any relevant role in the dynamical expectation values of the latter.

[k] Up to the first 2 significant digits.

We thank all the collaborators of this work, in particular Francesco Gozzini, without whom this would not have been possible, as well as Carlo Rovelli for useful discussions and comments. I explicitly thank my supervisor Francesca Vidotto for the constant support and for an accurate review in the drafting of this paper. I also thank Pietro Dona for countless contributions in various stages of.[1] Finally, we also thanks the Compute Canada staff for their help in using the Graham and Cedar clusters. This work is supported by the NSERC Discovery Grant.

A spin foam framework for the black-to-white hole transition

Farshid Soltani

Department of Physics and Astronomy, The University of Western Ontario, London, Ontario N6A 3K7, Canada
E-mail: fsoltan2@uwo.ca

Black holes formation and evolution have been extensively studied at the classical level. However, not much is known regarding the end of their lives, a phase that requires to consider the quantum nature of the gravitational field. A black-to-white hole transition can capture the physics of this phenomenon, in particular the physics of the residual small black holes at the end of the Hawking evaporation. This work shows how the spin foam formalism is able to describe this non-perturbative phenomenon. A thorough examination of the black hole spacetime region in which quantum effects cannot be neglected indicates that the scenario in which the black hole geometry undergoes a quantum transition in a white hole geometry is natural and conservative. This quantum transition is then studied using the spin foam formalism and the resulting transition amplitude is explicitly computed.

Keywords: Black holes, white holes, black-to-white hole transition, loop quantum gravity, spin foam formalism.

1. Introduction

The exterior region of a black hole is described extraordinarily well by general relativity. Its interior region, on the other hand, is not and it is thus not known what happens inside a black hole. The reason for this breakdown of predictability is the presence of a spacetime singularity in the interior of a black hole: since the quantum nature of the gravitational field cannot be neglected in the vicinity of a spacetime singularity, the classical theory cannot be trusted in this region. Although effective black hole models exhibiting a non-singular interior have been extensively studied in the literature, a non-singular black hole interior consisting of a black hole geometry that undergoes a quantum transition in a white hole geometry was proposed for the first time in Ref. 1.

A different open question concerning black holes is what happens at the end of their life. Working in semiclassical gravity, Hawking[2] famously showed that black holes evaporate and are thus not eternal. However, since the quantum nature of the gravitational field near the horizon can no longer be neglected when the horizon reaches Planckian size (or possibly even before then[1]), the end of the evaporation process of a black hole is a quantum gravity phenomenon. A very natural and conservative scenario for the end of the life of a black hole is the black-to-white hole transition.

The aim of this work is to report in a concise and coherent fashion the results obtained in Refs. 3 and 4. The black hole spacetime region in which quantum effects cannot be neglected is analyzed in detail and it is shown to be actually composed of three physically independent subregions, with one of them being a region surrounding the black hole horizon at the end of the evaporation process. As a consequence, the last stage of the life of a black hole can be studied focusing solely on this region. Independent analyses of the three separate quantum regions consistently point toward a black-to-white hole transition. The last stage of the life of a black hole in this scenario, that is the quantum region where the black hole horizon undergoes a quantum transition in a white hole horizon, is then studied using the spin foam formalism[5,6] (also known as covariant loop quantum gravity) and a concrete spin foam framework for the black-to-white hole transition is developed.

The discussion is here limited to the case of a Schwarzschild black hole. See however Ref. 7 for a generalization of the black-to-white hole geometry to the case of a charged black hole.

2. The three quantum regions of a black hole spacetime

The conformal diagram of the spacetime describing the formation of a black hole by gravitationally collapsed matter and its subsequent evaporation is reported in Fig. 1. The light grey region represents the interior of the collapsing matter, the dashed line represents the apparent horizon of the black hole and the dark grey region represents the spacetime region where the quantum nature of the gravitational field cannot be neglected and where consequently the classical (or semiclassical) theory can no longer be trusted.

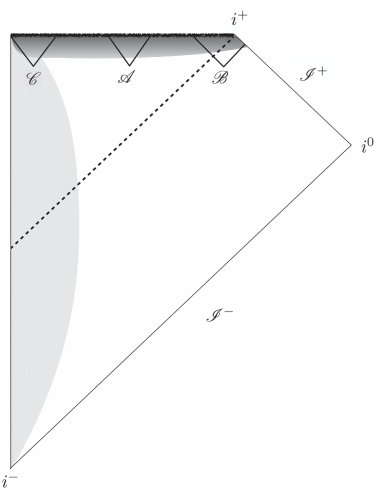

Fig. 1. Conformal diagram of the spacetime describing the formation of a black hole by gravitationally collapsed matter and its subsequent evaporation.

The quantum region can be divided[8] in three different subregions: region $\mathscr{C}$, where the collapsing matter reaches Planckian density; region $\mathscr{B}$, where the horizon reaches Planckian size at the end of the evaporation process; region $\mathscr{A}$, where the curvature reaches Planckian scale but the spacetime events belong neither to region $\mathscr{B}$ nor to region $\mathscr{C}$. In order to prove that these subregions are physically independent from each other, it is sufficient to show that their spatial separation is considerable. In the classical theory the principle of locality assures that two events whose separation is spacelike and significant cannot be causally connected. Furthermore, although the quantum theory may alter the causal structure of spacetime, quantum fluctuations cannot causally connect widely spacelike-separated events.

A rough estimate of the distance $d_{\mathscr{B}C}$ between regions $\mathscr{B}$ and $\mathscr{C}$ is[3]

$$d_{\mathscr{B}C} \sim \ell_{\mathrm{Pl}} \left(\frac{m_0}{m_{\mathrm{Pl}}}\right)^{\frac{10}{3}}, \tag{1}$$

where m_0 is the initial mass of the black hole before the start of the evaporation process and $\ell_{\mathrm{P}l}$ and $m_{\mathrm{P}l}$ are respectively the Planck length and the Planck mass. For a stellar black hole this distance is

$$d_{\mathscr{B}C}\big(m_0 = M_\odot\big) \sim 10^{75} \text{ light years}. \tag{2}$$

Regions $\mathscr{B}$ and $\mathscr{C}$ are thus spacelike separated and considerably distant from each other. It follows that regions $\mathscr{B}$ and $\mathscr{C}$ are physically independent from each other and they can thus be studied separately. Furthermore, since region $\mathscr{A}$ contains spacetime events that are physically independent from region $\mathscr{B}$ as well as spacetime events that are physically independent from region $\mathscr{C}$, the physics of region $\mathscr{A}$ must be independent from the physics of both region $\mathscr{B}$ and region $\mathscr{C}$. However, since region $\mathscr{A}$ contains spacetime events that are causally connected to region $\mathscr{B}$ as well as spacetime events that are causally connected to region $\mathscr{C}$, the physics of both region $\mathscr{B}$ and region $\mathscr{C}$ depend on the physics of region $\mathscr{A}$. These three quantum regions will be now analyzed separately.

2.1. *Region* $\mathscr{A}$

Since the physics of region $\mathscr{A}$ does not depend on the quantum gravity regime of the collapsing matter (region $\mathscr{C}$) or on the last stage of the life of the black hole (region $\mathscr{B}$), it can be studied in the context of an eternal (Schwarzschild) black hole.

The effort to understand the physics of region $\mathscr{A}$ has led to the development of several effective models (see Refs. 9–11 and references therein) that describe the internal region of an eternal black hole using techniques developed in the framework of loop quantum cosmology. Although the specifics of these models are different, they all exhibit a regular interior region where the trapped region of the black hole makes a smooth transition in an anti-trapped region bounded by a future horizon describing the interior of a white hole. This result, besides supporting the conjecture that classical curvature singularities are not a true physical prediction of the theory

but rather an indication that the classical theory can no longer be trusted, is the first evidence suggesting a black-to-white hole transition.

Interestingly, a hint of the same result can be found also at the classical level. It can indeed be shown[12,13] that, using specific coordinate systems, the geodesics in the interior region of a black hole can be naturally continued across the curvature singularity into the interior region of a white hole. The resulting geometry is still singular, but now it is geodesically complete and it can be interpreted as the classical limit of the quantum geometry of the effective models.

2.2. *Region* $\mathscr{C}$

The physics of region $\mathscr{C}$ is independent from the physics of region $\mathscr{B}$ and it can thus be studied neglecting the evaporation process of the black hole. However, it is not independent from the physics of region $\mathscr{A}$ and its analysis must be consistent with the scenario emerging from the investigation of region $\mathscr{A}$.

The study of the classical physics of the collapsing matter is a hard task. The analysis of its quantum gravity regime is even trickier. In Ref. 14 it was hypothesized that, in analogy with the cosmological singularity resolution in loop quantum cosmology,[15] the collapsing matter bounces due to a quantum-gravitational repulsion effect. This possibility, that will be assumed to accurately represent the physics of region $\mathscr{C}$ in the following, is consistent with the physics of region $\mathscr{A}$. A qualitative conformal diagram of the spacetime emerging from this partial analysis (region $\mathscr{B}$ still needs to be discussed) can be found in Fig. 2(a).

This scenario is further corroborated by several independent quantum descriptions of the phenomenon (see e.g. Refs. 16–19). Although these models use different techniques and focus on different aspects of the phenomenon, they all predict that the collapsing matter undergoes a bounce. This is a strong indication of the general validity of the scenario.

2.3. *Region* $\mathscr{B}$

The conformal diagram in Fig. 2(a) represents the black hole spacetime that emerges taking into account the quantum physics of regions $\mathscr{A}$ and $\mathscr{C}$. It is however immediate to see that this spacetime does not represent properly the physics of region $\mathscr{B}$. While the black hole evaporation process takes a finite amount of time to shrink the horizon to the Planck scale, in Fig. 2(a) region $\mathscr{B}$ is reached only asymptotically. The physics of region $\mathscr{B}$ thus need to be properly modified whilst remaining consistent with the scenario emerging from regions $\mathscr{A}$ and $\mathscr{C}$.

A scenario that is often considered for the end of the life of a black hole is the complete evaporation of the black hole. Having spent time investigating regions $\mathscr{A}$ and $\mathscr{C}$ separately, it is now easy to see that a complete evaporation of the black hole, besides being an ad hoc assumption with no foundation in any quantum gravity model, is hardly consistent with the global picture of the spacetime in Fig. 2(a).

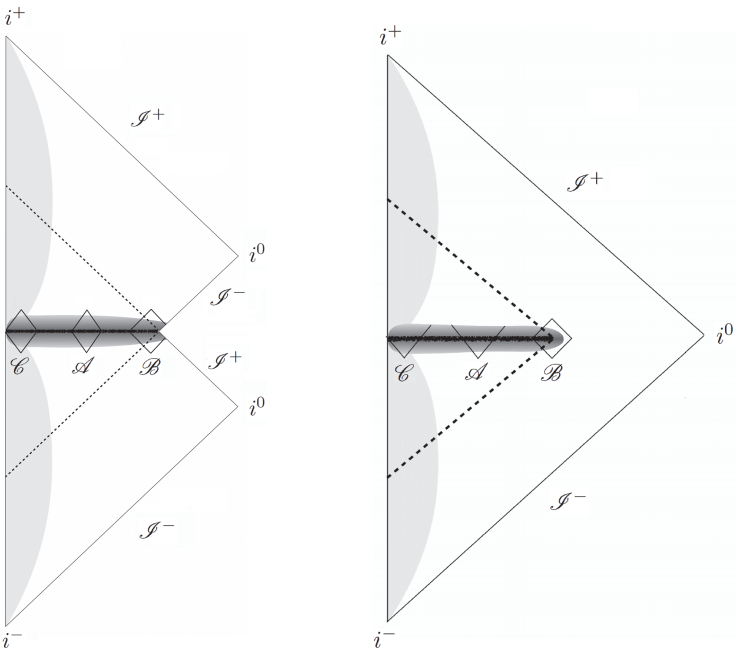

Fig. 2. (a) Qualitative conformal diagram of the black hole spacetime emerging from the analysis of regions $\mathscr{A}$ and $\mathscr{C}$. (b) Conformal diagram of the spacetime describing the black-to-white hole transition.

The most natural and conservative scenario for the end of the life of a black hole consistent with the physics of region $\mathscr{A}$ and region $\mathscr{C}$ is a quantum transition of the black hole horizon in a white hole horizon. The conformal diagram of the spacetime describing the complete black-to-white hole transition can be found in Fig. 2(b). The purpose of this work is to complete the analysis of region $\mathscr{B}$ by investigating its quantum physics using the spin foam approach.

The conformal diagram in Fig. 2(b) describes a physical phenomenon only if there exists a classical metric that satisfies the Einstein field equations and that covers the whole diagram except for the quantum region. This metric exists and it has been explicitly constructed in Refs. 1, 20, 21. This is an extraordinary result from the point of view of the classical theory and it provides yet another strong evidence in favor of the black-to-white hole transition scenario.

3. The black-to-white hole transition

In order to investigate in detail the physics of region $\mathscr{B}$ of the black-to-white hole spacetime it is necessary to specify its boundary $\Sigma := \partial\mathscr{B}$ and to compute the classical geometry that the black-to-white hole metric induces on it. This boundary

geometry represents the outcome of the quantum transition taking place in region $\mathscr{B}$ and it thus uniquely defines the quantum boundary state for the transition. The boundary Σ can be chosen freely as long as it bounds the entirety of the quantum subregion.

As a first approximation, the presence of the Hawking radiation near region $\mathscr{B}$ is neglected. Its inclusion is left for future work. The metric around region $\mathscr{B}$ is thus taken to be the Schwarzschild metric up to quantum corrections from region $\mathscr{A}$. The main quantum correction that the physics of region $\mathscr{A}$ induces on the boundary between regions $\mathscr{A}$ and $\mathscr{B}$ is the absence of the classical singularity. The black hole interior can be foliated with surfaces of topology $S^2 \times \mathbb{R}$. If one angular dimension is suppressed, these surfaces can be seen as long cylinders of different radii and heights. Closer is the singularity, smaller is the radius of the cylinder. In the classical theory the foliation ends at the singularity, where the cylinder has a null radius. In the quantum theory the cylinder radius shrinks (black hole geometry) until it reaches a minimum value r_* (smooth transition from black to white hole geometry) and then starts to increase again (white hole geometry). The presence of this minimum radius r_* in the effective geometry of region $\mathscr{A}$ has a significant impact on the physics of region $\mathscr{B}$.

Having neglected Hawking radiation, the physics of region $\mathscr{B}$ must be invariant under time-reversal. Accordingly, the boundary Σ can be decomposed as $\Sigma = \Sigma^p \cup \Sigma^f$, where the past surface Σ^p and the future surface Σ^f are equal up to time reflection. This means that to completely define Σ it is sufficient to only specify Σ^p. A convenient choice of Σ^p is reported in Fig. 3 and it can be constructed as follows. Let S_+ and S_- be the points in the conformal diagram of Schwarzschild spacetime defined by the ingoing Eddington-Finkelstein coordinates $S_+ = (v_+, r_+)$ and $S_- = (v_-, r_-)$. The point S_+ is taken to be on the surface of

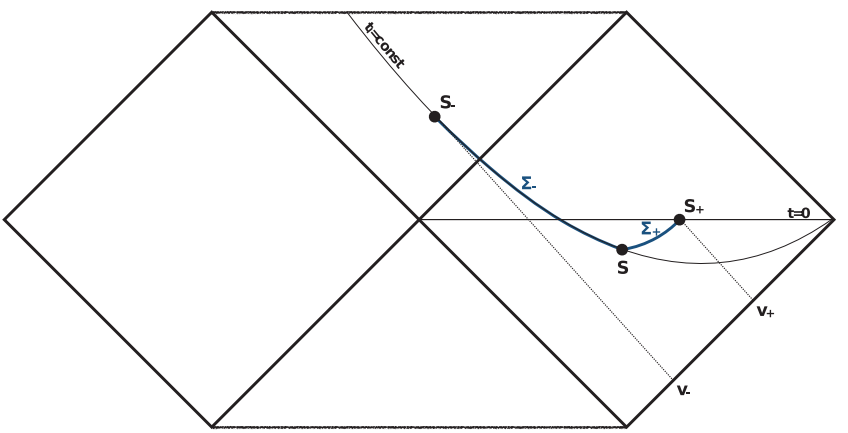

Fig. 3. The past portion $\Sigma^p = \Sigma^p_+ \cup \Sigma^p_-$ of the boundary Σ.

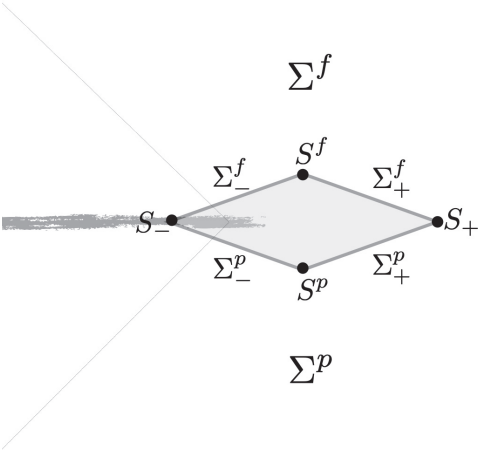

Fig. 4. Portion of the conformal diagram of the black-to-white hole transition depicting region $\mathscr{B}$ and its boundary Σ.

constant Schwarzschild time $t = 0$, thus fixing the value of v_+ in terms of r_+ (or viceversa), and the point S_- is taken to be on the surface of constant Schwarzschild radius $r = r_*$, thus fixing the value of r_- to be the minimum radius r_* characterizing the effective geometry of region $\mathscr{A}$. The values of r_+ and v_- can be chosen freely as long as they define a boundary Σ that bounds the entirety of the quantum subregion. Let then Σ^p_- be the surface of constant Lemaitre time coordinate

$$t_L := t + 2\sqrt{2mr} + 2m \log \left| \frac{\sqrt{r/2m} - 1}{\sqrt{r/2m} + 1} \right| \tag{3}$$

passing by S_-, where m is the mass of the black hole at the moment in which the quantum transition of the horizon takes place, and Σ^p_+ be the surface of equation

$$v - \beta\, r = \text{const}\,, \tag{4}$$

where β is an arbitrary constant in $\mathbb{R}$, passing by S_+. Given the point S^p of their intersection, the past boundary Σ^p is defined to be the union of the portion of the surface Σ^p_- bounded by S_- and S^p and the portion of the surface Σ^p_+ bounded by S_+ and S^p. Requiring the normal to Σ^p to be continuous at S^p uniquely fixes the value of β. The surface Σ^f is defined as the time-reversal of Σ^p. The portion of the conformal diagram of the black-to-white hole transition depicting region $\mathscr{B}$ and its boundary Σ can be found in Fig. 4.

The intrinsic and the extrinsic geometry of Σ^p_+ and Σ^p_- can be straightforwardly computed from their definition. The line element $\mathrm{d}s^2_+$ on Σ^p_+ reads

$$\mathrm{d}s^2_+ = \beta \left(2 - \beta\Big(1 - \frac{2m}{r}\Big)\right) \mathrm{d}r^2 + r^2\, \mathrm{d}\Omega^2 \tag{5}$$

and the line element $\mathrm{d}s^2_-$ on Σ^p_- reads

$$\mathrm{d}s^2_- = \mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2\,, \tag{6}$$

where $\mathrm{d}\Omega^2$ is the line element of the two-sphere. Let $k^\pm_{ij}$ be the extrinsic curvature tensor of $\Sigma^p_\pm$. Then it can be shown that

$$k_+ := k^+_{ij}\,\mathrm{d}x^i\,\mathrm{d}x^j = \frac{m\beta^{3/2}(r(3-\beta)+2m\beta)}{\sqrt{r^5(r(2-\beta)+2m\beta)}}\,\mathrm{d}r^2 - \frac{r(1-\beta)+2m\beta}{\sqrt{\beta(2-(1-2m/r)\beta)}}\,\mathrm{d}\Omega^2 \tag{7}$$

and

$$k_- := k^-_{ij}\,\mathrm{d}x^i\,\mathrm{d}x^j = \frac{m}{2r^3}\,\mathrm{d}r^2 - \sqrt{2mr}\,\mathrm{d}\Omega^2\,, \tag{8}$$

where x^i, $i = 1, 2, 3$, are coordinates on Σ^p.

The geometry of Σ is thus completely determined by four parameters: the mass m of the black hole at the moment in which the quantum transition of the horizon takes place; the external asymptotic (retarded) time $v = v_+ - v_-$ it takes for the transition to happen; the minimal external radius r_+ for which the classical theory can still be trusted; the minimal internal radius r_- (it is important to stress that r is a temporal coordinate in the interior region of the black hole) reached by the black hole interior in region $\mathscr{A}$.

Each set of data $\big(m,\, v,\, r_\pm\big)$ corresponds to a different outcome of the quantum transition taking place in region $\mathscr{B}$. This means that each set of data $\big(m,\, v,\, r_\pm\big)$ uniquely defines a different quantum boundary state $\Psi\big(m,\, v,\, r_\pm\big)$ for the transition. Given the boundary state Ψ, any sufficiently developed tentative theory of quantum gravity should be able to assign a transition amplitude $W\big(m,\, v,\, r_\pm\big) \equiv W\Big[\Psi\big(m,\, v,\, r_\pm\big)\Big]$ to it. The transition amplitude for the phenomenon can then be used to analyze the physics of region $\mathscr{B}$.

The next section is devoted to the computation of the transition amplitude $W\big(m,\, v,\, r_\pm\big)$ for the black-to-white hole transition using the spin foam approach.

4. Spin foam framework

The spin foam formalism[5,6] is a tentative path integral quantization of general relativity. The current state of the art is the EPRL-KKL spin foam model.[22–24] The theory is regularized and concretely defined in the discrete setting. The boundary Σ of a generic quantum region is discretized by a graph Γ with a finite number of nodes and a boundary Hilbert space $\mathcal{H}_\Gamma$ is assigned to it. The latter is the space of SU(2) spin-networks on Γ. Namely, the boundary Hilbert space is $\mathcal{H}_\Gamma := L^2\big[\mathrm{SU}(2)^L/\mathrm{SU}(2)^N\big]_\Gamma$, where N and L are respectively the total number of nodes and links in Γ. A boundary state is then given by a square integrable function $\psi(\{h_\ell\})$ that is gauge invariant at every node $\mathrm{n} \in \Gamma$. Each $h_\ell \in \mathrm{SU}(2)$ can be seen as the holonomy of the Ashtekar-Barbero connection along the link $\ell \in \Gamma$. The interior of the quantum region is then discretized by a two-complex $\mathcal{C}$ ($\partial\mathcal{C} \equiv \Gamma$) with a finite number of vertices.

Let f, e, v $\in \mathcal{C}$ denote respectively a face, an edge and a vertex in $\mathcal{C}$. To each internal oriented edge $\mathcal{C} \ni \mathrm{e} := (\mathrm{v}, \mathrm{v}')$ having source in v and target in v′ are assigned two $\mathrm{SL}(2,\mathbb{C})$ elements $g_{\mathrm{ve}} = g_{\mathrm{ev}}^{-1}$ and $g_{\mathrm{ev}'} = g_{\mathrm{v}'\mathrm{e}}^{-1}$. The oriented edge $\mathrm{e}^{-1} := (\mathrm{v}', \mathrm{v})$ is the edge e with opposite orientation. To each boundary edge $\mathrm{E} \in \mathcal{C}$, that is an edge linking an internal vertex $\mathrm{v} \in \mathcal{C}$ and a node $\mathrm{n} \in \Gamma$, is assigned an $\mathrm{SL}(2,\mathbb{C})$ element $g_{\mathrm{vn}} = g_{\mathrm{nv}}^{-1}$. A face $\mathrm{f} := (\mathrm{e}_1, \dots, \mathrm{e}_n)$ is the oriented face bounded by the edges $\mathrm{e}_1, \dots, \mathrm{e}_n$. The orientation of the face is given by the ordering of the edges. For easier reading, the latters are written oriented accordingly to the orientation that the face induces on them. An internal face $\mathrm{f} \in \mathcal{B} := \mathcal{C}/\Gamma$ is a face bounded by vertices and internal edges. A boundary face $\mathrm{F} \in \Gamma$ is a face containing a link $\ell \in \Gamma$ in its boundary. Finally, a face $\mathrm{f} \ni \mathrm{e}$ is a face f containing the edge e in its boundary, a face $\mathrm{f} \ni \mathrm{v}$ is a face f containing the vertex v in its boundary and an edge $\mathrm{e} \ni \mathrm{v}$ is an edge e containing the vertex v in its boundary.

Given an arbitrary boundary state $\psi \in \mathcal{H}_\Gamma$, the theory assigns to it the amplitude

$$W_{\mathcal{C}}[\psi] = \int_{\mathrm{SU}(2)} \prod_{\ell\in\Gamma} \mathrm{d}h_\ell \, W_{\mathcal{C}}\big(\{h_\ell\}\big)\, \psi\big(\{h_\ell\}\big)\,, \tag{9}$$

where the two-complex amplitude $W_{\mathcal{C}}(\{h_\ell\})$ can be defined in terms of elementary face amplitudes as

$$W_{\mathcal{C}}\big(\{h_\ell\}\big) = \int_{\mathrm{SL}(2,\mathbb{C})} \Big[\prod_{\mathrm{v}\in\mathcal{C}} \prod_{\mathrm{e}\ni\mathrm{v}}{}' \mathrm{d}g_{\mathrm{ve}}\Big] \Big[\prod_{\mathrm{f}\in\mathcal{B}} A_{\mathrm{f}}\big(\{g_{\mathrm{ve}}\}\big)\Big] \Big[\prod_{\mathrm{F}\in\Gamma} A_{\mathrm{F}}\big(\{g_{\mathrm{ve}}\}, h_{\ell_{\mathrm{F}}}\big)\Big]\,. \tag{10}$$

The product $\prod'_{\mathrm{e}\ni\mathrm{v}}$ stands for the product over all the edges $\mathrm{e} \ni \mathrm{v}$ except one (which can be chosen arbitrarily at each vertex), ℓ_{F} is the unique link in Γ that belongs to the boundary face $\mathrm{F} \in \Gamma$ and the face amplitudes $A_{\mathrm{f}}(\{g_{\mathrm{ve}}\})$ and $A_{\mathrm{F}}(\{g_{\mathrm{ve}}\}, h_{\ell_{\mathrm{F}}})$ are given by[a]

$$A_{\mathrm{f}}\big(\{g_{\mathrm{ve}}\}\big) := \sum_{j_{\mathrm{f}}} d_{j_{\mathrm{f}}} \mathrm{Tr}\Big[D_\gamma^{(j_{\mathrm{f}})}\big(g_{\mathrm{ev}} g_{\mathrm{ve}'}\big) \cdots D_\gamma^{(j_{\mathrm{f}})}\big(g_{\mathrm{e}^{(n)}\mathrm{v}^n} g_{\mathrm{v}^{(n)}\mathrm{e}}\big)\Big]\,, \tag{11}$$

$$A_{\mathrm{F}}\big(\{g_{\mathrm{ve}}\}, h_{\ell_{\mathrm{F}}}\big) := \sum_{j_{\mathrm{F}}} d_{j_{\mathrm{F}}} \mathrm{Tr}\Big[D_\gamma^{(j_{\mathrm{F}})}\big(g_{\mathrm{n}_t\mathrm{v}} g_{\mathrm{ve}'}\big) \cdots D_\gamma^{(j_{\mathrm{F}})}\big(g_{\mathrm{e}^{(n)}\mathrm{v}^n} g_{\mathrm{v}^{(n)}\mathrm{n}_s}\big) D^{(j_{\mathrm{F}})}\big(h_{\ell_{\mathrm{F}}}\big)\Big]\,. \tag{12}$$

The matrix $D^{(j)}$ is the Wigner D-matrix of the d_j-dimensional ($d_j = 2j+1$) representation of SU(2). The matrix $D_\gamma^{(j)}$ is the $d_j \times d_j$ matrix $\big[D_\gamma^{(j)}\big]_{mn}(g) = D^{(\gamma j,j)}_{jm\,jn}(g)$, $g \in \mathrm{SL}(2,\mathbb{C})$, where $D^{(\rho,k)}_{lm\,jn}$ are the matrix elements of the (ρ,k) unitary representation of the principal series of $\mathrm{SL}(2,\mathbb{C})$ in the basis labeled by the eigenfunctions of L^2 and L_z. The nodes n_s and n_t are respectively the source and the

[a]For the sake of simplicity, the orientation of every edge in each face is assumed to be the one induced from the face orientation. Since however this kind of orientation cannot be implemented consistently throughout the whole two-complex, in actual computations the orientation of the edges needs to be taken into account properly.

target of the link ℓ_{F} and γ is the Barbero-Immirzi parameter. The value of the label (n) in $\mathrm{v}^{(n)}$ and $\mathrm{e}^{(n)}$ is fixed for each face by the topology of the two-complex $\mathcal{C}$.

4.1. *Discretization of region $\mathscr{B}$*

In order to exploit the spin foam formalism to analyze the physics of region $\mathscr{B}$, the latter needs to be properly discretized. There is no unique or right way to perform the discretization. However, in order to get simpler and clearer calculations throughout the spin foam analysis it is particularly useful to preserve as much symmetries as possible during the procedure. In this subsection the combinatorial definition of both the cellular decomposition discretizing region $\mathscr{B}$ and its dual two-complex are given. Although the combinatorial definition of these objects is compact and complete, it does not convey as much geometrical insight as graphical representations do. For this reason, the interested reader is strongly encouraged to look at the graphical representations reported in Refs. 3 and 4.

As it can be seen from Fig. 4, the topology of region $\mathscr{B}$ is $S^2 \times [0,1] \times [0,1]$ and the topology of Σ is $S^2 \times S^1$. The geometry of Σ has two symmetries: the spherical SO(3) symmetry and the Z_2 time-reversal symmetry that exchanges p and f. There is also an additional topological Z_2 symmetry that exchanges $+$ and $-$. Since however the geometry of S_+ and S_- is different, this is not a symmetry of the geometry of Σ. Although the topology of Σ is not easy to discretize while preserving its symmetries, the discretization presented in this subsection is able to accomplish this task.

Before introducing the discretization, it is useful to fix some notational conventions. Let a, b, c, d be indices taking values in the set $\{1,2,3,4\}$, t be an index taking values in the set $\{p,f\}$ and ϵ be an index taking values in the set $\{+,-\}$. If the same expression contains several indices a, b, c, d, they are assumed to be all different from each other. The order of two consecutive indices is not important and the exchange of these indices results in the same element. If however two indices are separated by a comma, the exchange of these indices results in a different element.

Let p_a^+ be four points on S_+ and p_a^- be four points on S_-. The three-dimensional triangulation discretizing Σ is then defined by the points p_a^ϵ, the segments s_{ab}^ϵ and $s_{a,b}^t$, the triangles L_a^ϵ and $L_{a,b}^{t\epsilon}$, the tetrahedra $N_a^{t\epsilon}$ and N_{ab}^t, and their boundary relations:

$$\partial s_{ab}^\epsilon = (p_a^\epsilon, p_b^\epsilon); \tag{13}$$

$$\partial s_{a,b}^t = (p_a^-, p_b^+)^t; \tag{14}$$

$$\partial L_a^\epsilon = (s_{bc}^\epsilon, s_{cd}^\epsilon, s_{db}^\epsilon); \tag{15}$$

$$\partial L_{a,b}^{t+} = (s_{cd}^+, s_{a,c}^t, s_{a,d}^t); \tag{16}$$

$$\partial L_{a,b}^{t-} = (s_{cd}^-, s_{c,a}^t, s_{d,a}^t); \tag{17}$$

$$\partial N_a^{t\epsilon} = (L_{a,b}^{t\epsilon}, L_{a,c}^{t\epsilon}, L_{a,d}^{t\epsilon}, L_a^\epsilon); \tag{18}$$

$$\partial N_{ab}^t = (L_{a,b}^{t+}, L_{b,a}^{t+}, L_{c,d}^{t-}, L_{d,c}^{t-}). \tag{19}$$

Besides being a three-dimensional object of its own, this triangulation serves as the boundary of the cellular decomposition discretizing region $\mathscr{B}$. This four-dimensional cellular decomposition is defined by the two-dimensional surfaces $f_{a,b}$, the three-dimensional cells $e^{\epsilon}_{a,b}$, the four-dimensional cells v^{ϵ}_{a} and v_{ab}, and their boundary relations:

$$\partial f_{a,b} = (s^{p}_{a,b}, s^{f}_{a,b}); \tag{20}$$

$$\partial e^{\epsilon}_{a,b} = (L^{p\epsilon}_{a,b}, L^{f\epsilon}_{a,b}, f_{a,c}, f_{a,d}); \tag{21}$$

$$\partial v^{\epsilon}_{a} = (N^{p\epsilon}_{a}, N^{f\epsilon}_{a}, e^{\epsilon}_{a,b}, e^{\epsilon}_{a,c}, e^{\epsilon}_{a,d}); \tag{22}$$

$$\partial v_{ab} = (N^{p}_{ab}, N^{f}_{ab}, e^{+}_{a,b}, e^{+}_{b,a}, e^{-}_{c,d}, e^{-}_{d,c}). \tag{23}$$

Note that this cellular decomposition is not a triangulation.

The spin foam formalism is defined using the discrete object dual to the cellular decomposition. The graph Γ dual to the three-dimensional triangulation of Σ is defined as

Nodes
$$\mathrm{n}^{t\epsilon}_{a} \text{ and } \mathrm{n}^{t}_{ab}; \tag{24}$$

Links
$$\ell^{\epsilon}_{a} = (\mathrm{n}^{p\epsilon}_{a}, \mathrm{n}^{f\epsilon}_{a}); \tag{25}$$

$$\ell^{t+}_{a,b} = (\mathrm{n}^{t}_{ab}, \mathrm{n}^{t+}_{a}); \tag{26}$$

$$\ell^{t-}_{a,b} = (\mathrm{n}^{t}_{cd}, \mathrm{n}^{t-}_{a}). \tag{27}$$

The two-complex $\mathcal{C}$, whose boundary $\partial\mathcal{C}$ is Γ, dual to the four-dimensional cellular decomposition of region $\mathscr{B}$ is defined as

Vertices
$$\mathrm{v}^{\epsilon}_{a} \text{ and } \mathrm{v}_{ab}; \tag{28}$$

Edges
$$\mathrm{E}^{t\epsilon}_{a} = (\mathrm{v}^{\epsilon}_{a}, \mathrm{n}^{t\epsilon}_{a}); \tag{29}$$

$$\mathrm{E}^{t}_{ab} = (\mathrm{v}_{ab}, \mathrm{n}^{t}_{ab}); \tag{30}$$

$$\mathrm{e}^{+}_{a,b} = (\mathrm{v}^{+}_{a}, \mathrm{v}_{ab}); \tag{31}$$

$$\mathrm{e}^{-}_{a,b} = (\mathrm{v}^{-}_{a}, \mathrm{v}_{cd}); \tag{32}$$

Faces
$$\mathrm{F}^{\epsilon}_{a} = \left(\ell^{\epsilon}_{a}, (\mathrm{E}^{f\epsilon}_{a})^{-1}, \mathrm{E}^{p\epsilon}_{a}\right); \tag{33}$$

$$\mathrm{F}^{t+}_{a,b} = \left(\ell^{t+}_{a,b}, (\mathrm{E}^{t+}_{a})^{-1}, \mathrm{e}^{+}_{a,b}, \mathrm{E}^{t}_{ab}\right); \tag{34}$$

$$\mathrm{F}^{t-}_{a,b} = \left(\ell^{t-}_{a,b}, (\mathrm{E}^{t-}_{a})^{-1}, \mathrm{E}^{-}_{a,b}, \mathrm{E}^{t}_{cd}\right); \tag{35}$$

$$\mathrm{f}_{a,b} \overset{c\leq d}{=} \left(\mathrm{e}^{+}_{a,c}, (\mathrm{e}^{-}_{b,d})^{-1}, \mathrm{e}^{-}_{b,c}, (\mathrm{e}^{+}_{a,d})^{-1}\right). \tag{36}$$

The orientation of each element of the two-complex can be easily read from this combinatorial definition.

It is interesting to analyze how many of the topological symmetries of region $\mathscr{B}$ are preserved under this discretization. The spherical SO(3) symmetry of region $\mathscr{B}$ is discretized to a tetrahedral symmetry of the two-complex, which is realized as an even permutation of the indices a, b, c, d. The Z_2 time-reversal symmetry that exchanges the indices p and f and the Z_2 symmetry that exchanges the indices $+$ and $-$ are instead preserved exactly.

4.2. *Discrete geometrical data and boundary state*

The continuous geometry of Σ is approximated by the assignment of discrete geometrical data to the triangulation discretizing Σ (or equivalently to is dual graph Γ). There is once again no unique or right way to do it. Different assignments of discrete geometrical data simply define different approximations of the same continuous geometry. The discrete geometry presented in this subsection preserves the two geometrical symmetries of the continuous geometry of Σ.

To preserve the Z_2 time-reversal symmetry is sufficient to firstly construct the discrete geometrical data for the triangulation discretizing Σ^p and then to define the discrete geometrical data for the triangulation discretizing Σ^f as their time reversal. The sphere S_+ (S_-) in Σ is discretized by the tetrahedron bounded by the four triangles $\{L_a^+\}$ ($\{L_a^-\}$) in the triangulation. In order to preserve as much symmetry as possible in the discretization process of the geometry, the same area $a_+ = \pi r_+^2$ ($a_- = \pi r_-^2$), which is one fourth of the area of the sphere S_+ (S_-), is assigned to each triangle L_a^+ (L_a^-).

The continuous intrinsic geometry of Σ^p is specified by the line element

$$\mathrm{d}s^2 = f^2(r)\,\mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2\,, \tag{37}$$

in which $f^2(r) = \beta\left(2 - \beta\,(1 - 2m/r)\right)$ on Σ_+^p and $f^2(r) = 1$ on Σ_-^p. To begin with, this line element is approximated with

$$\mathrm{d}s^2 = \xi^2\,\mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2\,, \tag{38}$$

where ξ is a constant that is fixed by requiring the volume of Σ^p computed with the line element in Eq. (38) to coincide with the volume of Σ^p computed with the line element in Eq. (37). This condition uniquely fixes the value of ξ in terms of the four parameters $\left(m,\, v,\, r_\pm\right)$ characterizing the continuous geometry of Σ^p. Requiring the discrete geometrical data to preserve the topological tetrahedral symmetry of the triangulation of Σ, the same area A_+ (A_-) must be assigned to each triangle $L_{a,b}^{p+}$ ($L_{a,b}^{p-}$). The line element in Eq. (38) is then used to compute the value of $A_\pm$, which is

$$A_\pm = \pi r_\pm^2 \sqrt{\frac{\xi^2}{18}\Big(1 - 3\,\frac{r_\mp}{r_\pm}\Big)^2 + \frac{2}{3}}\,. \tag{39}$$

The symmetry conditions together with the values of the areas $a_\pm$ and $A_\pm$ completely define the discrete intrinsic geometry of the triangulation of Σ. Analogously, the discrete extrinsic geometry of the triangulation is completely defined by the assignment of the extrinsic angles $\theta_\pm$ between $N_a^{p\pm}$ and $N_a^{f\pm}$ at $L_a^\pm$ and the extrinsic angles $\Theta_\pm$ between $N_a^{p\pm}$ and $N_{a,b}^p$ at $L_{a,b}^{p\pm}$.

Let $n_\mu^{t\epsilon}$ be the normal one-form of Σ_ϵ^t. From the definition of $\theta_\pm$ it follows that

$$\cos(\theta_\pm) = \Big(\, g^{\mu\nu}\, n_\mu^{f\,\pm}\, n_\nu^{p\,\pm}\,\Big)\Big|_{S_\pm}\,, \tag{40}$$

where $g^{\mu\nu}$ is the inverse of the metric tensor defined by the line element in Eq. (37), giving

$$\cos(\theta_+) = \frac{1 + \Big[\big(1 - 2m/r_+\big)\,\beta - 1\Big]^2}{\big|\,\beta\,\big(\,\beta - 2 - 2m\beta/r_+\big)\big|\,\big(1 - 2m/r_+\big)} \tag{41}$$

and

$$\cos(\theta_-) = \frac{1 + 2m/r_-}{1 - 2m/r_-}\,. \tag{42}$$

The angles $\Theta_\pm$ represent a discrete approximation of the continuous extrinsic curvature of $\Sigma_\pm$. A convenient discretization that preserves the symmetries of the triangulation is

$$\Theta_\pm = \frac{1}{12}\int_{\Sigma^p_\pm} \big(k^\pm\big)^i{}_i\,, \tag{43}$$

where $k^\pm_{ij}$ is the extrinsic curvature tensor of $\Sigma^p_\pm$ defined in Eqs. (7) and (8).

The discrete geometry of the triangulation of Σ has thus been explicitly constructed in terms of the four parameters $\big(m,\, v,\, r_\pm\big)$ characterizing the continuous geometry of Σ. From the point of view of the dual graph Γ, the discrete geometry consists in the assignment of an area and an angle to each link of Γ. The area assigned to each link represents the area of the triangle that is dual to the link and the angle assigned to each link represents the extrinsic curvature between the two tetrahedra that share the triangle dual to the link. This geometrical data uniquely specifies an extrinsic coherent state[5] $\Psi_{BW} = \Psi_{BW}\big(a_\pm,\, \theta_\pm,\, A_\pm,\, \Theta_\pm\big) = \Psi_{BW}\big(m,\, v,\, r_\pm\big) \in \mathcal{H}_\Gamma$ that is peaked on the discrete classical geometry defined by $\big(a_\pm,\, \theta_\pm,\, A_\pm,\, \Theta_\pm\big)$. The boundary state $\Psi_{BW} \in \mathcal{H}_\Gamma$ is the quantum state representing the outcome of the transition taking place in region $\mathscr{B}$.

4.3. *Transition amplitude*

Having explicitly constructed the two-complex discretizing region $\mathscr{B}$ and the boundary state describing the outcome of the quantum transition, the spin foam transition amplitude for the black-to-white hole transition can be readily computed using the formulas in Eqs. (9) and (10).

The assignment of group elements to the edges and the links of the two-complex $\mathcal{C}$ is:

$$\ell^\epsilon_a \longleftrightarrow h^\epsilon_a \in \mathrm{SU}(2)\,; \tag{44}$$

$$\ell^{t\epsilon}_{a,b} \longleftrightarrow h^{t\epsilon}_{a,b} \in \mathrm{SU}(2)\,; \tag{45}$$

$$\mathrm{E}^{t\epsilon}_a \longleftrightarrow g^{t\epsilon}_a \in \mathrm{SL}(2,\mathbb{C})\,; \tag{46}$$

$$\mathrm{E}^t_{ab} \longleftrightarrow g^t_{ab} \in \mathrm{SL}(2,\mathbb{C})\,; \tag{47}$$

$$\mathrm{e}^\epsilon_{a,b} \longleftrightarrow g^\epsilon_{a\to b}\,,\; g^\epsilon_{a\leftarrow b} \in \mathrm{SL}(2,\mathbb{C})\,. \tag{48}$$

The group elements $g^{\epsilon}_{a\leftrightarrow b}$ are assigned to the two oriented half-edges of $\mathrm{e}^{\epsilon}_{a,b}$. The element $g^{\epsilon}_{a\to b}$ is assigned to the oriented half-edge with source in the source of $\mathrm{e}^{\epsilon}_{a,b}$ and target in the center of $\mathrm{e}^{\epsilon}_{a,b}$. The element $g^{\epsilon}_{a\leftarrow b}$ is assigned to the oriented half-edge with source in the target of $\mathrm{e}^{\epsilon}_{a,b}$ and target in the center of $\mathrm{e}^{\epsilon}_{a,b}$. Carefully considering the topology and the orientation pattern of the two-complex, the elementary face amplitudes (see Eqs. (11) and (12)) for $\mathcal{C}$ can be computed:

$$A^{\epsilon}_{a}\big(\{g^{t\epsilon}_{a}\},\, h^{\epsilon}_{a}\big) = \sum_{j} d_j \,\mathrm{Tr}\Big[D^{(j)}_{\gamma}\big(\big(g^{f\epsilon}_{a}\big)^{-1}\, g^{p\epsilon}_{a}\big)\, D^{(j)}\big(h^{\epsilon}_{a}\big)\Big], \tag{49}$$

$$\begin{aligned} A^{t+}_{a,b}\big(g^{t+}_{a},\, g^{t}_{ab},\, g^{+}_{a\leftrightarrow b}, h^{t+}_{a,b}\big) = \sum_{j} d_j \,\mathrm{Tr}\Big[& D^{(j)}_{\gamma}\big(\big(g^{t+}_{a}\big)^{-1}\, g^{+}_{a\to b}\big) D^{(j)}_{\gamma}\big(\big(g^{+}_{a\leftarrow b}\big)^{-1}\; g^{t}_{ab}\big) \\ & \times D^{(j)}\big(h^{t+}_{a,b}\big)\Big], \end{aligned} \tag{50}$$

$$\begin{aligned} A^{t-}_{a,b}\big(g^{t-}_{a}, g^{t}_{cd}, g^{-}_{a\leftrightarrow b}, h^{t-}_{a,b}\big) = \sum_{j} d_j \,\mathrm{Tr}\Big[& D^{(j)}_{\gamma}\big(\big(g^{t-}_{a}\big)^{-1}\, g^{-}_{a\to b}\big) D^{(j)}_{\gamma}\big(\big(g^{-}_{a\leftarrow b}\big)^{-1}\; g^{t}_{cd}\big) \\ & \times D^{(j)}\big(h^{t-}_{a,b}\big)\Big], \end{aligned} \tag{51}$$

$$\begin{aligned} A_{a,b}\big(\{g^{+}_{a\leftrightarrow c}\},\, \{g^{-}_{b\leftrightarrow c}\}\big) \overset{c\leq d}{=} \sum_{j} d_j \,\mathrm{Tr}\Big[& D^{(j)}_{\gamma}\big(\big(g^{+}_{a\to d}\big)^{-1}\, g^{+}_{a\to c}\big)\, D^{(j)}_{\gamma}\big(\big(g^{+}_{a\leftarrow c}\big)^{-1}\, g^{-}_{b\leftarrow d}\big) \\ & \times D^{(j)}_{\gamma}\big(\big(g^{-}_{b\to d}\big)^{-1}\, g^{-}_{b\to c}\big)\, D^{(j)}_{\gamma}\big(\big(g^{-}_{b\leftarrow c}\big)^{-1}\, g^{+}_{a\leftarrow d}\big)\Big]. \end{aligned} \tag{52}$$

The two-complex transition amplitude $W_{\mathcal{C}}(\{h_\ell\})$ can then be written as

$$\begin{aligned} W_{\mathcal{C}}\big(\{h^{\epsilon}_{a}\},\, \{h^{t\epsilon}_{a,b}\}\big) = \int_{\mathrm{SL}(2,\mathbb{C})} & \prod_{\epsilon a} \mathrm{d}g^{p\epsilon}_{a} \prod_{a<b} \mathrm{d}g^{p}_{ab} \prod_{\epsilon ab} \mathrm{d}g^{\epsilon}_{a\leftrightarrow b} \\ & \times \prod_{\epsilon a} A^{\epsilon}_{a}\big(\{g^{t\epsilon}_{a}\},\, h^{\epsilon}_{a}\big) \prod_{ab} A_{a,b}\big(\{g^{+}_{a\leftrightarrow c}\},\, \{g^{-}_{b\leftrightarrow c}\}\big) \\ & \times \prod_{tab} A^{t+}_{a,b}\big(g^{t+}_{a},\, g^{t}_{ab},\, g^{+}_{a\leftrightarrow b}, h^{t+}_{a,b}\big) \\ & \times \prod_{tab} A^{t-}_{a,b}\big(g^{t-}_{a}, g^{t}_{cd}, g^{-}_{a\leftrightarrow b}, h^{t-}_{a,b}\big). \end{aligned} \tag{53}$$

Since Eq. (10) dictates to drop one integration per vertex, the integration over the $\{g^{f\epsilon}_{a}\}$ and $\{g^{f}_{ab}\}$ variables has been dropped.

Finally, the black-to-white hole transition amplitude $W\big(m,\, v,\, r_{\pm}\big)$ is

$$\begin{aligned} W\big(m,\, v,\, r_{\pm}\big) = W\big[\Psi_{BW}\big] = \int_{\mathrm{SU}(2)} & \prod_{\epsilon a} \mathrm{d}h^{\epsilon}_{a} \prod_{t\epsilon ab} \mathrm{d}h^{t\epsilon}_{a,b}\; W_{\mathcal{C}}\big(\{h^{\epsilon}_{a}\},\, \{h^{t\epsilon}_{a,b}\}\big) \\ & \times \Psi_{\mathrm{BW}}\big(\{h^{\epsilon}_{a}\},\, \{h^{t\epsilon}_{a,b}\}\big). \end{aligned} \tag{54}$$

This expression contains the whole physics of the phenomenon. Its investigation is currently ongoing and it will be reported elsewhere.

5. Summary and outlook

The quantum region of a black hole spacetime can be divided in three different subregions: region $\mathscr{C}$, where the collapsing matter enters its quantum gravity regime; region $\mathscr{B}$, where the horizon reaches Planckian size at the end of the evaporation process; region $\mathscr{A}$, where the curvature reaches Planckian scale independently from region $\mathscr{B}$ and region $\mathscr{C}$. The principle of locality demands that these regions are independent from each other and that they can subsequently be studied separately. The evidence in favor of the black-to-white hole transition scenario resulting from the separate analysis of the physics of these regions is overwhelming.

Focusing on the black-to-white hole horizon transition in region $\mathscr{B}$, that is the last stage of the life of a black hole in this scenario, the physics of the boundary of the quantum region is completely determined by four parameters: the mass m of the black hole at the moment in which the transition takes place; the external asymptotic (retarded) time v it takes for the transition to happen; the minimal external radius r_+ for which the classical theory can still be trusted; the minimal internal radius r_- reached by the black hole interior in region $\mathscr{A}$.

The spin foam formalism provides a clear framework to study this scenario. However, since the theory is properly defined in the discrete setting, to compute the transition amplitude for the phenomenon the physics of region $\mathscr{B}$ needs to be appropriately discretized. From a practical point of view the discretization needs to be both sufficiently refined to capture the relevant degrees of freedom of the phenomenon and sufficiently simple for the transition amplitude to be explicitly computed and analyzed. In this work a convenient discretization that preserves the symmetries of the continuous geometry is explicitly constructed and the resulting transition amplitude $W\big(m, v, r_\pm\big)$ is computed. Although the two-complex $\mathcal{C}$ discretizing region $\mathscr{B}$ is rather complicated, its high degree of symmetry allows the transition amplitude to be expressed in a remarkably compact way. Due to the severe complexity of spin foam amplitudes, an analytical study of the transition amplitude $W\big(m, v, r_\pm\big)$ for the black-to-white hole transition is not feasible at this point. On the other hand, recent developments[25–28] in the numerical computation of spin foam amplitudes and the high degree of symmetry of the constructed discretization should allow a numerical investigation of the transition amplitude.

In this work the black hole lifetime is assumed to be of the order of the evaporation process (although the constructed framework can describe also smaller timescales). This choice is motivated by the analysis of the black-to-white hole transition performed in Refs. 29 and 30, where, neglecting Hawking radiation, the lifetime of the black hole was estimated to be much longer of the evaporation process, thus proving that the assumption of neglecting Hawking radiation was not justified. However, due to the use of a fairly coarse discretization and of several rough approximations it is unclear whether this result is reliable. Furthermore, recent results[17] seems to support the black hole lifetime of the order m_0^2 heuristically suggested in Ref. 1. The numerical analysis of the transition amplitude $W\big(m, v, r_\pm\big)$

computed in this work may provide an estimation of the black-to-white hole transition timescales and improve the understanding of its phenomenology.[31–34]

Holographic properties of the bulk-to-boundary transmission of information in regions of quantum space

Eugenia Colafranceschi
School of Mathematical Sciences, University of Nottingham, Nottingham NG7 2RD, United Kingdom
E-mail: eugenia.colafranceschi@nottingham.ac.uk

We show that quantum gravity states associated to open spin network graphs implicitly define maps from the bulk to the boundary of the corresponding region of quantum space. Employing random tensor network techniques, we then investigate under which conditions the flow of information from the bulk to the boundary is an isometric map, which is a necessary condition for holography.

Keywords: Holography; Spin Networks; Random Tensor Networks.

1. Introduction

Over the past two decades, quantum information has been playing an increasingly prominent role in quantum gravity.[1] A crucial factor in this is the relation between entanglement and geometry, which has been highlighted by various results in different quantum gravity contexts. As an example, within the AdS/CFT correspondence,[2] which describes quantum gravity in asimptotically anti-de Sitter (AdS) spacetime in terms of a conformal field theory (CFT) living on its boundary, the Ryu-Takayanagi (RT) formula[3,4] relates the entanglement entropy of the boundary CFT in a subregion to the area of a codimension-2 surface in the dual bulk spacetime. The entanglement-geometry relation pointed out by the RT formula is further strengthened by the observation that entanglement (of boundary degrees of freedom) is a necessary condition for the connectivity of the dual spacetime.[5,6] More generally, quantum correlations are assumed to be at the origin of spacetime geometry in all those approaches to quantum gravity that regard spacetime as emerging from fundamental quantum entities.[7] This aspect is particularly emphasised in the approach we adopt here, group field theories[8–10] (GFT), where discrete geometries arise as pattern of entanglement among space quanta. Specifically, the GFT quanta are fundamental simplices dual to spin network vertices, which upon becoming entangled (in their edge degrees of freedom) form spin network graphs dual to simplicial complexes. In this respect, GFT realises what the aforementioned results suggest: the idea of *quantum spacetime as a geometric representation of entanglement*.

Remarkably, a geometric representation of entanglement is the key feature of a quantum information tool, tensor networks[11–13] (TN), which consists in a

decomposition of many-body wave-functions (specifically, of their entanglement structure) into interconnected (one-body) tensors. This feature has been largely exploited in the AdS/CFT correspondence, starting from Ref. 14, which showed that the entanglement renormalization of CFT boundary states carries out a TN decomposition of the latter, with the possibility to interpret the emerging network as (a spatial slice of) AdS spacetime (upon definition of a metric from combinatorial ingredients). Exactly-solvable models of the AdS/CFT correspondence have then been constructed through perfect[15] and random[16] tensors.

However, in these works (and others of similar nature) tensor networks, which *a priori* have nothing to do with gravity, are provided with a spatiotemporal interpretation by defining a metric on the network through combinatorial elements. We make a change of perspective[17] here, in which (suitably generalised) tensor networks are identified, through the match with the GFT formalism, with a quantum gravity language, where the "bodies" of the many-body system are quanta of space, and link-entanglement expresses adjacency relations between them; in other terms, the GFT-generalised tensor networks naturally carry a quantum-geometry interpretation. This identification leads to the possibility of using tensor network techniques in a full quantum gravity context, to study entanglement-based properties of spin network states, which are of interest to a wider part of the quantum gravity community (as they enter other approaches as well, such as loop quantum gravity, spinfoam models and lattice quantum gravity).

On this ground, we look at what is supposed to be a constitutive feature of quantum gravity, originally prompted by the Bekenstein-Hawking area law for the black hole entropy: holography. The holographic principle,[18,19] of which the AdS/CFT correspondence is a realization, argues that the three-dimensional world is the holographic image of data living on a two-dimensional space. Crucially, certain classes of tensor networks turn out to possess holographic features[20] (and have in fact been largely employed in the AdS/CFT context, as recalled earlier). Within the perspective change mentioned above, we thus exploit tensor network methods to highlight properties of spin network states that are related to holography.

We specifically look at the transmission of information from the bulk to the boundary of an open spin network graph (where the bulk is made by the intertwiner degrees of freedom associated to the vertices, and the boundary by spin degrees of freedom on open links of the graph), pointing out that every spin network state can be seen as a map between these two sets. As we shall see, the map then turns out to be an isometry (which is a necessary condition for an holographic bulk-to-boundary transmission of information) if and only if the reduced bulk state has maximum entanglement entropy. Assuming a random distribution of weights associated to the individual spin network vertices, we carry out the entropy calculation via random tensor network techniques, and thereby manage to highlight the properties of spin network graphs that favour in them an holographic behaviour. The results reported here have been obtained as part of the work presented in Ref. 21.

2. Quantum space from spin network entanglement graphs

The GFT models for quantum gravity[8–10] are quantum field theories defined on d copies of a group G, whose fundamental excitations are $(d-1)$-simplices (to be understood as quanta of space), decorated by group variables (one for each face) that capture their geometric properties. In the model of $4D$ quantum gravity, $d = 4$ and the usual choice for the group is $G = SU(2)$; the space quanta are then quantized tetrahedra. In a dual picture, the fundamental $(d-1)$-simplex is represented as a d-valent vertex, with an edge dual to each face and carrying the corresponding geometric data, i.e. a spin network vertex.

As we are going to detail in the following, spatial geometries, in the form of simplicial complexes dual to spin network graphs, arise in GFT from the gluing of fundamental simplices/spin-network vertices, given by entanglement of their edge degrees of freedom.

2.1. *Combinatorial structure of spin network graphs*

We start by introducing some combinatorics notions needed to construct spin network states in the GFT framework.

Let $V = \{1, ..., N\}$ be a set of vertices. The d lines departing from a vertex are distinguished by a "colour" $i = 1, ..., d$, and the i-th line of a vertex v is denoted as e^i_v. In graph theory, a connectivity pattern among N vertices is encoded in a $N \times N$ matrix A, called *adjacency matrix*, such that its element A_{vw} is equal to 1 or 0 if, respectively, vertices v and w are connected or not by a link. To include the information of the colour labelling the links between vertices, we can use a $(N \cdot d) \times (N \cdot d)$ generalised adjacency matrix; we also assume that vertices can be connected only along edges of the same colour. Then:

- e^i_v and e^i_w form a link, denoted by e^i_{vw}, if and only if $A_{(v-1)\cdot d+i,(w-1)\cdot d+i} = 1$
- e^i_v is an open edge if and only if $A_{(v-1)\cdot d+i,(w-1)\cdot d+i} = 0 \ \forall \ w \in V$

The connectivity pattern defined by the adjacency matrix A, also called *graph*, is indicated as γ; the two notions A and γ thus contain the same information. Given the graph γ, we denote as L the set of internal links: $L = \{e^i_{vw} | A_{(v-1)\cdot d+i,(w-1)\cdot d+i} = 1\}$, and as $\partial\gamma$ the set of boundary links: $\partial\gamma = \{e^i_v | A_{(v-1)\cdot d+i,(w-1)\cdot d+i} = 0 \ \forall \ w \in V\}$. We also call E the set of all edges of the graph: $E = L \cup \partial\gamma$.

2.2. *Spin network entanglement graphs*

The d-valent vertices introduced above, dressed with group geometric data, are spin network vertices dual to $(d-1)$-simplices, representing fundamental excitations of the GFT field. In particular, each line e^i_v of a vertex v, corresponding to a face of the dual simplex, is decorated with a group variable g^i_v, and the complete set $g^1_v, ..., g^d_v$ specifies the geometry of the $(d-1)$-simplex up to global action of the group G; the associated Hilbert space is thus given by $\mathcal{H}_v = L^2(G^d/G)$.

A spin network graph (dual to a simplicial complex) can be constructed out of a set $V = \{1, ..., N\}$ of vertices by correlating their edge degrees of freedom (which graphically amounts to gluing their open edges); the corresponding state thus lives in a subspace of the Hilbert space associated to the set of (a priori, open) vertices $\mathcal{H}_V = \bigotimes_{v=1}^{N} \mathcal{H}_v$. In particular, invariance of the state under right action of the group on the variables g_v^i and g_w^i implies that e_v^i and e_w^i are glued together to form a link e_{vw}^i, which carries the element $g_{vw}^i = g_v^i (g_w^i)^{-1}$. The wavefunction ψ_γ associated with a graph γ can thus be obtained by a generic $\psi \in \mathcal{H}_V$ as follows:

$$\psi_\gamma(..., g_{vw}^i = g_v^i (g_w^i)^{-1}, ...) = \int \mathrm{d}h \; \psi(..., g_v^i h, ..., g_w^i h, ...) \tag{1}$$

and pertains to the Hilbert subspace $\mathcal{H}_\gamma = L^2(G^E/G^V) \subseteq \mathcal{H}_V$. Note that, although GFT and LQG associate the same set of states to a given graph γ (namely, the ones of $\mathcal{H}_\gamma$), the nature of such states in the two theories is radically different.[22] In fact, the GFT ones live in a Hilbert space ($\mathcal{H}_V$) which describes a collection of possibly disconnected vertices; the graph structure, and hence the simplicial complex associated with it, is not given *a priori*, but emerges from the particular form of the state (specifically, from its entanglement structure, as explained below).

By the Peter-Weyl theorem, the single-vertex Hilbert space can be decomposed into irreducible representations j of $SU(2)$ (spin network representation):

$$\mathcal{H}_v = \bigoplus_{\vec{j}_v} \left(\mathcal{I}^{\vec{j}_v} \otimes \bigotimes_{i=1}^{d} V^{j_v^i} \right) \tag{2}$$

where $\vec{j}_v = j_v^1, ..., j_v^d$ are the $SU(2)$ representations associated to the edges $e_v^1, ..., e_v^d$ of vertex v, V^j is the space carrying the representation j, and $\mathcal{I}^{\vec{j}} = \mathrm{Inv}_{SU(2)} \left[V^{j^1} \otimes ... \otimes V^{j^d} \right]$ is the space of d-valent intertwiners recoupling spins $j^1, ..., j^d$. A basis state for Eq. (2) is denoted by $|\vec{j}_v \vec{n}_v \iota_v\rangle$, where $\vec{n}_v = n_v^1, ..., n_v^d$ with n_v^i quantum number (spin projection) labelling a basis of $V^{j_v^i}$, and $\iota_v \in \mathcal{I}^{\vec{j}_v}$.

In the spin network basis, gluing vertices corresponds to imposing maximal entanglement between edge spins:

$$|\psi_\gamma\rangle = \left(\bigotimes_{e_{vw}^i \in L} \langle e_{vw}^i | \right) |\psi\rangle \tag{3}$$

where $|e_{vw}^i\rangle$ is a maximally entangled state of spins associated to e_v^i and e_w^i. The entanglement pattern of a state thus constitutes the graph dual to the simplicial complex the state represents. For this reason we refer to states like that in Eq. (3) as *entanglement graphs*.

Denoting by J an assignment of spins to all edges of γ, i.e. $J = \{j_e | e \in E\}$, the Hilbert subspace of $\mathcal{H}_V$ associated to γ can be written as follows:

$$\mathcal{H}_\gamma = \bigoplus_{J} \left(\bigotimes_{v} \mathcal{I}^{\vec{j}_v} \otimes \bigotimes_{e \in \partial\gamma} V^{j_e} \right) \tag{4}$$

It is clear from Eq. (4) that we can identify, for each graph, two different sets of degrees of freedom: intertwiners attached to the vertices, which we refer to as *bulk degrees of freedom*, and spin projections attached to the boundary edges, the *boundary degrees of freedom*. Note that the two sets are not independent, as intertwiners also recouple spins that pertain to the boundary; however, as can be easily seen from Eq. (4), they can be considered independent within each fixed-spin subspace of the direct sum.

2.2.1. *Classes of spin network entanglement graphs as tensor networks*

A tensor network[11–13] is, formally, a set of tensors whose indices are contracted according to a certain patter; when each tensor accounts for the state of a quantum system (say a "particle"), the tensor network is a many-body wavefunction. Its peculiarity (underlying the efficiency of this quantum information tool) is that the network represents the skeleton of quantum correlations (typically, entanglement) among the individual particles. This recalls the GFT graphs, which represent the entanglement structure of a many-vertex state. Let us illustrate the analogy with an example: consider a set of *open* vertices in the factorized state $\bigotimes_v |f_v\rangle \in \mathcal{H}_V$, where

$$|f_v\rangle = \bigoplus_{\vec{j}_v} \sum_{\vec{n}_v \iota_v} (f_v)^{\vec{j}_v}_{\vec{n}_v \iota_v} |\vec{j}_v \vec{n}_v \iota_v\rangle \tag{5}$$

is the generic state of vertex v, and glue them according to a given combinatorial pattern γ:

$$|\phi_\gamma\rangle = \left(\bigotimes_{e^i_{vw} \in L} \langle e^i_{vw}| \right) \bigotimes_v |f_v\rangle \tag{6}$$

In the case where every f_v is picked on specific values $\vec{j}_v$ of the edge spins, the state of Eq. (6) is an ordinary tensor network, specifically a PEPS, having j_e with $e \in E$ as bond dimensions[13]:

$$(\phi_\gamma)^{\{j_{e\in E}\}}_{\{n_{e\in\partial\gamma}\}\{\iota_{v\in V}\}} = (f_1)^{\vec{j}_1}_{\vec{n}_1 \iota_1} \cdots (f_N)^{\vec{j}_N}_{\vec{n}_N \iota_N} \prod_{e^i_{vw} \in L} \delta_{j^i_v j^i_w} \delta_{n^i_v n^i_w} \tag{7}$$

In the more general case where every f_v runs over all possible values of the edge spins, Eq. (6) corresponds to a generalised tensor network, whose bond dimensions are dynamical variables. For a detailed discussion on the analogy between GFT entanglement graphs and tensor networks see Ref. 17.

3. Bulk-to-boundary transmission of information

3.1. *Spin network entanglement graphs as bulk-to-boundary maps*

By considering a bipartition of the degrees of freedom of an entanglement graph (like the one in Eq. (3)) into *bulk* (intertwiners on vertices, collectively indicated as $\dot{\gamma}$)

and *boundary* (spin projections on open edges), we can regard it as a map between these two sets. Such a viewpoint is quite natural when we consider an entanglement graph with fixed spins $J = \{j_e | e \in E\}$, whose Hilbert space factorizes, as can be seen from Eq. (4), into a bulk space $\mathcal{H}_{\dot{\gamma}}(J) = \bigotimes_v \mathcal{I}^{\vec{j}_v}$ and a boundary space $\mathcal{H}_{\partial\gamma}(J_\partial) = \bigotimes_{e\in\partial\gamma} V^{j_e}$, where $J_\partial = \{j_e | e \in \partial\gamma\} \subset J$ is the set of spins on the boundary edges. In particular, to every state $|\psi_\gamma\rangle \in \mathcal{H}_\gamma(J) = \mathcal{H}_{\dot{\gamma}}(J) \otimes \mathcal{H}_{\partial\gamma}(J_\partial)$ we can associate a map $M[\psi_\gamma] : \mathcal{H}_{\dot{\gamma}}(J) \to \mathcal{H}_{\partial\gamma}(J_\partial)$ acting as follows:

$$M[\psi_\gamma]: \quad |\zeta\rangle \in \mathcal{H}_{\dot{\gamma}}(J) \quad \to \quad \langle\zeta|\psi_\gamma\rangle = |\psi_{\partial\gamma}(\zeta)\rangle \in \mathcal{H}_{\partial\gamma}(J_\partial) \tag{8}$$

In the more general case of $|\psi_\gamma\rangle$ spreading over all possible values of the edge spins we can still define an associated bulk-to-boundary map $M[\psi_\gamma]$: by embedding the graph Hilbert space $\mathcal{H}_\gamma$, which is given by Eq. (4), into $\mathcal{H}_{\dot{\gamma}} \otimes \mathcal{H}_{\partial\gamma}$, where

$$\mathcal{H}_{\dot{\gamma}} = \bigoplus_J \mathcal{H}_{\dot{\gamma}}(J), \tag{9}$$

$$\mathcal{H}_{\partial\gamma} = \bigoplus_{J_\partial} \mathcal{H}_{\partial\gamma}(J_\partial), \tag{10}$$

we can regard Eq. (9) as *bulk input space* and Eq. (10) as *boundary output space*, and define the map action similarly to the fixed-spin case.

3.2. *Isometry condition*

A necessary condition for the bulk and boundary information in $|\psi_\gamma\rangle$ to be holographically related is that the map $M[\psi_\gamma]$ is an isometry. As we are going to show, this property can be verified by studying the entanglement entropy of the reduced bulk state. We focus, for simplicity, on the spin-fixed case. Let $\{|\vec{\iota} = \iota_1 ... \iota_N\rangle\}$ be a basis of $\mathcal{H}_{\dot{\gamma}}(J)$; by writing the state $|\psi_\gamma\rangle$ in terms of the corresponding map (denoted with M only, for brevity),

$$|\psi_\gamma\rangle = \sum_{\vec{\iota}} (M \otimes \mathbb{I}) |\vec{\iota}\rangle \otimes |\vec{\iota}\rangle, \tag{11}$$

we obtain the following expression for the (normalised) reduced bulk state:

$$\rho_{\dot{\gamma}} = \mathrm{Tr}_{\partial\gamma} \left(\frac{|\psi_\gamma\rangle\langle\psi_\gamma|}{D_{\dot{\gamma}}} \right) = \frac{1}{D_{\dot{\gamma}}} \sum_{\vec{\iota}\vec{\iota}'} \left(M^\dagger M\right)^*_{\vec{\iota}\vec{\iota}'} |\vec{\iota}\rangle\langle\vec{\iota}'| \tag{12}$$

where $D_{\dot{\gamma}} = \prod_v D_{\vec{j}_v}$ is the dimension of the bulk, with $D_{\vec{j}_v}$ dimension of the intertwiner at vertex v. From Eq. (12) we can easily see that the isometry condition $M^\dagger M = \mathbb{I}$ translates into the requirement that the bulk state is maximally mixed, i.e. $\rho_{\dot{\gamma}} = \frac{\mathbb{I}}{D_{\dot{\gamma}}}$, namely that it has maximum entropy.

4. Investigating holography in spin networks via random tensor networks

We focus on states having the form

$$|\phi_\gamma\rangle = \left(\bigotimes_{e\in L}\langle e|\right)\bigotimes_v |f_v\rangle, \tag{13}$$

with the single-vertex wavefunctions $f_1, ..., f_N$ chosen randomly according to a uniform probability distribution, corresponding to a random tensor network; moreover, we assume that in γ each vertex has at most one boundary edge.

Our goal is to identify the combinatorial and dimensional features of $|\phi_\gamma\rangle$ that make the corresponding bulk-to-boundary map isometric; to accomplish this, we check under which conditions the reduced bulk state has maximum entropy.

4.1. *Rényi-2 entropy of random tensor networks*

We start by illustrating how to compute the average Rényi-2 entropy of a generic region of the entanglement graph in Eq. (13), consisting of a boundary portion $A \in \partial\gamma$ and a bulk portion $\Omega \in \dot{\gamma}$, under the assumption that the random wavefunctions f_v are picked on specific values of the edge spins. Through the replica trick, and in the large-spins regime, the average Rényi-2 entropy of $\rho_{A\cup\Omega}$, where $\rho = |\phi_\gamma\rangle\langle\phi_\gamma|$, is given by

$$\overline{S_2(\rho_{A\cup\Omega})} \approx -\log\left(\frac{\overline{Z_1}}{\overline{Z_0}}\right) \tag{14}$$

with

$$\overline{Z_0} = \mathrm{Tr}\left[\rho_L^{\otimes 2}\bigotimes_v \overline{\rho_v^{\otimes 2}}\right], \quad \overline{Z_1} = \mathrm{Tr}\left[\rho_L^{\otimes 2}\bigotimes_v \overline{\rho_v^{\otimes 2}}\,\mathcal{S}_{A\cup\Omega}\right], \tag{15}$$

where $\rho_L = \bigotimes_{e\in L}|e\rangle\langle e|$ and $\rho_v = |f_v\rangle\langle f_v|$, the average $\overline{\rho_v^{\otimes 2}}$ is computed by randomizing over vertex wavefunctions with a uniform probability measure, and $\mathcal{S}_{A\cup\Omega}$ is the copy-swap operator on $A\cup\Omega$. The characterizing aspects of the calculation are summarized hereafter. The randomization over vertex wavefunctions yields, by the Schur's lemma, a linear combination of the identity and the copy-swap operator for each vertex v; the quantities $\overline{Z_1}$ and $\overline{Z_0}$ thus involve a sum of 2^N terms, and can be written as partition functions for configurations of two-level spins, $\sigma_v = \pm 1$ with $v = 1, ..., N$, controlling the presence ($\sigma = -1$) or absence ($\sigma_v = +1$) of a copy-swap operator for each vertex v in all terms of the resulting sum. Such partition functions also depend on two-level "pinning fields": boundary fields, $\mu_e = \pm 1$ with $e \in \partial\gamma$, each one controlling the presence ($\mu_e = -1$) or absence ($\mu_e = +1$) of a copy-swap operator on the corresponding boundary edge e, potentially contained in $\mathcal{S}_A$; and bulk fields, $\nu_v = \pm 1$ with $v = 1, ..., N$, each one controlling the presence ($\nu_v = -1$)

or absence ($\nu_v = +1$) of a copy-swap operator on the corresponding vertex v, potentially deriving from $\mathcal{S}_\Omega$. As a result, $\overline{Z_0}$ and $\overline{Z_1}$ turn out to be particular values of the partition function

$$\overline{Z}\left(\vec{\mu},\vec{\nu}\right) = \sum_{\vec{\sigma}} e^{-\mathcal{A}[\vec{\mu},\vec{\nu}](\vec{\sigma})} \tag{16}$$

where

$$\begin{aligned}\mathcal{A}[\vec{\mu},\vec{\nu}]\left(\vec{\sigma}\right) = &-\frac{1}{2}\sum_{e^i_{vw}\in L}\left(\sigma_v\sigma_w - 1\right)\log d_{j^i_{vw}} - \frac{1}{2}\sum_{e\in\partial\gamma}\left(\sigma_v\mu_e - 1\right)\log d_{j_e} \\ &- \frac{1}{2}\sum_v(\sigma_v\nu_v - 1)\log D_{\vec{j}_v} + k\end{aligned} \tag{17}$$

is an Ising-type action (k is a constant), having a parametric dependence on the pinning fields $\vec{\mu} = \{\mu_e | e \in \partial\gamma\}$ and $\vec{\nu_v} = \{\nu_v | v \in V\}$; specifically, $\overline{Z_0}$ is given by Eq. (16) with all pinning fields pointing up (i.e. $\mu_e = +1$ for all e, and $\nu_v = +1$ for all v), while $\overline{Z_1}$ corresponds to the case in which the pinning fields within $A \cup \Omega$ are flipped down (i.e. $\mu_e = -1$ if and only if $e \in A$, and $\nu_v = -1$ if and only if $v \in \Omega$). By defining the free energies $F_0 = -\log\overline{Z_0}$ and $F_1 = -\log\overline{Z_1}$, the average Rényi-2 entropy is then given by $\overline{S_2(\rho_{A\cup\Omega})} = F_1 - F_0$.

We consider the large-spins regime (corresponding to a low-temperature regime of the Ising model), in which the partition functions are estimated by the contribution of the configuration $\vec{\sigma}$ that minimizes the action, i.e.

$$F(\vec{\mu},\vec{\nu}) = -\log\overline{Z}(\vec{\mu},\vec{\nu}) \approx \min_{\vec{\sigma}}\mathcal{A}[\vec{\mu},\vec{\nu}](\vec{\sigma}) \tag{18}$$

Note that F_0 is independent of the particular reduction of ρ we want to compute the entropy of; in fact, all pinning fields in $\overline{Z_0}$ take the "neutral value" $+1$. In the low-temperature regime all Ising spins get aligned with them, reaching the all-up configuration that minimizes $\mathcal{A}_0$, which takes the value $\mathcal{A}_{0\min} = k$. Therefore, from Eq. (18), $F_0 = k$. Since what matters is the difference $F_1 - F_0$, the constant k can be set equal to zero, and the calculation of $\overline{S_2(\rho_{A\cup\Omega})}$ thus be reduced to that of F_1 via Eq. (18), with $k = 0$ in the action.

4.2. *Checking the isometry condition for bulk-to-boundary maps*

We exploit the above technique to compute the average Rényi-2 entropy of the reduced bulk state: $\overline{S_2(\rho_{\dot{\gamma}})}$. This requires setting $A = \emptyset$ and $\Omega = \dot{\gamma}$; the partition function $\overline{Z_1}$ is thus given by Eq. (16) with all boundary fields $\vec{\mu}$ equal to $+1$, and all bulk fields $\vec{\nu}$ equal to -1.

4.2.1. *Homogeneous case*

In the homogeneous case, i.e. when all spins on the graph take the same value j, the quantity $\log d_j = \beta$ plays the role of inverse Ising temperature, as can be seen

by expressing the action as $\mathcal{A}(\vec{\sigma}) = \beta H(\vec{\sigma})$, with

$$H(\vec{\sigma}) = -\frac{1}{2}\left[\sum_{e^i_{vw}\in L}(\sigma_v\sigma_w - 1) + \sum_{e\in\partial\gamma}(\sigma_v - 1) + \frac{\log D_j}{\beta}\sum_v(\sigma_v\nu_v - 1)\right], \quad (19)$$

where D_j is the dimension of an intertwiner recoupling d j-spins; we then obtain, for the partition function of Eq. (16), the form $\overline{Z} = \sum_{\vec{\sigma}} e^{-\beta H(\vec{\sigma})}$ (we removed the dependence on $\vec{\mu}$, $\vec{\nu}$ for brevity).

In the range $\beta \gg 1$ we have that $\overline{Z} \approx \exp\{-\beta \min_{\vec{\sigma}} H(\vec{\sigma})\}$, and the free energy is thus given by $F \approx \beta \min_{\vec{\sigma}} H(\vec{\sigma})$. In this range the maximum value of the entropy is obtained when the free energy F_1 is estimated through the configuration with all Ising spins pointing up (in short, $\vec{\sigma} = \uparrow$); in fact,

$$\overline{S_2(\rho_{\dot{\gamma}})} = F_1 - F_0 \approx \beta H_1(\vec{\sigma} = \uparrow) = \log(D_j^N), \quad (20)$$

which is the maximum entropy the reduced bulk state can have, as D_j^N is the bulk dimension in the homogeneous case.

Based on this consideration, we can translate the isometry condition into the requirement of stability of the all-up configuration:

$$H_1(\vec{\sigma}) > H_1(\vec{\sigma} = \uparrow) \quad \forall\vec{\sigma} \quad (21)$$

By inserting Eq. (19) into Eq. (21), and denoting by $X(\vec{\sigma})$ the region that, for a given configuration $\vec{\sigma}$, contains the Ising spins that point down (i.e. $\sigma_v = -1$ if and only if $v \in X(\vec{\sigma})$), the stability condition of Eq. (21) can be written as follows:

$$|\partial X(\vec{\sigma})| \log d_j > |X(\vec{\sigma})| \log D_j \quad \forall\vec{\sigma} \quad (22)$$

We are interested in graphs made of 4-valent vertices; in that case $D_j = d_j = 2j + 1$, and Eq. (22) becomes

$$|\partial X(\vec{\sigma})| > |X(\vec{\sigma})| \quad \forall\vec{\sigma}, \quad (23)$$

which cannot be satisfied for $\vec{\sigma} = \downarrow$, as $X(\vec{\sigma} = \downarrow) = \dot{\gamma}$ and every vertex has at most one boundary link. This implies that no bulk-to-boundary map associated to an homogeneous graph, made of 4-valent vertices and with at most one boundary link for each vertex, can be an isometry.

4.2.2. *Inhomogeneous case*

In the generic, inhomogeneous case, we can still put in evidence the parameter $\beta = \log d_j$, where j is now the average spin, and write the partition function as $\overline{Z} = \sum_{\vec{\sigma}} e^{-\beta H(\vec{\sigma})}$ with

$$H(\vec{\sigma}) = -\frac{1}{2}\sum_{e^i_{vw}\in L}(\sigma_v\sigma_w - 1)\frac{\log d_{j^i_{vw}}}{\beta} - \frac{1}{2}\sum_{e\in\partial\gamma}(\sigma_v - 1)\frac{\log d_{j_e}}{\beta} - \frac{1}{2}\sum_v(\sigma_v\nu_v - 1)\frac{\log D_{\vec{j}_v}}{\beta} \quad (24)$$

Similarly to the homogeneous case, when the partition function $\overline{Z_1}$ is dominated by the all-up configuration, and so $F_1 \approx \beta H_1(\vec{\sigma} = \uparrow)$, the entropy takes its maximum value: $\overline{S_2(\rho_{\hat{\gamma}})} = \log\left(\prod_v D_{\vec{j}_v}\right)$. We can therefore express the isometry condition of the bulk-to-boundary map as stability condition of the $\vec{\sigma} = \uparrow$ configuration; by making use of the $\vec{\sigma}$-dependent region $X(\vec{\sigma})$ previously defined, that takes the following form:

$$\sum_{e\in\partial X(\vec{\sigma})} \log d_{j_e} > \sum_{v\in X(\vec{\sigma})} \log D_{\vec{j}_v} \quad \forall\vec{\sigma} \tag{25}$$

Let us now focus on graphs with 4-valent vertices. By renaming the spins of every vertex with labels a, b, c, d according to their increasing order, i.e. $j^a \leq j^b \leq j^c \leq j^d$, we can write the intertwiner dimension as follows: $D_{j^a j^b j^c j^d} = \min\{j^a + j^d, j^b + j^c\} - \Delta + 1$, where $\Delta = j^d - j^a$ is the difference between the maximum and the minimum spin[a]. Equation (25) then becomes

$$\sum_{e\in\partial X(\vec{\sigma})} \log d_{j_e} > \sum_{v\in X(\vec{\sigma})} \log\left(\min\{j_v^a + j_v^d, j_v^b + j_v^c\} - \Delta_v + 1\right) \quad \forall\vec{\sigma} \tag{26}$$

To highlight the trend of the isometric character of the map as a function of Δ, we consider the scenarios corresponding to the extreme values of Δ:

(i) $\Delta_v = 0\ \forall v$: homogeneous case, the bulk-to-boundary map is not an isometry
(ii) $\Delta_v = j_v^b + j_v^c - 1\ \forall v$: the stability condition becomes

$$\sum_{e\in\partial X(\vec{\sigma})} \log d_{j_e} > |X(\vec{\sigma})| \log 2 \quad \forall\vec{\sigma} \tag{27}$$

which is satisfied for sufficiently high values of the edge spins.

5. Conclusions and outlook

We investigated the holographic features of spin networks by regarding them as emerging from the entanglement of individual vertices, in the group field theory approach to quantum gravity. This enabled us to highlight the entanglement structure of spin network states, and write them in the language of tensor networks. Based on this correspondence, we showed that spin networks naturally define bulk-to-boundary maps, whose properties can efficiently be investigated via tensor network techniques. Specifically, we used the latter to identify which (entanglement-induced) features of a spin network can give rise to an isometric mapping of quantum data from the bulk to the boundary, which is the pre-condition for an holographic behaviour. In the case of graphs made of four-valent vertices (which is the interesting one for 4D quantum gravity) we found that homogeneity of the spin assignment to the spin network prevents the latter to be an isometric bulk-to-boundary map,

[a]Note that $\Delta \leq j^b + j^c$; however, since for $\Delta = j^b + j^c$ the intertwiner degree of freedom is suppressed, in the following we assume $\Delta \leq j^b + j^c - 1$.

while increasing the range of spins attached to each vertex favours the attainment of the isometry condition. The results presented here are part of Ref. 21, which also contains an extension of the above analysis to states involving spin superposition, with randomization diagonal with respect to the sum over spins. Importantly, a full generalization to the case of spin superposition, as well as graph superposition, is crucial for a promotion of our results to the dynamical level, since both features can be produced by the quantum dynamics.

Besides contributing to the understanding of the entanglement origin of holography in quantum gravity, our work is meant to be the starting point of a research direction that exploits quantum information techniques in a quantum gravity framework having a purely information-theoretic characterisation, i.e. the one in which spin networks are regarded as generalised tensor networks in the group field theory formalism for quantum gravity. In fact, we have recently used the techniques presented here to study how the boundary entropy depends on the bulk entanglement, specifically that determining the graph connectivity (internal-link entanglement) and that among intertwiner degrees of freedom[23]; in particular, we have analysed under which conditions the latter gives rise to a black hole-like region, analogously to what has been shown in Ref. 16. These methods and results, combined with the typicality approach to the study of the local behaviour of spin networks,[24,25] should pave the way for an information-theoretic characterization of black hole horizons and thus provide important insights into the structure of quantum black holes.

We argue that the minimal length discretization generalizing the Heisenberg uncertainty principle, in which the gravitational impacts on the non–commutation relations are thoughtfully taken into account, radically modifies the spacetime geometry. The resulting metric tensor and geodesic equation combine the general relativity terms with additional terms depending on higher–order derivatives. Suggesting solutions for the modified geodesics, for instance, isn't a trivial task. We discuss on the properties of the resulting metric tensor, line element, and geodesic equation.

Keywords: Quantum gravity, Noncommutative geometry, Relativity and gravitation, Line element, Metric tensor, Geodesic equation, Generalized uncertainty principle

1. Introduction

Suggesting a consistent theory for quantum gravity is an ultimate goal of recent research aiming at unifying quantum mechanics (QM) with the theory of general relativity (GR). The quantum nature of gravity is still an open question in physics. It turns to form an enigma occupying the minds of many physicists for many decades, for instance, so–far there is no scientific explanation for the origin of the gravitational fields and how particles behave inside them! This makes the gravity foundamentally different from the other fources of nature. There were various attempts to reconcile some principles of GR in a quantum framework.[1,2] The quantum gravity - on one hand - is conjectured to add new elements to GR and QM. On the other hand, the Einstein field equations combine classical geometry with quantum stress–energy–momentum tensor! For QM, we recall the possible modification in the Heisenberg uncertainty principle due to gravitational effects[a], known as generalized uncertainty princile (GUP).[3,4] The present work introduces some insights on the possible impacts of GUP on the metric tensor and the geodesic equation and their properties.

Couple decades ago, the line element modification and the gravity quantization have been suggested in litrature.[5–7] A review of these models could be found in Refs.[8–10]. An extended class of the metric tensors which are functions of a field of an

[a]They weren't taken into considration in the original Heisenberg uncertainty principle.

internal vectors $y^\alpha(x)$, $g_{\mu\nu}(x^\alpha \cdot y^\alpha(x))$, was also discussed in litrature.[11] Accordingly, the origin of the gravitational field of spin-1 massless particle could be determined.[11] Regarding the equivalence principle of gravitationan and enirtial mass in extended gravity and non–geodesic motion, a machian request was scratched,[12] where a direct coupling between the Ricci curvature scalar and the matter Lagrangian could be fixed in cosmological observations.[12]

The present script aims at tackling the long–standing essential puzzle that the Einstein field equations relate *non–quantized* semi–Riemannian geometry expressed in Ricci and Einstein tensors, which are basically depending on the metric tensor $g_{\mu\nu}(x^\alpha)$, with the *full–quantized* stress–energy-momentum tensor $T_{\mu\nu}$.[13] The approach applied here is the finite minimal length uncertainty obtained from GUP. GUP was inspired by black hole physics, doubly special relativity, and string theory.[3,4] It is worthy highligting that GUP is comparable with the Planck length, where quantum fluctuations in *quasi–quantized* manifold likely emerge.[14–16]

The modifications in the metric tensor and geodesic equation due to GUP shall be introduced. Accordingly, we believe that the present study offers a theoretical framework for the observations that the universe acceleratingly expands. Alongside forces deriving this type of expansion, such as dark energy[16] and cosmological constant,[17] we suggest that it might be also originated to interdependence of GR on QM, especially at the Planck scale.

The present paper is organized as follows. Section 2 reviews the generalized uncertainly principle and minimal length uncertainty. The discretized metric tensor and its properties shall be discussed in section 3. The discretized geodesic equation and its properties shall be introduced in section 4. Section 5 is devoted to the final conclusions.

2. Generalized uncertainly principle and minimal length uncertainty

The Heisenberg uncertainty principle (HUP) is a recipe on how the uncertainties are constrained in the quantum non–commutation relations of length and momentum operators, for instance. This was originally suggested in absence of any gravitational field. Analyzing HUP in gravitational fields comes up with modifications, know as GUP. Such a phenomenological aspect can be originated in black hole physics, doubly special relativity, and string theory.[3,4] Phenomenology because so–far there is no theoretical explanation of the gravitational fields origin making gravity substantially different from the other three forces of nature. A finite minimal length was suggested as,[18]

$$\Delta x\, \Delta p \geq \frac{\hbar}{2}\left[1+\beta(\Delta p)^2\right], \tag{1}$$

where Δx and Δp are length and momentum uncertainties, respectively. $\beta = \beta_0(\ell_p/\hbar)^2 = \beta_0/(m_p c)^2$, is the GUP parameter with $\ell_p = \sqrt{\hbar G/c^3} = 1.977 \times 10^{-16}$ GeV^{-1} the Planck length and $m_p = \sqrt{\hbar c/G} = 1.22 \times 10^{19}$ GeV$/c^2$ the

Planck mass. An upper bound on β_0 is based on astronomical observations, such as, $\beta_0 \lesssim 5.5 \times 10^{60}$ based on recent gravitational waves observations. From Eq. (1), then the minimum length uncertainty reads

$$\Delta x_{\min} \approx \hbar\sqrt{3\beta_0} = \ell_p\sqrt{\beta_0}. \tag{2}$$

The experimental estimations[19] of β_0 range from $\sim 10^{21}$ to $\sim 10^{39}$. Another GUP approach motivated by quantum deformation of the Pioncarre algebra[20,21] suggests that the minimal length associated with is given as

$$\Delta x_{\min} \simeq \frac{\hbar G}{\gamma_0} = \frac{\ell_p^2}{\gamma_0}, \tag{3}$$

where γ_0 is photon's wavelength sent from infinity to be absorbed in a black hole. Its experimental estimations[19] range from $\sim 10^{26}$ to $\sim 10^{34}$.

The UV/IR correspondence can be applied on various phenomena in which short and long distance physics play a characterized role. For example, gravity[22] and the "*deformed*" commutation relations have features of UV/IR correspondence.[23] Therefore, we assume that the minimal length discretization could be analyzed from the UV/IR correspondence.[10] Indeed, Δx rapidly increases (IR) as the Δp increases beyond the Planck scale (UV).[24–26]

Analogous to expression (1), the canonical non–commutation relation of length and momentum quantum operators is given as

$$[\hat{x}_i\,, \hat{p}_j] \geq \delta_{ij} i\,\hbar\left(1 + \beta p^2\right), \tag{4}$$

where $p^2 = g_{ij}p^{0i}\,p^{0j}$ and g_{ij} is Minkowski spacetime metric tensor, for instance $(-,+,+,+)$. Both length and momentum operators, respectively, read

$$\hat{x}_i = \hat{x}_{0i}(1 + \beta p^2), \tag{5}$$

$$\hat{p}_j = \hat{p}_{0j}, \tag{6}$$

in which $\hat{x}_{0i}$ and $\hat{p}_{0j}$ can be derived from the corresponding non–communitation relation,

$$[\hat{x}_{0i}, \hat{p}_{0j}] = \delta_{ij} i\,\hbar. \tag{7}$$

3. Discretized metric tensor and its properties

With the quantum non–commutation operations discussed in section 2 the four–dimensional Minkowskian manifold of the line element can be given as

$$ds^2 = g_{\mu\nu}dx^\mu dx^\nu, \tag{8}$$

where μ, ν, and $\lambda = 0, 1, 2, 3$. This could be extended to eight–dimensional spacetime tangent bundle with coordinates $x^A = (x^\mu(\zeta^a), \beta\dot{x}^\mu(\zeta^a))$, where $\dot{x}^\mu = dx^\mu/d\zeta^\mu$.[27] Obviously, the line element reads

$$d\tilde{s}^2 = g_{AB}\,dx^A\,dx^B, \tag{9}$$

where $x^A = x^A(\zeta^\mu)$, $g_{AB} = g_{\mu_\nu} \otimes g_{\mu\nu}$, and the indices A and $B = 0, 1, \ldots, 7$. With some assumptions and approximations, this manifold could be reformulated as an effective four–dimensional spacetime manifold,

$$\tilde{g}_{\mu\nu} = g_{AB} \frac{\partial x^A}{\partial \zeta^\mu} \frac{\partial x^B}{\partial \zeta^\nu} \simeq g_{ab} \Big[\frac{\partial x^a}{\partial \zeta^\mu} \frac{\partial x^b}{\partial \zeta^\nu} + \beta \frac{\partial \dot{x}^a}{\partial \zeta^\mu} \frac{\partial \dot{x}^b}{\partial \zeta^\nu} \Big] \simeq \big(1 + \beta \ddot{x}^\lambda \ddot{x}_\lambda\big)\, g_{\mu\nu}. \quad (10)$$

$\ddot{x}^\mu = \partial \dot{x}^\mu / \partial \zeta^\mu$ is four–dimensional acceleration. The indices a, and $b = 0, 1, \ldots, 7$.

It is now proper to highlight a number of the discretized metric tensor properties. First, we distinguish between flat and curved spacetime:

- For flat spacetime, $g_{\mu\nu} = \eta_{\mu\nu}$ and the modified metric tensor reads

$$\tilde{g}_{\mu\nu} \simeq \eta_{\mu\nu} + \beta \ddot{x}^\lambda \ddot{x}_\lambda \eta_{\mu\nu} \simeq \eta_{\mu\nu} + h_{\mu\nu}, \quad (11)$$

  where $h_{\mu\nu} = \beta \ddot{x}^\lambda \ddot{x}_\lambda \eta_{\mu\nu}$. The quantum fluctuations from which the minimal length uncertainty likely emerges are compassed in $h_{\mu\nu}$. In other words, both GR metric tensor and this modified one are only distinguishable, at finite $h_{\mu\nu}$.
- For curved spacetime, the modified metric tensor reads

$$\tilde{g}_{\mu\nu} \simeq g_{\mu\nu} + \beta \ddot{x}^\lambda \ddot{x}_\lambda g_{\mu\nu}. \quad (12)$$

  Again, $\beta \ddot{x}^\lambda \ddot{x}_\lambda g_{\mu\nu}$ represents the minimal length contributions.

The $\tilde{g}_{\mu\nu}$, Eq. (12), seems to play the same role as that of $g_{\mu\nu}$, namely it turns a covariant tensor into a contravariant tensor and vice versa. $\tilde{g}_{\mu\nu}$ is apparently symmetric in its indices μ and ν as its components are likely equal upon exchanging the indices. The $\tilde{g}_{\mu\nu}$ symmetric properties are invariant upon basis transformation only if its indices are of the same type; variant or covariant. For spacetime represented by a four–dimensional differentiable manifold $\mathcal{M}$, the metric tensor, $\tilde{g}_{\mu\nu}$, Eq. (12), is covariant, second–degree, symmetric on $\mathcal{M}$. Such manifold is Lorentzian. In local coordinates x^μ, the metric can be expressed in dx^μ (one–form gradients of the scalar coordinate fields x^μ), and the coefficients $\tilde{g}_{\mu\nu}$ (16 real–valued functions). If the local coordinates are specified, the metric can be written as a 4×4 symmetric matrix with the coefficients $\tilde{g}_{\mu\nu}$. If the matrix is non–singular having non–vanishing determinant, $\tilde{g}_{\mu\nu}$ is non–degenerate. The Lorentzian signature of $\tilde{g}_{\mu\nu}$ obviously implies that the matrix has one negative and three positive eigenvalues. Under a change of the local coordinates $x^\mu \to x^{\bar{\mu}}$, we obtain

$$\tilde{g}_{\bar{\mu}\bar{\nu}} = \frac{\partial x^\alpha}{\partial x^{\bar{\mu}}} \frac{\partial x^\beta}{\partial x^{\bar{\nu}}}\, \tilde{g}_{\alpha\beta} = \Theta^\alpha_{\bar{\mu}}\, \Theta^\beta_{\bar{\nu}}\, \tilde{g}_{\alpha\beta} \quad (13)$$

If dx^μ are regarded as the components of an infinitesimal coordinate displacement four–vector, the metric determines the invariant square of an infinitesimal line element. Also, it is apparent that the principle of the general covariance is satisfied even in absence of gravitational effects on the modified Minkowski metric. Then,

the modified four–dimensional line element can be expressed as

$$d\tilde{s}^2 = g_{\mu\nu}\left(dx^\mu dx^\nu + \beta^2 d\dot{x}^\mu\, d\dot{x}^\nu\right) = ds^2 + \beta^2 \ddot{x}^\lambda \ddot{x}_\lambda\, ds^2, \tag{14}$$

and $d\tilde{s}^2$ manifests the causal structure of the spacetime. Only timelike four–dimensional line element, $d\tilde{s}^2 < 0$, can physically covered by a massive object. If $d\tilde{s}^2 = 0$ the line element is lightlike (covered by massless photon). On the other hand, for $d\tilde{s}^2 > 0$, the four–dimensional line element is an incremental proper length, i.e., spacelike.

4. Discretized geodesic equation and its properties

The properties of the manifold including geodesics in GR [$\ddot{x}^\mu + \Gamma^\mu_{\alpha\beta}\dot{x}^\mu\dot{x}^\nu = 0$ with $\dot{x}^\mu = \partial x^\mu/\partial s$, Christopher symbols $\Gamma^\mu_{\alpha\beta} = (g^{\mu\gamma}/2)(\partial g_{\gamma\alpha}/\partial x^\beta) + \partial g_{\gamma\beta}/\partial x^\alpha - \partial g_{\alpha\beta}/\partial x^\gamma)$, and s is a scalar parameter of motion such as a proper time] can be generalized. For example, the notion of a "*straight line*" is to be generalized to "*curved spacetime*". The consequences of the length discretization or minimal length uncertainty based on GUP, generalize the world line of a free particle. GR assumes that gravity couldn't be regarded as a force but it should be emerged from "*classical*" curved spacetime geometry and "*quantized*" stress–energy–momentum tensor is causing the "*classical*" spacetime curvature. The approach utilized here is discretized minimal length, which modifies both metric tensor and line element.

As discussed in Ref.[10], using the variational principle and extremization of the path s_{AB}, the geodesic equation could be derived as follows.

- In flat spacetime (Minkowski space)

$$\beta\mathcal{L}\frac{d^2\dot{x}^\mu}{ds^2} - \frac{dx^\mu}{ds} + c = 0. \tag{15}$$

  Even if β, the GUP parameter vanishes, the geodesic equation reduces to that of a straight line, at constant velocity, i.e., both β terms disappear.
- and in curved spacetime

$$\begin{aligned}\frac{d^2x^\eta}{ds^2} + \Gamma^\eta_{\mu\nu}\frac{dx^\mu}{ds}\frac{dx^\nu}{ds} &= \beta\frac{d}{ds}\left(\mathcal{L}\frac{d^3x^\eta}{ds^3}\right)\\ &+ \beta g^{\eta\alpha} g_{\mu\nu,\alpha}\frac{d^2x^\mu}{d^2s}\frac{d^2x^{nu}}{ds^2}\\ &+ \beta\mathcal{L} g^{\eta\alpha} g_{\mu\alpha,\gamma}\left[\frac{dx^\gamma}{ds}\frac{d^2\dot{x}^\mu}{ds^2} + \frac{d}{ds}\left(\frac{dx^\gamma}{ds}\frac{d\dot{x}^\mu}{ds}\right)\right]\\ &+ \beta\mathcal{L} g^{\eta\alpha} g_{\mu\alpha,\gamma,\delta}\frac{dx^\delta}{ds}\frac{dx^\gamma}{ds}\frac{d\dot{x}^\mu}{ds},\end{aligned} \tag{16}$$

where the proper time can be deduced from the Lagrangian, $\tau = \int \mathcal{L}(s, \dot{x}, \ddot{x})\, ds$,

$$\frac{\partial \tau}{\partial s} = \mathcal{L}(s, \dot{x}, \ddot{x}) = -\left[g_{\mu\nu} \left(\frac{dx^\mu}{ds} \frac{dx^\nu}{ds} + \beta \frac{d\dot{x}^\mu}{ds} \frac{d\dot{x}^\nu}{ds} \right) \right]^{1/2},$$

$$\Gamma^\eta_{\mu\nu} = \frac{1}{2} g^{\eta\alpha} \left[g_{\mu\alpha,\nu} - g_{\alpha\nu,\mu} + g_{\mu\nu,\alpha} \right],$$

$$g_{\mu\nu,\alpha} = \frac{\partial g_{\mu\nu}}{\partial x^\alpha},$$

$$g_{\mu\alpha,\gamma,\delta} = \frac{\partial}{\partial x^\delta} \left(\frac{\partial g_{\mu\alpha}}{\partial x^\gamma} \right).$$

The β–terms in Eq. (16) distinguish this expression of discretized geodesics from the GR geodesics,

$$\frac{d^2 x^\mu}{ds^2} + \Gamma^\mu_{\alpha\beta} \frac{dx^\mu}{ds} \frac{dx^\nu}{ds} = 0, \tag{17}$$

which could be solved when, for instance, assuring that the proper time reads $ds^2 = g_{\mu\nu} dx^\mu dx^\nu$. Under the condition that

$$g_{\mu\nu} \frac{dx^\mu}{ds} \frac{dx^\nu}{ds} = \epsilon, \tag{18}$$

where $\epsilon = 0$ for photon and $\epsilon = 1$ for massive particles, the geodesic equation is supplemented. For conserved energy and angular momentum the geodesic equation can be expressed as an ordinary first–order differential equation.[28]

Solving the discretized geodesic equation, Eq. (16), is not a trivial task, because of the finite terms in rhs, which encompass higher–order derivatives.

5. Conclusions

The approach of minimal length uncertainty conserves both Christoffel connection[b] and the equivalence principle of the gravitational and inertial mass. They are not affected. This allows to recover any violations in the equivalence principle, especially as a possible reason of quantum gravity. We highlight that this conclusion contradicts previous studies.[29,30] The reason could be the rigorous procedure implemented in the present study. We have first determined the modified metric tensor. Accordingly, we have obtained the modified line element. Both are key principles of the proposed theory of discretized geometry. We could also derive the corresponding geodesics, in which the appearance of higher–order derivatives substantially distinguishes this expression from the GR geodesics.

The modification to the line element is summarized in the term $\beta^2 \ddot{x}^\lambda \ddot{x}_\lambda$, which highlights the essential contributions added by the acceleration of the test particle.

[b]The metric connection characterizes the affine connection to a manifold provided with the metric. This allows lengths, for instance, to be measured on that manifold.

We conclude that the length discretization ensures that the line element wouldn't only expand but apparently accelerates. The metric tensor is also modified by the term $\beta\ddot{x}^{\lambda}\ddot{x}_{\lambda}$. The properties of the modified metric tensor has been elaborated.

We find that the modified geodesics is not only providing the acceleration of a test particle inside the gravitational field. Higher–order derivatives are also present,[31] namely the jerk, $\dddot{x}^{\mu}$, which in turn is derived from the time derivative of the acceleration. In contract to GR geodesics, solving the modified geodesics isn't a trivial task. The corresponding differential equations are complex and non–linear.

The structure of the multiverse from the entanglement entropy

Samuel Barroso Bellido
Institute of Physics, University of Szczecin

E-mail: samuel.barroso-bellido@usz.edu.pl

Third quantization of canonical quantum gravity allows us to consider the multiverse as the playground of a field theory of universes. In the scenario where two universes are created by analogy with pair production in quantum field theory, we analyze the entanglement entropy between them and get some conclusions about the structure of the multiverse.

Keywords: Multiverse, Entanglement Entropy, Third Quantization

1. What is Time and Space?

Canonical quantum gravity[1,2] is one of the most natural ways to venture in search of a theory which combines gravity and the quantum world. Even though it is an old topic, there are several fundamental problems one needs to sort out to get satisfactory predictions from it.[3,4] However, the theory has got quite important results we should not ignore.[2,5]

This approach to a quantum theory of gravity predicts the existence of a wave function of the universe, which describes the universe as a whole.[6,7] It is defined by the Wheeler-DeWitt equation

$$\mathcal{H}\Psi = 0, \tag{1}$$

where $\mathcal{H}$ is the Hamiltonian which considers all possible degrees of freedom from fields and gravity, and Ψ is such wave function. To assume a homogeneous and isotropic universe where there is a limited number of fields, is the simplest way to reduce the complexity of the calculations. Then, the Hamiltonian is quantized by replacement of the momenta by their associated operators, and the wave function of the universe is found solving the differential equation (1).

For instance, let us choose the proper factor ordering for the scale factor a, and the parametrization $\alpha = \ln(a)$, to write its associated momentum as[2]

$$p_a^2 = -\frac{1}{a}\frac{\partial}{\partial a}\left(a\frac{\partial}{\partial a}\right) = -\mathrm{e}^{-2\alpha}\frac{\partial^2}{\partial \alpha^2}. \tag{2}$$

A single scalar field is going to be quantized as usual by

$$p_\phi^2 = -\frac{\partial^2}{\partial \phi^2}. \tag{3}$$

Thus, the Wheeler-DeWitt equation (1) has the shape of a wave equation

$$\left[\frac{\partial^2}{\partial\alpha^2} - \frac{\partial^2}{\partial\phi^2} + f(\alpha,\phi,...)\right]\Psi(\alpha,\phi) = 0, \tag{4}$$

where $f(\alpha,\phi,...)$ contains the information of the curvature of the universe, the cosmological constant, and so on.

In this theory, *time* is not present. Usually, the scale factor, or a function like α, is the variable which replaces time, but it is an arbitrary choice that leads to physical and even philosophical problems.[8] Since the scale factor as a function of time is not an isomorphism, it is not a well-behaved parametrization of time. Expanding and contracting phases of a closed universe will be described by the same scale factor at two different times, and so big bang and big crunch will have no differences at all. In a practical sense, our universe has never gone through a phase of contraction,[9] and it looks like it will never be in such phase.[10] Hence, the parametrization could still be valid for realistic purposes. On the contrary, *space* is replaced by the scalar field, the one which has the opposite sign in the hyperbolic differential equation (4).

Third quantization of canonical quantum gravity[11–14] is the next step behind a more essential description. By means of it, our universe is seen as one of many universes of a multiverse, where a full quantum field theory takes place, the wave function of the universe plays now the role of an operator over vectors of a Fock space, and annihilation and creation operators can also be defined.

One might expect the number of universes from this picture to be infinite. All of them interacting under the rules of the field theory. Therefore, pair creation of universes is somewhat natural in this picture,[15] as it is in quantum electrodynamics, and two universes can be seen as particle and antiparticle, born at the same time and space in the multiverse (whether *time* and *space* exist or not), being entangled since then.[16] One of those two universes could be our universe. We need to assume that the moment we know as the origin of our universe is the same as that precise moment when our universe is created. Thereafter, we have not notice much difference from what the classical theory of gravity tells us,[17] so we can say that there has not been any interaction with any other universe, and therefore the trajectory through the multiverse has been unaffected. According to this, the pair has *always* been a pair, and the number of universes of this subsystem of the multiverse, has always been constant since its origin.

When considering a curved background, third quantization suffers from the lack of definition of particle as in quantum field theory in curved spacetimes,[18] and so the number of universes is variable. In general, the number of universes appears to be infinite with a certain distribution of modes,[19–21] which are defined by the proper Fock space. To solve this, we turn to an invariant representation[22,23] in which the number operator remains constant, and so the number of universes.

The quantum state at the birth of the pair[24–26] is going to be denoted by $|00\rangle$, which is the same in the natural description due to the diagonal Hamiltonian and in the invariant representation we would like to work with. The Bogoliubov

transformation between both representations at different time lets us to write the density operator $\rho = |00\rangle_{\text{inv}}\langle 00|$ in terms of the vectors of the diagonal representation, where $|00\rangle_{\text{inv}}$ is the vacuum state in the invariant representation. Finally, the entanglement entropy as the von Neumann entropy of the bipartite system is found tracing out the degrees of freedom of one of the two universes.

2. How is the Multiverse?

First of all, the quantum field theory we are used to, is not in perfect harmony with third quantization picture. By ordinary field theory, we states that fundamental particles are really fundamental, and so, they have no internal structure.

In the third quantization picture, particles are universes where we could be living *in*, where all laws of Physics seem to be satisfied. They have an internal structure. As far as it seems, we have no idea about how this multiverse really affects the internal structure of the universes. It is, for example, how the interactions between universes in the multiverse could change the dynamics of our universe. Some attempts have been done previously,[27] but it is not conclusive since the power spectrum of the cosmic microwave background is only affected by an interacting multiverse in the low multipoles interval.

The multiverse is a *place* where time and space are not well defined. We can imagine a particle and antiparticle distancing one from the other, since our laboratory is a *place* where they can be moving away. A pair of universes could have not that place to move freely. Assuming the existence of such place could be imprudent.

When an electron and a positron are created from a virtual photon, their spins are entangled. At that moment, the entanglement[28] is maximum, and it can only be reduced or removed naturally by decoherence. The entanglement cannot be increased naturally in any case after they start to travel freely. For the case in which there is not environment with which the particles can interact, the entanglement must be constant.

For most of the models where there are critical points along the classical evolution, the entanglement entropy of a pair of universes has been found[25,26] to be high or divergent at the initial singularity (when they are created), and divergent at those critical points of the expansion of each universe. It implies that the quantum entanglement of the pair is high at their origin, and at the moment when the expansion of the universes is maximum or minimum.

If such notion of usual space is present in this kind of multiverse, where the universes move and interact, the rules of entanglement should be different from the ones we know from our experiments. It must allow the possibility for the entanglement to increase naturally, such that at the maximum of the expansion of the universes, the entanglement is high again. Alternatively, the multiverse might not be a *place* like the ordinary one we are used to.

Somehow, if we consider the entanglement to work like in our laboratories, the structure of this multiverse cannot be seen as a laboratory where entangled particles

run away from each other, otherwise the entanglement would be constant or vanishing while time goes by. And perhaps, the problem is not only about the space but also the time. If a time-like variable exists for the multiverse, we cannot tell what it is, or how it is intermingled with the spatial variable.

3. Conclusions

The results of the entanglement entropy of the multiverse, assuming that third quantization is correct, indicate that the multiverse is a different *space* from the one we know from the experience in our universe, or maybe it is the *time* the one which is different, or both at the same time. Here, when we talk about time we mean any notion of time, whether it is the usual time, thermodynamic entropy, or any other physical variable which controls the regular arrow of time.

There could be another possibility where the quantum entanglement works differently in the multiverse than into the universes. In such case, the relationship between both behaviors is unknown. Furthermore, taking for granted that the laws of Physics are satisfied anywhere else could be mistaken. If they hold, we know that the sweet spot where our universe is to let life occurs[29] is highly unlikely. If the rest of the universes exist, and the fundamental constants are different from the ones in our universe, it is expected not to harbor life or, more importantly, avoid immediate recollapse after creation.[30] Indeed, for inflation to occur and let the universe expands, the initial conditions of a universe must also satisfy some requirements, otherwise that universe would recollapse and disappear. There is not much doubt then, that whenever we are able to check the presence of other universes, we would better believe in the possibility that there are different laws of Physics out there.

The manner in which the actual theory of quantum gravity describes this kind of multiverse is in terms of the *internal* degrees of freedom of the universes, like the scale factor or the fields. It could not be the appropriate way to do it, since they have not a good definition out of each universe, and so either space and time.

The emergence of a universe which is exact to ours is probabilistic as long as we are assuming a full quantum behavior of the multiverse. The curvature, the cosmological constant, and the rest of the characteristics of a universe are subject to the probabilistic rules of the multiverse. Therefore, the chance for the existence of a universe like ours cannot be far from null.

There is, of course, the possibility that third quantization picture is not correct at all and the multiverse, as it is described by it, is not realistic. Nevertheless, our results could also be showing that third quantization is unavoidably wrong. If our results are correct, then canonical quantum gravity is correct and the third quantization picture is wrong, or both are wrong. The interpretation of third quantization scenario is also a bit odd, and many improvements can be done behind a more strict field theory of universes.

At present, there seems not to be a way out of our ignorance when multiverse comes in context. We are making so many assumptions when we talk about the

multiverse that the most likely outcome seems to be reasonably incorrect. The remaining work for us is to check whether our theories are, by coincidence, in agreement with the observations or not. The cosmic microwave background is still effectively blind to the effects of the entanglement and other interactions in the multiverse, whatever the kind of multiverse is analyzed.[31–35] So, we may wait for a future discovery of the cosmic neutrino background, or the spectrum of the primordial gravitational waves to confirm that some of the theories fit to the observations. Up to that day and even later, the multiverse will remain an unsolvable mystery.

Theories of Quantum Gravity predict a minimum measurable length and a corresponding modification of the Heisenberg Uncertainty Principle to the so-called Generalized Uncertainty Principle (GUP). However, this modification is usually formulated in non-relativistic language, making it unclear whether the minimum length is Lorentz invariant. We have formulated a Relativistic Generalized Uncertainty Principle, resulting in a Lorentz invariant minimum measurable length and the resolution of the composition law problem. This proved to be an important step in the formulation of Quantum Field Theory with minimum length. We derived the Lagrangians consistent with the existence of minimal length and describing the behaviour of scalar, spinor, and U(1) gauge fields. We calculated the Feynman rules (propagators and vertices) associated with these Lagrangians. Furthermore, we calculated the Quantum Gravity corrected scattering cross-sections for a lepton-lepton scattering. Finally, we compared our results with current experiments, which allowed us to improve the bounds on the scale at which quantum gravity phenomena will become relevant.

Keywords: Quantum Gravity: Quantum Gravity Phenomenology, Effective Field theory, Generalized Uncertainty Principle

1. Introduction

The quantization of gravity is one of the major outstanding problems of fundamental physics. The family of theories tackling this problem is known as Quantum Gravity (QG). This family is home to a large diversity of ideas and approaches to the problem. The most prevalent members of the family, namely String Theory, Loop Quantum Gravity in addition to models such as Doubly-Special Relativity theories as well as many others, agree on the existence of a minimum measurable length or a similar scale in spacetime. The minimum length is usually considered to be the proportional to the Planck length, $\ell_{Pl} = 10^{-35}m$, and it signifies the scale at which quantum gravity effects would manifest. Currently, we have no access to energy regimes anywhere close to the Planck scale, therefore all theories of QG lack a direct experimental confirmation. The field of Quantum Gravity Phenomenology (QGP) tackles this problem by using the existing theories to make models in order of finding low energy remnants of QG phenomena in already existing experiments.

As we already mentioned, one phenomenon that most theories of QG agree on is the existence of a minimum measurable length, which is in direct contradiction with

the Heisenberg uncertainty principle (HUP), since the latter allows for infinitely small uncertainties in position. The solution is the introduction of a new model which deforms the HUP in order to accommodate for a minimal uncertainty in position. The deformed HUP is known as Generalized Uncertainty Principle (GUP), and was first introduced by Kempf, Mangano, and Mann in 1995.[1] One of the possible position-momentum commutators corresponding to a GUP model has the following form

$$[x_i, p_j] = i\hbar\delta_{ij}(1 + \beta_1 p^2) + i\hbar\beta_2 p_i p_j \,, \tag{1}$$

where $\beta_1 = \beta_1^*(\ell_{\rm Pl}/\hbar)^2$, $\beta_2 = \beta_2^*(\ell_{\rm Pl}/\hbar)^2$, and β_1^*, β_2^* are numerical coefficients. The GUP model has been successful in modeling a wide array of corrections to quantum mechanical phenomena,[1–58] and has provided compelling bound on the minimum length scale, by comparing the result to existing experimental data.

However, the model introduced by Eq. (1) has two shortcomings:

- The position-momentum commutator and the corresponding uncertainty relation are not Lorentz covariant, and therefore the resulting minimum length is frame dependent,
- *Composition Law Problem*: Energies and momenta do not sum up linearly.[59]

The composition law problem arises due to the fact that deformation of the HUP is done through a generalization of the momentum operator. Namely terms of higher order in momentum are added in order to deform the commutator. This leads to a deformation of the Einstein dispersion relation of the form

$$E^2 = p^2c^2 + m^2c^4 \;\rightarrow\; E^2 = p^2c^2 + m^2c^4 + \mathcal{O}(p^4) \,. \tag{2}$$

Consequently one can show that if there are terms of higher than second order in momentum in the dispersion relation, for a composite system moving in the same speed the energies and momenta do not sum up linearly,

$$\vec{p}_3 \neq \vec{p}_2 + \vec{p}_1 \qquad E_3 \neq E_1 + E_2 \,. \tag{3}$$

It is important to note that solutions of this problem have been developed, some examples are.[60,61]

Such problems prevents us to apply the GUP models to Relativistic Quantum Mechanics and Quantum Field Theory, which essentially restricts the energy regimes in which we can search for the remnants of QG effects, by preventing us from using the highest energy experiments currently available, *i.e.* LHC.

In the following sections, we will address these problems by extending the GUP up to second order in Planck length, to relativistic regimes (RGUP), we will explore the deformations of the Lorenz group and symmetries associated with it, and we will obtain Lagrangians allowing for the existence of minimum length for fields of spin-$0, 1/2, 1$.

2. Relativistic Generalized Uncertainty Principle[62]

Inspired by,[63] we will use the most general form of quadratic GUP algebra and extend it to a covariant expression in Minkowski spacetime with the following signature $\{-,+,+,+\}$. The particular form obtained for the commutator is as follows

$$[x^\mu, p^\nu] = i\hbar\,(1 + (\varepsilon - \kappa)\gamma p^\rho p_\rho)\,\eta^{\mu\nu} + i\,\hbar(\beta + 2\varepsilon)\gamma p^\mu p^\nu\,, \tag{4}$$

where $\mu\,, \nu \in \{0, 1, 2, 3\}$. For convenience it is useful to separate the dimensionality of the corrections into a dimensionful parameter γ, with the dimension of inverse momentum, and dimensionless parameters κ, β and ϵ (and also ξ in Eq. (7) below). The scale of the QG effects γ is defined as $\gamma = \frac{1}{(c\,M_{Pl})^2} = \frac{\ell_{\rm Pl}^2}{\hbar^2}$, where M_{Pl} is the Planck mass, and $\ell_{\rm Pl}$ is the Planck length. The minimum length we can obtain from the algebra Eq. (4) is of the order of the Planck length. Important to note is that Eq. (4) reduces in the non-relativistic ($c \to \infty$) limit to the one proposed in.[1] Furthermore, in the non-relativistic ($c \to \infty$), and non-GUP limit ($\gamma \to 0$) limit, Eq. (4) reduces to the standard Heisenberg algebra. We can clearly see from the commutator Eq. (4) that while x^μ and p^ν are the physical position and momentum, they are no longer canonically conjugate variables. Therefore, we introduce two auxiliary 4-vectors, x_0^μ and p_0^ν which are canonically conjugate, such that

$$p_0^\mu = -\,i\hbar\frac{\partial}{\partial x_{0\,\mu}}, \qquad\qquad [x_0^\mu, p_0^\nu] = i\hbar\eta^{\mu\nu}. \tag{5}$$

Then we assume that the physical position and momentum are both functions of the auxiliary ones,

$$x^\mu = x^\mu(x_0, p_0), \quad p^\mu = p^\mu(x_0, p_0)\,. \tag{6}$$

By expanding Eq. (6) in Taylor series, which we truncate up to first order in the QG scale γ, and imposition of commutativity in momentum space $[p_\mu, p_\nu] = 0$, we can write the general expressions of the physical position and momentum are as follows

$$x^\mu = x_0^\mu - \kappa\gamma p_0^\rho p_{0\rho} x_0^\mu + \beta\gamma p_0^\mu p_0^\rho x_{0\rho} + \xi\hbar\gamma p_0^\mu, \tag{7}$$

$$p^\mu = p_0^\mu\,(1 + \varepsilon\gamma p_0^\rho p_{0\rho})\,. \tag{8}$$

Using Eqs. (7) and (8), we can calculate the following expression for the position-position commutator

$$[x^\mu, x^\nu] = i\hbar\gamma\frac{-2\kappa + \beta}{1 + (\varepsilon - \kappa)\gamma p^\rho p_\rho}\,(x^\mu p^\nu - x^\nu p^\mu)\,. \tag{9}$$

Therefore as in,[1] in this case as well we arrive at a non-commutative spacetime.

We also note that the last two terms in Eq. (7) introduce a preferred direction of p_0^μ and therefore break isotropy of spacetime. Since this violates the principles of relativity, we will assume that $\beta = \xi = 0$ from now on.

2.1. *Lorentz and Poincaré algebra*

Using Eqs. (7) and (8), we now construct the generators of the Lorentz group

$$M^{\mu\nu} = p^\mu x^\nu - p^\nu x^\mu = [1 + (\varepsilon - \kappa)\gamma p_0^\rho p_{0\,\rho}]\, \tilde{M}^{\mu\nu}\,, \tag{10}$$

where $\tilde{M}^{\mu\nu} = p_0^\mu x_0^\nu - p_0^\nu x_0^\mu$ is the Lorentz generators constructed from the canonical variables x_0 and p_0. The commutator representative of the Poincaré algebra for the physical operators can then be calculated

$$[x^\mu, M^{\nu\rho}] = i\hbar[1 + (\varepsilon - \kappa)\gamma p^\rho p_\rho]\,(x^\nu \delta^{\mu\rho} - x^\rho \delta^{\mu\nu}) + i\hbar 2(\varepsilon - \kappa)\gamma p^\mu M^{\nu\rho} \tag{11a}$$

$$[p^\mu, M^{\nu\rho}] = i\hbar[1 + (\varepsilon - \kappa)\gamma p^\rho p_\rho]\,(p^\nu \delta^{\mu\rho} - p^\rho \delta^{\mu\nu})\,, \tag{11b}$$

$$[M^{\mu\nu}, M^{\rho\sigma}] = i\hbar\,(1 + (\varepsilon - \kappa)\gamma p^\rho p_\rho)\,(\eta^{\mu\rho} M^{\nu\sigma} - \eta^{\mu\sigma} M^{\nu\rho} - \eta^{\nu\rho} M^{\mu\sigma} + \eta^{\nu\sigma} M^{\mu\rho})\,. \tag{11c}$$

From Eqs. (11a,11b,11c), we can see that on the line $\varepsilon = \kappa$ in the parameter space, one has a non-trivial RGUP with an *unmodified* Poincaré algebra. On this line in parameter space, the RGUP algebra and the non-commutativity of spacetime coming from Eqs. (4) and (9) takes this form:

$$[x^\mu, p^\nu] = i\hbar\,(\eta^{\mu\nu} + 2\kappa\gamma p^\mu p^\nu)\,, \tag{12}$$

$$[x^\mu, x^\nu] = -2i\hbar\kappa\gamma\,(x^\mu p^\nu - x^\nu p^\mu)\,, \tag{13}$$

where $\kappa > 0$. We notice that for any one-dimensional spatial component, Eq. (12) mirrors the one obtained in.[1] Eqs. (12) and (13) have similarities to the ones proposed in.[53]

2.2. *Lorentz invariant minimum length and the Composition Law Problem*

The main reason for extending GUP to relativistic frameworks is to make its minimum uncertainty in position Lorentz invariant, or in other words to make a minimum length frame independent. In relativistic QM, position and momentum are promoted to operators and the Lorentz transformations Λ are represented by a unitary operator $U(p^\nu, M^{\rho\sigma})$, *i.e.* $U^* = U^{-1}$, where p^ν is the generator of translation and $M^{\rho\sigma}$ is the generator of rotations of the Poincaré group. The position and momentum in this case transform as follows

$$x'^\mu = U(p^\nu, M^{\rho\sigma}) x^\mu U^{-1}(p^\nu, M^{\rho\sigma})\,, \tag{14}$$

$$p'^\mu = U(p^\nu, M^{\rho\sigma}) p^\mu U^{-1}(p^\nu, M^{\rho\sigma})\,. \tag{15}$$

The operator $U(p^\nu, M^{\rho\sigma})$ can be expressed from the generators of the Poincaré algebra as

$$U(p^\nu, M^{\rho\sigma}) = \exp\left[i a_\nu p^\nu\right] \exp\left[i \frac{\omega_{\rho\sigma} M^{\rho\sigma}}{2}\right]\,, \tag{16}$$

where the coordinate system is translated by a vector a_μ and is rotated by $\omega_{\rho\sigma}$.

The position-momentum commutator transforms as follows

$$[x'^{\mu}, p'^{\nu}] = U[x^{\mu}, p^{\nu}]U^{-1}\,. \tag{17}$$

Substituting $[x^{\mu}, p^{\nu}]$ for its expression as given in Eq. (4), we get

$$[x'^{\mu}, p'^{\nu}] = U\left\{i\hbar\,(1+(\varepsilon-\kappa)\gamma p^{\rho}p_{\rho})\,\eta^{\mu\nu} + i\,\hbar(\beta+2\varepsilon)\gamma p^{\mu}p^{\nu}\right\}U^{-1} \tag{18a}$$

$$= i\hbar\,\left(1+(\varepsilon-\kappa)\gamma p'^{\rho}p'_{\rho}\right)\eta^{\mu\nu} + i\,\hbar(\beta+2\varepsilon)\gamma U p^{\mu}U^{-1}Up^{\nu}U^{-1} \tag{18b}$$

$$= i\hbar\,\left(1+(\varepsilon-\kappa)\gamma p'^{\rho}p'_{\rho}\right)\eta^{\mu\nu} + i\,\hbar(\beta+2\varepsilon)\gamma p'^{\mu}p'^{\nu}\,. \tag{18c}$$

Therefore, the commutator between position and momentum has the same form in every frame. Then, we can safely conclude that every frame will observe the same minimum measurable length.

For the composition law problem, we need to find the dispersion relation and see if it is quadratic or it has terms of higher order in momentum. As we know, the dispersion relation is connected to the Casimir invariants of the Poincaré algebra. In the unmodified case, there are two Casimir invariants: the momentum squared $p_0^{\mu}p_{0\mu}$; and the physical Pauli-Lubanski vector squared $\tilde{W}^{\mu}\tilde{W}_{\mu}$, where

$$\tilde{W}_{\mu} \equiv \frac{1}{2}\varepsilon_{\mu\nu\rho\sigma}\tilde{M}^{\nu\rho}p_0^{\sigma}\,. \tag{19}$$

In our case, both the Poincare algebra and the momentum and Pauli-Lubanski vectors are deformed. However, by taking the commutator between the physical momentum squared $p^{\mu}p_{\mu}$ and all the other generators of the algebra, it can easily be shown that it is a Casimir invariant of the modified Poincaré algebra presented in Eq. (11). This can be repeated for the Pauli-Lubanski vector squared as well.

This shows that our dispersion relation can be written as

$$p_{\mu}p^{\mu} = -m^2c^4\,. \tag{20}$$

As we can see, the dispersion relation is quadratic in the physical momentum which means that energies and momenta sum up linearly as they should. It is important to note that due to the fact that the physical momentum is a polynomial of the auxiliary one, the resulting equations of motion will be of higher than second order.

3. Effective Quantum Field Theory with Minimum Length[64,65]

Having cleared up the frame dependence and the composition law problem for our model, we can proceed to apply it to quantum field theory.

In the general case, the commutation relation we get for the position-position operator depends on the momentum. Therefore, it does not form an algebra and it cannot be represented by a smooth Lie manifold. For that reason we have chosen for further calculations to fix the model by making $\kappa = 0$ and $\epsilon = \gamma_0$. We can redefine the RGUP parameter as follows

$$\gamma = \frac{\gamma_0}{(M_{\mathrm{Pl}}c)^2}\,. \tag{21}$$

In this particular model, the physical position and momentum take the form

$$x^\mu = x_0^\mu \,, \tag{22a}$$
$$p^\mu = p_0^\mu \left(1 + \gamma p_0^\rho p_{0\rho}\right). \tag{22b}$$

From now on, the results will be presented in natural units, *i.e.* $c = \hbar = 1$. With the parameters redefined as such, the position-momentum commutator is

$$[x^\mu, p^\nu] = i\,\left(1 + \gamma p^\rho p_\rho\right)\eta^{\mu\nu} + 2i\,\gamma p^\mu p^\nu \,. \tag{23}$$

The Poincaré group corresponding to the RGUP above is represented by the following algebra

$$[x^\mu, M^{\nu\rho}] = i[1 + \gamma p^\rho p_{\,\rho}]\left(x^\nu \delta^{\mu\rho} - x^\rho \delta^{\mu\nu}\right) + i2\gamma p^\mu M^{\nu\rho} \,, \tag{24a}$$
$$[p^\mu, M^{\nu\rho}] = i[1 + \gamma p^\rho p_{\,\rho}]\left(p^\nu \delta^{\mu\rho} - p^\rho \delta^{\mu\nu}\right) \,, \tag{24b}$$
$$[M^{\mu\nu}, M^{\rho\sigma}] = i\left(1 + \gamma p^\rho p_{\,\rho}\right)\left(\eta^{\mu\rho} M^{\nu\sigma} - \eta^{\mu\sigma} M^{\nu\rho} - \eta^{\nu\rho} M^{\mu\sigma} + \eta^{\nu\sigma} M^{\mu\rho}\right) . \tag{24c}$$

It is important to note that the deformed Poincaré algebra presented above has the same irreducible representations, and therefore describes the same particles as the standard Poincaré algebra. This feature can be seen derived in Appendix B. As we already showed, the physical momentum squared is a Casimir invariant of the modified Poincaré algebra presented above in Eq. (24). Therefore, the Einstein dispersion relation for our case is

$$p^\mu p_\mu = -m^2 \,, \tag{25}$$

where p_μ is the physical momentum, the differential form of which is an equation of motion for any Lagrangian describing a boson field. The Dirac equations *i.e.*, the equations of motion describing the dynamics of fermion fields, can also be easily derived. Starting from the dispersion relation Eq. (25) and expressing it in terms of the auxiliary variables defined in Eq. (22a), we get the modified Klein-Gordon equation in its differential form

$$\left[\partial_\mu \partial^\mu \left(1 + \gamma \partial_\nu \partial^\nu\right)^2 + m\right]\phi = 0 \,. \tag{26}$$

Similarly, the differential form of the Dirac equation is shown to be

$$\left(\tau^\mu p_\mu - m\right)\psi = \left[\tau^\mu p_{0\,\mu}(1 + \gamma p_{0\rho} p_0^\rho) - m\right]\psi = 0 \,, \tag{27}$$

where τ^μ are the Dirac matrices and ψ is a Dirac spinor. We can show that as part of the Lorentz group the generators of the Clifford algebra $Cl_{(3,1)}(\mathbb{R})$, if the Casimir is preserved then the properties of the Clifford algebra will remain unchanged, as well. This is true in our case, thus,

$$\left[i\tau^\mu \partial_\mu (1 + \gamma \partial_\rho \partial^\rho)^2 - m\right]\psi = 0 \,, \tag{28}$$

and its Dirac conjugate are the equations of motion for the RGUP-QED Lagrangian.

4. RGUP Modified Lagrangians

In the previous section, we established the modified equations of motion for the scalar, vector, and spinor fields. Note that the equations of motion are differential equations of higher than second order. Therefore, the Lagrangians corresponding to these equations of motion need to have higher than second derivative. The methodology of working with higher derivative Lagrangians

$$L = L(\phi, \dot{\phi}, \ddot{\phi}, \ldots, \overset{(n)}{\phi}), \tag{29a}$$

$$\mathcal{L} = \mathcal{L}(\phi, \partial_{\mu_1}\phi, \partial_{\mu_1}\partial_{\mu_2}\phi, \ldots, \partial_{\mu_1}\ldots\partial_{\mu_n}\phi), \tag{29b}$$

is given by the Ostrogradsky method.[66–68] The Euler-Lagrange equations for theories with higher derivatives will have the form:

$$\frac{dL}{dq} - \frac{d}{dt}\frac{dL}{d\dot{q}} + \frac{d^2}{dt^2}\frac{dL}{d\ddot{q}} + \ldots + (-1)^n \frac{d^n}{dt^n}\frac{dL}{d(d^n q/dt^n)} = 0, \tag{30}$$

which in the case of fields is

$$\frac{\partial\mathcal{L}}{\partial\phi} - \partial_\mu \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)} + \partial_{\mu_1}\partial_{\mu_2}\frac{\partial\mathcal{L}}{\partial(\partial_{\mu_1}\partial_{\mu_2}\phi)} + \ldots + (-1)^m \partial_{\mu_1}\ldots\partial_{\mu_m}\frac{\partial\mathcal{L}}{\partial(\partial_{\mu_1}\ldots\partial_{\mu_m}\phi)} = 0. \tag{31}$$

The Ostrogradsky method allows us to reconstruct the Lagrangian describing the dynamics of scalar and spinor fields from their equations of motion.

4.1. *Scalar field Lagrangian*

We begin by assuming the most general form of higher derivative Lagrangian, which is one order higher than the equations of motion

$$\begin{aligned}\mathcal{L} = {} & \frac{1}{2}\partial_\mu\phi\partial^\mu\phi + \gamma\left(C_1\,\partial_\mu\partial^\mu\phi\,\partial_\nu\partial^\nu\phi + C_2\,\partial_\mu\phi\,\partial^\mu\partial_\nu\partial^\nu\phi + C_3\,\partial_\nu\partial^\nu\partial^\mu\phi\,\partial_\mu\phi\right) \\ & + \gamma^2\left(C_4\,\partial_\mu\partial^\mu\partial_\nu\phi\,\partial^\nu\partial_\rho\partial^\rho\phi + C_5\,\partial_\mu\partial^\mu\partial_\nu\partial^\nu\phi\,\partial_\rho\partial^\rho\phi + C_6\,\partial_\mu\partial^\mu\partial_\nu\partial^\nu\partial_\rho\phi\,\partial^\rho\phi\right. \\ & \left. + C_7\,\partial_\mu\partial^\mu\phi\,\partial_\nu\partial^\nu\partial_\rho\partial^\rho\phi + C_8\,\partial_\mu\phi\,\partial^\mu\partial_\nu\partial^\nu\partial_\rho\partial^\rho\phi\right) + C_9 m^2\phi^2,\end{aligned} \tag{32}$$

where $\partial_\mu = \partial/\partial x^\mu$. Using the Euler-Lagrange equation prescribed by the Ostrogradsky method Eq. (30), we obtain the following Lagrangian

$$\mathcal{L}_{\phi,\mathbb{R}} = \frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}m^2\phi^2 + \gamma\,\partial_\nu\partial^\nu\partial^\mu\phi\,\partial_\mu\phi + \frac{\gamma^2}{2}\partial_\mu\phi\,\partial^\mu\partial_\nu\partial^\nu\partial_\rho\partial^\rho\phi, \tag{33}$$

As for the Lagrangian for a complex scalar field ϕ, we generalize Eq. (33) by including additional terms obtaining

$$\begin{aligned}\mathcal{L}_{\phi,\mathbb{C}} = {} & \frac{1}{2}\left(\partial_\mu\phi\right)^\dagger\partial^\mu\phi - \frac{1}{2}m^2\phi^\dagger\phi + \gamma\left[\left(\partial_\nu\partial^\nu\partial^\mu\phi\right)^\dagger\partial_\mu\phi + \partial_\nu\partial^\nu\partial^\mu\phi\left(\partial_\mu\phi\right)^\dagger\right] \\ & + \frac{\gamma^2}{2}\left[\left(\partial_\mu\phi\right)^\dagger\partial^\mu\partial_\nu\partial^\nu\partial_\rho\partial^\rho\phi + \partial_\mu\phi\left(\partial^\mu\partial_\nu\partial^\nu\partial_\rho\partial^\rho\phi\right)^\dagger\right],\end{aligned} \tag{34}$$

such that hermiticity is restored, *i.e.* $\mathcal{L}^\dagger_{\phi,\mathbb{C}} = \mathcal{L}_{\phi,\mathbb{C}}$. Furthermore, it is worth noticing that Eq. (34) is consistent with Eq. (55) in[42] up to a numerical factor.

4.2. *Spinor field Lagrangian*

The first step in the derivation of the spinor field Lagrangian is to assume a general form of the Lagrangian, where the order of derivatives is determined by the order of the equation of motion Eq. (28). Moreover, an assumption is made that different terms will be multiplied by an arbitrary numerical coefficient

$$\mathcal{L}_\psi = \bar{\psi}\,[iC_1\tau^\mu\partial_\mu(1 + C_2\gamma\partial_\rho\partial^\rho) - C_3 m]\,\psi\,. \tag{35}$$

Next step is to prove that it has Eq. (28) as an equation of motion. Applying the Ostrogradsky method, one gets the following equations of motion for the field and its complex conjugate

$$C_1 i\tau^\mu\partial_\mu\psi + C_1C_2\gamma\partial_\rho\partial^\rho\psi - C_3 m\psi = 0, \tag{36}$$

$$C_1 i\tau^\mu\partial_\mu\bar{\psi} + C_1C_2\gamma\partial_\rho\partial^\rho\bar{\psi} - C_3 m\bar{\psi} = 0\,. \tag{37}$$

The equations of motion obtained through the Ostrogradsky method from Eq. (35) need to be identical to Eq. (28), which is obtained from the dispersion relation. Therefore, the Lagrangian corresponding to the QFT spinor with minimum length will be of the form

$$\mathcal{L}_\psi = \bar{\psi}\,[i\tau^\mu\partial_\mu(1 - \gamma\,\partial_\rho\partial^\rho) - m]\,\psi\,. \tag{38}$$

4.3. *$U(1)$ gauge field theory*

The gauge field Lagrangian is obtained in a different way. The Ostrogradsky method is not utilized in this case. The derivation is done by firstly assuming that the vector boson A^μ obeys the ususal $U(1)$ gauge symmetries. For the equations of motion, we assume that they have the same RGUP corrections as the KG equation of the form Eq. (26)

$$\partial_\mu F^{\mu\nu} = \partial_\mu\partial^\mu A^\nu + 2\gamma\partial_\mu\partial^\mu\partial_\rho\partial^\rho A^\nu = 0\,. \tag{39}$$

Defining the standard gauge invariant field strength tensor as

$$F_0^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu, \tag{40}$$

one can express the RGUP modified field strength tensor in terms of the standard one up to first order in γ, as follows:

$$F^{\mu\nu} = F_0^{\mu\nu} + 2\gamma\,\partial_\rho\partial^\rho F_0^{\mu\nu}\,. \tag{41}$$

Then Eq. (39) can be rewritten as

$$\partial_\mu F^{\mu\nu} = \partial_\mu F_0^{\mu\nu} + 2\gamma\partial_\rho\partial^\rho\partial_\mu F_0^{\mu\nu} + \gamma^2\partial_\sigma\partial^\sigma\partial_\rho\partial^\rho\partial_\mu F_0^{\mu\nu}\,. \tag{42}$$

A test of gauge invariance of $F^{\mu\nu}$ is carried through by considering the following gauge transformation of the four-potential

$$A^\mu \to A'^\mu = A^\mu + \partial^\mu\Lambda\,, \tag{43}$$

and the field strength tensor is shown to be gauge invariant. Thus, up to first order in the RGUP parameter γ, the gauge field Lagrangian reads

$$\mathcal{L}_A = -\frac{1}{4}F^{\mu\nu}F_{\mu\nu} = -\frac{1}{4}F_0^{\mu\nu}F_{\mu\nu 0} - \frac{\gamma}{2}F_{\mu\nu 0}\partial_\rho\partial^\rho F_0^{\mu\nu}\,. \tag{44}$$

Notice that both the field tensor in Eq. (41) and the gauge field Lagrangian Eq. (44) are invariant under $U(1)$ gauge transformations.

5. Feynman Rules

We use the Lagrangians derived above to formulate a RGUP deformed scalar and spinor electrodynamics. This is achieved by minimally coupling the lepton to the gauge fields. The Feynman rules, consisting of the propagators and vertices for both cases, are calculated using the standard methodology, which can be found in any QFT textbook.

5.1. *Propagators*

The Feynman propagator for the scalar field with a minimum length is the Green's function of the the modified KG equation in Eq. (26)

$$\left[\partial_\mu\partial^\mu\left(1+\gamma\partial_\nu\partial^\nu\right)+(mc)^2\right]G(x-x') = -i\delta(x-x')\,. \tag{45}$$

Expressing the Green's function $G(x-x')$ in terms of its Fourier transform

$$G(x-x') = \int\frac{d^4p_0}{(2\pi)^4}\tilde{G}(p_0)e^{-ip_0\cdot(x-x')}, \tag{46}$$

and substituting it in Eq. (45), we get

$$\int\frac{d^4p_0}{(2\pi)^4}\tilde{G}(p_0)\left[-p_0^2(1-\gamma p_0^2)+(mc)^2\right]e^{-ip_0\cdot(x-x')} = -i\int\frac{d^4p_0}{(2\pi)^4}e^{-ip_0\cdot(x-x')}\,. \tag{47}$$

The Fourier transform of the Feynman propagator is

$$\tilde{G}(p_0) = \frac{-i}{-p_0^2(1+\gamma p_0^2)+(mc)^2}\,, \tag{48}$$

while the propagator itself is

$$G(x-x') = \int\frac{d^4p_0}{(2\pi)^4}\frac{-i}{-p_0^2(1+\gamma p_0^2)+(mc)^2}e^{-ip_0\cdot(x-x')}\,. \tag{49}$$

With the exception of a little trick consisting of multiplying both sides by

$$\left[\tau^\mu p_{0\,\mu}(1-\gamma p_{0\rho}p_0^\rho)+m\right]\,, \tag{50}$$

we find the Dirac field propagator in the same way

$$G(x-x') = \int\frac{d^4p_0}{(2\pi)^4}\frac{-i\left[\tau^\mu p_{0\,\mu}(1+\gamma p_{0\rho}p_0^\rho)+m\right]}{p_0^\mu p_{0\,\mu}(1+\gamma p_{0\rho}p_0^\rho)^2-m^2}e^{-ip_0\cdot(x-x')}\,. \tag{51}$$

Again, the gauge field propagator can be treated in a similar manner. And the Feynman propagator is found to be

$$G(x-x') = \int \frac{d^4q_0}{(2\pi)^4} \frac{-i}{-q_0^2 + 2\gamma q_0^4} e^{-iq_0\cdot(x-x')}\,, \tag{52}$$

where q_0 is the auxiliary four-momentum of the gauge field.

This construction assumes that one can define Dirac delta functions in position space, and the minimal length arises when one tries to localize the fields.

5.2. *Vertices*

The complete set of Feynman rules for the system requires the calculation of the vertices for the charged and gauge fields. Starting from the Lagrangian in Eq. (34), one introduces the minimal coupling as follows

$$\partial_\mu \to D_\mu = \partial_\mu - ieA_\mu\,, \tag{53}$$

where A_μ is the four-potential or the gauge field.

Replacing partials in Eq. (34) by covariant derivatives, the full action of the minimally coupled complex scalar field and the gauge field is obtained. The action reads as follows

$$\begin{aligned}\int \mathcal{L}\, d^4x = \int \left[\mathcal{L}_A + \mathcal{L}_{\phi,\mathbb{C}}\right] d^4x = \int \Bigg\{ & \frac{1}{2}\left(D_\mu\phi\right)^\dagger D^\mu\phi - \frac{1}{2}m^2\phi^\dagger\phi \\ & - \frac{1}{4}F^{\mu\nu}F_{\mu\nu} + \gamma\left[\left(D_\nu D^\nu D^\mu\phi\right)^\dagger D_\mu\phi + D_\nu D^\nu D^\mu\phi\left(D_\mu\phi\right)^\dagger\right]\Bigg\} \\ & + \frac{\gamma^2}{2}\left[\left(D_\mu\phi\right)^\dagger D^\mu D_\nu D^\nu D_\rho D^\rho\phi + D_\mu\phi\left(D^\mu D_\nu D^\nu D_\rho D^\rho\phi\right)^\dagger\right]\Bigg\}\, d^4x\,.\end{aligned} \tag{54}$$

By expanding the Lagrangian we get a very rich theory

$$\begin{aligned}\mathcal{L} = {} & \frac{1}{2}\left(\partial_\mu\phi\right)^\dagger\partial^\mu\phi - ieA^\mu\left[\phi^\dagger\partial_\mu\phi - \phi\left(\partial_\mu\phi\right)^\dagger\right] - \frac{1}{2}m^2\phi^\dagger\phi + e^2A_\mu A^\mu\phi^\dagger\phi \\ & - \frac{1}{4}F^{\mu\nu}F_{\mu\nu}\gamma\Bigg\{\left(\partial_\nu\partial^\nu\partial^\mu\phi\right)^\dagger\partial_\mu\phi + \partial_\nu\partial^\nu\partial^\mu\phi\left(\partial_\mu\phi\right)^\dagger - \frac{1}{4}F^{\mu\nu}F_{\mu\nu}\partial_\mu\partial_\nu F^{\mu\nu} \\ & - ie\Bigg\{\left(\partial_\nu\partial^\nu A^\mu\right)\left[\phi^\dagger\partial_\mu\phi - \phi\left(\partial_\mu\phi\right)^\dagger\right] + 2\partial_\nu A^\mu\left[\left(\partial^\nu\phi\right)^\dagger\partial_\mu\phi - \partial^\nu\phi\left(\partial_\mu\phi^\dagger\right)\right] \\ & + A^\mu\left[\left(\partial_\nu\partial^\nu\phi\right)^\dagger\partial_\mu\phi - \partial_\nu\partial^\nu\phi\left(\partial_\mu\phi^\dagger\right)\right]\Bigg\} + e^2\Bigg\{A^\nu(\partial_\nu A_\mu)\left[\left(\partial^\mu\phi\right)^\dagger\phi + \left(\partial^\mu\phi\right)\phi^\dagger\right] \\ & + 2A^\nu A_\mu\left[\left(\partial^\mu\phi\right)^\dagger\partial_\nu\phi + \left(\partial^\mu\phi\right)\left(\partial_\nu\phi\right)^\dagger\right] + A^\nu A_\nu\left[\left(\partial^\mu\phi\right)^\dagger\partial_\mu\phi + \left(\partial^\mu\phi\right)\left(\partial_\mu\phi\right)^\dagger\right] \\ & - 2A^\mu A^\nu\left[\phi^\dagger\partial_\nu\partial_\mu\phi + \phi\left(\partial_\nu\partial_\mu\phi\right)^\dagger\right] + 2A^\mu(\partial_\nu\partial^\nu A_\mu)\phi^\dagger\phi \\ & + A^\mu(\partial^\nu A_\mu)\left[\phi^\dagger\partial_\nu\phi + \phi\left(\partial_\nu\phi\right)^\dagger\right] + A^\mu A_\mu\left[\phi^\dagger\partial_\nu\partial^\nu\phi + \phi\left(\partial_\nu\partial^\nu\phi\right)^\dagger\right]\Bigg\} \\ & + ie^3\Bigg\{A_\mu A_\nu A^\nu\left[\phi\left(\partial^\mu\phi\right)^\dagger - \phi^\dagger\partial^\mu\phi\right] + 2A^\mu A_\mu A^\nu\left[\phi^\dagger\partial_\nu\phi - \phi\left(\partial_\nu\phi\right)^\dagger\right]\Bigg\} \\ & + 2e^4A^\mu A_\mu A^\nu A_\nu\phi^\dagger\phi\Big\} + \mathcal{O}(\gamma^2)\,.\end{aligned} \tag{55}$$

The above expression contains all terms relevant to Feynman diagrams predicted by the usual scalar Quantum Electrodynamics (QED) Lagrangian with the addition of RGUP corrections. By counting the fields in each term, it is easy to see that up to 6-point vertices (2 scalar and 4 gauge) are allowed. This Lagrangian contains 74 Feynman diagrams, with coupling constants classified by powers of the fine structure constant α and the minimum length parameter γ, see Table 1. It is also worth mentioning that in the low energy limit $\gamma \to 0$ we recover the usual Lagrangian for a complex scalar fields.

Table 1. Classification of the Feynman vertices arising from Eq. (55) in terms of the powers of the coupling constants: α the fine structure constant; γ the minimum length coefficient.

	Powers of γ			
Powers of α	$\alpha^{1/2}$	$\alpha^{1/2}\gamma$	$\alpha^{1/2}\gamma^2$	$\alpha^{1/2}\gamma^3$
	α	$\alpha\gamma$	$\alpha\gamma^2$	$\alpha\gamma^3$
	N/A	$\alpha^{3/2}\gamma$	$\alpha^{3/2}\gamma^2$	$\alpha^{3/2}\gamma^3$
	N/A	$\alpha^2\gamma$	$\alpha^2\gamma^2$	$\alpha^2\gamma^3$
	N/A	$\alpha^{5/2}\gamma$	$\alpha^{5/2}\gamma^2$	$\alpha^{5/2}\gamma^3$
	N/A	$\alpha^3\gamma$	$\alpha^3\gamma^2$	$\alpha^3\gamma^3$

Similar procedure is done for the Dirac field Lagrangian the full RGUP-QED action reads

$$\begin{aligned} S = \int \mathcal{L}\, d^4x &= \int \left[\mathcal{L}_A + \mathcal{L}_\psi\right] d^4x \\ &= \int \bar{\psi}\left[i\tau^\mu D_\mu\psi - \gamma\bar{\psi}i\tau^\mu D_\mu D_\nu D^\nu\psi - \frac{1}{4}F^{\mu\nu}F_{\mu\nu}\right] d^4x\,. \end{aligned} \tag{56}$$

We can read off the vertices after we expand the covariant derivatives in the minimally coupled modified Dirac field Lagrangian Eq. (38)

$$\begin{aligned} \mathcal{L}_\psi = {} & i\bar{\psi}\tau^\mu\partial_\mu\psi + i\gamma\bar{\psi}\tau^\mu\partial^\rho\partial_\rho\partial_\mu\psi - m\bar{\psi}\psi \\ & - e\left[\bar{\psi}\tau^\mu A_\mu\psi - 2\gamma\bar{\psi}\tau^\mu\left(\partial_\mu A^\rho\right)\partial_\rho\psi - 2\gamma\bar{\psi}\tau^\mu A^\rho\partial_\mu\partial_\rho\psi - \gamma\bar{\psi}\tau^\mu A_\mu\partial^\rho\partial_\rho\psi\right] \\ & - ie^2\gamma\left[2\bar{\psi}\tau^\mu A_\mu A^\rho\partial_\rho\psi + 2\bar{\psi}\tau^\mu\left(\partial_\mu A^\rho\right)A_\rho\psi - \bar{\psi}\tau^\mu A^\rho A_\rho\partial_\mu\psi\right] \\ & - e^3\gamma\bar{\psi}\tau_\mu A^\mu A^\rho A_\rho\psi\,. \end{aligned} \tag{57}$$

Up to five particle vertices allowed, they include always two fermions and from one to three gauge bosons. Furthermore, the coupling constants for each vertex are a product of powers of the electronic charge e and the RGUP coefficient γ. In fact, the power of the electronic charge determines how many bosons couple to the vertex and the power of γ is 0 for the usual terms and 1 for the RGUP corrections terms. As before we can classify the coupling constants in Table 2.

Table 2. Classification of the coupling constants in Eq. (57) in terms of the powers: α the fine structure constant; γ the minimum length coefficient.

	Powers of γ	
	$\alpha^{1/2}$	$\alpha^{1/2}\gamma$
Powers of α	N/A	$\alpha\gamma$
	N/A	$\alpha^{3/2}\gamma$

6. RGUP Corrections to QED Scattering Amplitudes

The calculations for the scattering amplitudes can be quite cumbersome so we will not present them in full here. If the reader is interested the full calculations are presented in.[64,65,69]

The particular case we will be studying is an electron-muon scattering. We made this choice to avoid mass degeneracies which will complicate our calculations without helping in clarifying the concept. First when calculating the scattering amplitudes the focus will be on the 3-point vertices, containing up to first order the RGUP coefficient γ. This approximation is justified by the fact that the 3-point vertices will have the largest contribution to the scattering amplitudes.

In brief, we begin by calculating the transition amplitudes for a single three legged vertex. For the scalar field we get

$$\begin{aligned} T_{fi} =& -i\int eA^{\mu}\left[\phi_f^{\dagger}\partial_{\mu}\phi_i - \phi_f\partial_{\mu}\phi_i^{\dagger}\right]d^4x \\ & -i\int e\gamma A^{\mu}\left[4\partial_{\nu}\partial^{\nu}\phi^{\dagger}\partial_{\mu}\phi + 4\partial^{\nu}\phi^{\dagger}\partial_{\nu}\partial_{\mu}\phi + \phi^{\dagger}\partial_{\nu}\partial^{\nu}\partial_{\mu}\phi - 4\partial_{\nu}\partial^{\nu}\phi\partial_{\mu}\phi^{\dagger}\right. \\ & \left. -4\partial^{\nu}\phi\partial_{\nu}\partial_{\mu}\phi^{\dagger} - \phi\partial_{\nu}\partial^{\nu}\partial_{\mu}\phi^{\dagger}\right]d^4x\,. \end{aligned} \tag{58a}$$

In the QED case we get for the different components

$$\begin{aligned} T_{fi} =& \, i\int e\bar{\psi}_f\tau^{\mu}A_{\mu}\psi_i\,d^4x + i\int 2e\gamma\partial_{\rho}\bar{\psi}_f\tau^{\rho}A^{\mu}\partial_{\mu}\psi_i\,d^4x\,, \\ & -i\int e\gamma\bar{\psi}\tau^{\mu}A_{\mu}\partial^{\rho}\partial_{\rho}\psi\,d^4x\,. \end{aligned} \tag{59a}$$

The separation in different terms is purely for convenience.

We then couple two Feynman vertices thorough a gauge boson A^{μ}, and isolate the modified invariant amplitude squared

$$\left|\mathfrak{M}_{\text{Scalar}}\right|^2 = 4\pi\alpha\frac{3+\cos\theta}{1-\cos\theta}\left[1+8\gamma E^2(1-\cos\theta)\right]\,, \tag{60a}$$

$$\left|\mathfrak{M}_{\text{spinor}}\right|^2 = 32\pi^2\epsilon_0^2\alpha\left[\frac{t^2+u^2}{s^2} + \frac{1}{2}\gamma(m_e^2+m_{\text{muon}}^2)\frac{tu-u^2}{s^2}\right]\,, \tag{60b}$$

where s, t, u are the Mandelstam variables given by

$$s = (k + k')^2 = (p + p')^2 \approx 2k \cdot k' \approx 2p \cdot p' \,, \tag{61a}$$

$$t = (k - p)^2 = (p' - k')^2 \approx -2k \cdot p \approx -2k' \cdot p' \,, \tag{61b}$$

$$u = (k - p')^2 = (p - k') \approx -2k \cdot p' \approx -2p \cdot k' \,. \tag{61c}$$

From here, it is easy to calculate the RGUP scaled transition rates, from which we can isolate a formula for the differential cross-ectons for both cases. For the scalar fields, the differential cross-section is

$$\left.\frac{d\sigma}{d\Omega}\right|_{CM} = \frac{1}{4\,s}\alpha^2 \left(\frac{3 + \cos\theta}{1 - \cos\theta}\right)^2 \left[1 + 16\gamma E^2(1 - \cos\theta)\right] \,, \tag{62}$$

and for the spinors

$$\left.\frac{d\sigma}{d\Omega}\right|_{CM} = \frac{\alpha^2}{4\,s}\left[\frac{1}{2}\left(1 + \cos^2\theta\right) + \frac{1}{4}\gamma(m_e^2 + m_{\text{muon}}^2)\left(\cos\theta + \cos^2\theta\right)\right] \,. \tag{63}$$

As one can see from the differential cross-section for the scalar fields Eq. (62), the magnitude og QG effects depends on the energy of the scattering squared, and it will be largest for the backscattering. We can see that this is also the case in the spinor case Eq. (63). It is interesting to note that for the spinor case the corrections depend on the mass squared of the particles involved. This suggests that minimum length effects on scattering amplitudes may be measurable for electromagnetic scattering of heavier systems, such as scattering of heavy ions. Applied to existing data from the Xe-Xe scattering observed in the ATLAS experiment, the order of magnitude of the corrections is $\gamma\, m_{\text{Xe}}^2/4 \sim 10^{-34}$.[70] The respective upper bounds on the RGUP parameter are then set to be $\gamma_0 < 10^{34}$.

7. Conclusion

In this work we have extended the Generalized Uncertainty Principle to relativistic framework. This leads to the solution of two major problems: the dependence of the minimum measurable length on the frame of reference; and the composition law problem. This allowed us to extend the reach of GUP from experiments and effects in Quantum Mechanics into Quantum Fired Theory. We achieved that through the formulation of Effective Field Theory with minimum length. Further, we were able to calculate the scattering amplitudes for high-enegy scattering of scalar and spinor particles. Comparing our results to data collecd in the ATLAS experiments, we were able to obtain bounds on the RGUP parameters, *i.e.* $\gamma_0 < 10^{34}$. This bound does not seem impressive on the first glance, however, it is sixteen orders of magnitude improvement compared to previous results from purely quadratic GUP models.

Additionally, we have already been able to obtain RGUP modified action for a spin-2 particle, and through the classical limit connect it to quadratic gravity, allowing us to test our ideas into fields like cosmological inflation.

The results presented here provide a valuable step to extend the reach of Quantum Gravity Phenomenology to the most highly energetic earthbound experiments like LHC. For example, we need to generalize the results here for the gauge group of the Standard Model $U(1)\otimes SU(2)\otimes SU(3)$. Additionally, the gauge field Lagrangian can be used to calculate corrections to phenomena in classical electrodynamics and light propagation, amongst others, like cosmology with weakly self-interacting photons, gravitational waves, and Higgs mechanism and mass.

Appendix A. Ostrogradsky Method and Vacuum Instability

The Ostrogradsky method is a mathematical constructions allowing one to work with higher derivative Lagrangians.[66–68] One of the major issues with it, is the instability of the Hamiltonian, arising when one considers higher than second order derivative. The instability for the particular case presented in here is discussed in the following appendix. We show that the Hamiltonian for a scalar field is positively defined in sub Planckian regimes, thus fixing the applicable domain for our Effective field theory.

We from the equation of motion for the real scalar field, obtained from the modified dispersion relation which corresponds to the Casimir operator of the modified Poincaré group defined in[62]

$$p_0^\rho p_{0\rho}(1+2\alpha\gamma^2 p_0^\sigma p_{0\sigma}) = -(mc)^2\,. \tag{A.1}$$

The Lagrangian for a real scalar field is derived by assuming the most general form of the Lagrangian, and applying the Ostrogradsky method to obtain its equations of motion and comparing to Eq. (A.1). The form of the Lagrangian is

$$\mathcal{L}_{\phi,\mathbb{R}} = \frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}m^2\phi^2 + \gamma\,\partial_\nu\partial^\nu\partial^\mu\phi\,\partial_\mu\phi\,. \tag{A.2}$$

The generalized coordinates are defined as

$$q_1 \equiv \phi \quad q_2 \equiv \partial_\mu\partial^\mu\phi\,. \tag{A.3}$$

The generalized momenta are then derived as

$$\pi^{\mu\rho}_{\rho} = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\partial_\rho\partial^\rho\phi)} = 2\gamma\partial^\mu\phi\,, \tag{A.4a}$$

$$\pi^\mu = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)} - \partial_\sigma\partial^\sigma\pi^{\mu\rho}_{\rho} = \partial^\mu\phi\,. \tag{A.4b}$$

The Hamiltonian density is then obtained using the Ostrogradsky Legendre transformations

$$\mathcal{H} = \pi^\mu\partial_\mu\phi + \pi^{\mu\rho}_{\rho}\partial_\sigma\partial^\sigma\partial_\mu\phi - \frac{1}{2}\pi^\mu\pi_\mu - \pi^{\mu\rho}_{\rho}\partial^\sigma\partial_\sigma\pi_\mu + \frac{1}{2}m\phi^2 \tag{A.5a}$$

$$= \frac{1}{2}\pi^\mu\pi_\mu + \frac{1}{2}m^2\phi^2\,. \tag{A.5b}$$

We can easily see that the above is positive definite. However, we can also see that the correction terms cancel, the Quantum Gravity corrections are hidden in the dispersion relation of ϕ. The field ϕ is solution of Eq. (A.1) which has four different solutions all containing Quantum Gravity corrections. The calculation above is done in the framework of De Donder Weyl Covariant Hamiltonian Formulation of Field Theory.

Considering the same definition of generalized coordinates presented in Eq. (A.3), one can derive the field momenta outside of the De Donder Weyl formulation as

$$\pi^{\rho}_{\rho} = \frac{\partial \mathcal{L}}{\partial(\partial_{\rho}\partial^{\rho}\dot{\phi})} = 2\gamma\dot{\phi}\,, \tag{A.6a}$$

$$\pi = \frac{\partial \mathcal{L}}{\partial(\dot{\phi})} - \partial_{\sigma}\partial^{\sigma}\pi^{\rho}_{\rho} = \dot{\phi}\,. \tag{A.6b}$$

Performing the Legendre transformation the Hamiltonian density is obtained as

$$\begin{aligned}\mathcal{H} &= \pi\dot{\phi} + \pi^{\rho}_{\rho}\partial_{\sigma}\partial^{\sigma}\dot{\phi} - \frac{1}{2}\pi\pi - \pi^{\rho}_{\rho}\partial^{\sigma}\partial_{\sigma}\pi + \frac{1}{2}m\phi^2 \\ &\quad + \frac{1}{2}\left(\nabla\phi\right)\cdot\left(\nabla\phi\right) + \gamma\left(\nabla\phi\right)\cdot\left(\partial_{\sigma}\partial^{\sigma}\nabla\phi\right) \qquad \text{(A.7)} \\ &= \frac{1}{2}\pi\pi + \frac{1}{2}m\phi^2 + \frac{1}{2}\left(\nabla\phi\right)\cdot\left(\nabla\phi\right) + \gamma\left(\nabla\phi\right)\cdot\left(\partial_{\sigma}\partial^{\sigma}\nabla\phi\right)\,. \qquad \text{(A.8)}\end{aligned}$$

We can not be sure if he Hamiltonian density is positive definite. This is due to the fact that one is not sure of the sign of the term proportional to $\gamma = \frac{\gamma_0}{(M_{\mathrm{Pl}}\,c)^2}$. If one assumes that γ_0 is of the order one, the coefficient is $\gamma \sim 10^{-38}$. Therefore, for energies smaller than the Planck energy $E < E_{Pl}$, the leading order terms in Eq. (A.7) are several orders of magnitude bigger than the quantum gravity corrections, which means that the Hamiltonian density on the whole is positive definite and does *not* have Ostrogradsky instability. Conclusion about the positive definition of the Hamiltonian for energies bigger than the Planck energy $E > E_{Pl}$ cannot be drawn. Making the QFT presented here an effective theory.

Appendix B. Modified Poincaré Algebra Representations

Let us explore the RGUP modified Poincaré algebra. The physical position x_{μ} and momentum p_{μ} are functions of the auxiliary ones represented as

$$x^{\mu} = x^{\mu}_{0} \tag{B.1a}$$

$$p^{\mu} = p^{\mu}_{0}\left(1 + \gamma p^{\rho}_{0}p_{0\rho}\right). \tag{B.1b}$$

While the Lorentz generators are defined as

$$M^{\mu\nu} = p^{\mu}x^{\nu} - p^{\nu}x^{\mu} = \left[1 + \gamma p^{\rho}_{0}p_{0\,\rho}\right]\tilde{M}^{\mu\nu}\,, \tag{B.2}$$

where it is wort mentioning that all the results are truncated to first order in the RGUP parameter γ. The modified Poincaré algebra is then calculated to be

$$[x^\mu, M^{\nu\rho}] = i\hbar[1+\gamma p^\rho p_\rho]\,(x^\nu\delta^{\mu\rho} - x^\rho\delta^{\mu\nu}) + i\hbar 2\gamma p^\mu M^{\nu\rho} \tag{B.3a}$$

$$[p^\mu, M^{\nu\rho}] = i\hbar[1+\gamma p^\rho p_\rho]\,(p^\nu\delta^{\mu\rho} - p^\rho\delta^{\mu\nu})\,, \tag{B.3b}$$

$$[M^{\mu\nu}, M^{\rho\sigma}] = i\hbar\,(1+\gamma p^\rho p_\rho)\,(\eta^{\mu\rho}M^{\nu\sigma} - \eta^{\mu\sigma}M^{\nu\rho} - \eta^{\nu\rho}M^{\mu\sigma} + \eta^{\nu\sigma}M^{\mu\rho})\,. \tag{B.3c}$$

We can show that the physical rotations J_i and boosts K_i are as follows

$$J_i = \frac{1}{2}\varepsilon_{imn}M^{mn} = \frac{1}{2}\,(1+\gamma p^\rho p_\rho)\,\varepsilon_{imn}\tilde{M}^{mn} \tag{B.4a}$$

$$K_i = M_{0i} = (1+\gamma p^\rho p_\rho)\,\tilde{M}_{0i}\,, \tag{B.4b}$$

The algebra for which is

$$[J_i, J_j] = -i\varepsilon_{ijk}\,(1+\gamma p^\rho p_\rho)\,J^k\,, \tag{B.5a}$$

$$[K_i, K_j] = i\varepsilon_{ijk}\,(1+\gamma p^\rho p_\rho)\,J^k\,, \tag{B.5b}$$

$$[J_i, K_j] = i\varepsilon_{ijk}\,(1+\gamma p^\rho p_\rho)\,K^k\,. \tag{B.5c}$$

Once again we can define new set of this time physical operators A_i and B_i

$$A_i = \frac{1}{2}\,(J_i + iK_i) = \frac{1}{2}\,(1+\gamma p^\rho p_\rho)\,\left(\tilde{J}_i + i\tilde{K}_i\right) \tag{B.6a}$$

$$B_i = \frac{1}{2}\,(J_i - iK_i) = \frac{1}{2}\,(1+\gamma p^\rho p_\rho)\,\left(\tilde{J}_i - i\tilde{K}_i\right)\,. \tag{B.6b}$$

Which form the following algebra

$$[A_i, A_j] = -i\varepsilon_{ijk}\,(1+\gamma p^\rho p_\rho)\,A^k\,, \tag{B.7a}$$

$$[B_i, B_j] = -i\varepsilon_{ijk}\,(1+\gamma p^\rho p_\rho)\,B^k\,, \tag{B.7b}$$

$$[A_i, B_j] = 0\,. \tag{B.7c}$$

We notice that once again this algebra is equivalent to $SU(2)\otimes SU(2)$ algebra. The irreducible representation of which are scalar $(0,0)$, spinors/fermions $(0,1/2)$ and $(1/2,0)$, vector bosons/ photons $(1/2,1/2)$, and potentially gravitons $(1,1)$. We have taken two things in consideration: First that the modified Poincaré algebra has both the auxiliary momentum squared $p_{0\,\mu}p_0^\mu$ and the physical momentum squared $p_\mu p^\mu$ as Casimir invariants; And second that those quantities are scalars and therefore modify the structure constants of the algebra without actually changing its physical properties.

Many quantum gravity theories predict several interesting phenomenological features such as minimal length scales and maximal momenta. Generalized uncertainty principles (GUPs), which are extensions of the standard Heisenberg uncertainty principle, have proven very useful in modelling the effects of such features on physics at sub-Planck energy scales. In this talk, we use a GUP modelling maximal momentum to establish a correspondence between the GUP modified dynamics of a massless spin 2 field and Stelle gravity with suitably constrained parameters. Thus, Stelle gravity can be regarded as the classical manifestation of the imposition of a momentum cutoff at the quantum gravity level. We then study the applications of Stelle gravity to cosmology. Specifically, we analytically show that Stelle gravity, when applied to a homogeneous, isotropic background, leads to inflation with exit. Lastly, using numerical simulations and data from CMB observations, we obtain strong bounds on the GUP parameter. Unlike previous works which fixed only upper bounds for GUP parameters, we show that we can bound the GUP parameter from above and from below.

Keywords: Generalized Uncertainty Principles, Quadratic Gravity, Inflation, Based on [1]

1. Introduction

Generalized Uncertainty Principles (GUPs) are phenomenological tools used to model generic features of Quantum Gravity theories such as minimal measurable length-scales[2] and maximal momentum.[3] Since GUPs have traditionally been formulated in non-covariant settings, they have primarily been used for computing Planck scale corrections to classical and quantum *mechanics*. Studying corrections to quantum *field theory* necessitates the use of a covariant GUP. Recently, Todorinov et al. introduced a class of such GUPs, and their effects on relativistic quantum mechanics were elucidated.[4] Following this, the authors considered a covariant, maximal momentum GUP modeled by the modified commutator (we set $\hbar = c = 1$)

$$[x^\mu, p^\nu] = i\eta^{\mu\nu}(1 - \gamma p^\sigma p_\sigma) - 2i\gamma p^\mu p^\nu \tag{1}$$

and studied the effects of this RGUP on free spin-0,[5] spin-1/2[6] and spin-1 fields. Combining these observations, the corrections to scalar and spinor electrodynamics were also obtained.[5,6] A natural follow-up would be to study the effects of GUPs on spin-2 fields (and, by extension, General Relativity). We would then have a complete lexicon detailing the effects of GUPs on all the "basic" quantum fields. Practically, such a study would also allow us to study deviations from General Relativity (GR) in the strong-field regime.

2. Computing RGUP Corrections — An Overview

From the RGUP (1), it is clear that the position and momentum operators are no longer canonically conjugate. The introduction of a "canonical" 4-momentum p_0^μ satisfying $[x^\mu, p_0^\nu] = i\eta^{\mu\nu}$ simplifies calculations considerably. The "physical" 4-momentum p^μ can be expressed in terms of p_0^μ as[5,6]

$$p^\mu = p_0^\mu(1 - \gamma p_{0\nu} p_0^\nu). \tag{2}$$

We can break down the procedure followed for computing RGUP corrections to QED into stages:

A. Compute the RGUP modified Poincare algebra and show that $p^\mu p_\mu$ is a Casimir operator.
B. Starting with the free field equations for spin-0, spin-1/2 and spin-1, obtain the modified EOM by replacing the canonical 4-momentum by the physical 4-momentum.
C. Using the Ostrogradsky approach, find actions that yield the modified EOM.
D. Minimally couple the matter and gauge field actions to obtain the modified QED action.
E. Compute corrections to cross-sections arising from additional interaction terms and compare with existing high-energy experiments.

When computing corrections to the spin-2 field, our aim is not to evaluate cross-sections but to search for modifications to GR. Hence, the procedure we must follow is slightly different. As with QED, we proceed with finding the GUP-modified EOM for the spin-2 field. After this, however, to connect our results to GR, we search for modified gravity theories *whose EOM, in the linear limit, match the GUP modified spin-2 field equations*. We then claim that this modified gravity theory can be regarded as the classical limit of spin-2 theory with the imposition of a maximal momentum scale.

3. RGUP Corrections to the Spin-2 Field

While the spin-2 field equations can be obtained by simply linearizing the Einstein field equations, the RGUP corrections to the EOM seem more natural if we instead

begin with a field theoretical approach. Such an approach was first outlined by Gupta[7] and popularized by Feynman[8] and can be summarized as follows:

A. The Lagrangian for the *free* spin-2 field must be bilinear in the field, $h_{\mu\nu}$, and its derivatives. The relevant bilinears are easily listed out.
B. Since the gravitational force is long range, the mediating gauge bosons must be massless. Thus, we may assume that the Lagrangian has no mass term and is strictly a function of field derivatives.
C. We can construct a *minimal* list by identifying pairs of bilinears that differ by surface terms. We can thus fix the action up to undetermined coefficients. In particular, we have

$$\mathcal{L} = ah_{\mu\nu,\sigma}h^{\mu\nu,\sigma} + bh_{\mu\nu}{}^{,\nu}h^{\mu\sigma}{}_{,\sigma} + ch_{\mu\nu}{}^{,\nu}h^{\sigma}{}_{\sigma,\mu} + dh_{\mu}{}^{\mu}{}_{,\sigma}h^{\nu}{}_{\nu}{}^{,\sigma} \tag{3}$$

D. *If* matter-gravity interactions were present, we would presumably have an interaction term of the form $\lambda h_{\mu\nu}T^{\mu\nu}$. By adding such a term to the above action and appealing to energy-momentum conservation (i.e. $T^{\nu}_{\mu\nu} = 0$), we get

$$(2a+b)\Box h_{\mu\nu}{}^{\nu} + (b+c)h^{;\nu\sigma}_{\nu\sigma}{}_{,\mu} + (c+2d)\Box h_{\nu}{}^{\nu}{}_{,\mu} = 0 \tag{4}$$

which fixes the coefficients.

Thus, up to an irrelevant scale factor, we see that the Lagrangian for the free spin-2 field is given by

$$\mathcal{L}_{free} = \frac{1}{2}h_{\mu\nu,\sigma}h^{\mu\nu,\sigma} - h_{\mu\nu}{}^{,\nu}h^{\mu\sigma}{}_{,\sigma} + h_{\mu\nu}{}^{,\nu}h^{\sigma}{}_{\sigma,\mu} - \frac{1}{2}h_{\mu}{}^{\mu}{}_{,\sigma}h^{\nu}{}_{\nu}{}^{,\sigma} \tag{5}$$

The EOM are obtained from the resulting action by variation

$$-G^{L}_{\mu\nu} = \Box h_{\mu\nu} - h_{\mu\sigma,\nu}{}^{\sigma} - h_{\nu\sigma,\mu}{}^{\sigma} + h_{\sigma,\mu\nu}{}^{\sigma} + \eta_{\mu\nu}h^{;\sigma\rho}_{\sigma\rho} - \eta_{\mu\nu}\Box h_{\sigma}{}^{\sigma} = 0, \tag{6}$$

where $G^{L}_{\mu\nu}$ is the linearized Einstein tensor. The RGUP modified EOM are obtained from the position space representation of (2) (i.e. $\partial_\mu \to \partial_\mu(1-\gamma\Box)$). We have

$$G^{L}_{\mu\nu} + \gamma\mathcal{G}_{\mu\nu} = 0, \tag{7}$$

where

$$\mathcal{G}_{\mu\nu} = \Box^2 h_{\mu\nu} - \Box h_{\mu\sigma,\nu}{}^{,\sigma} - h_{\nu\sigma\mu}{}^{,\sigma}. + \Box h_{\sigma,\mu\nu}{}^{,\sigma} + \eta_{\mu\nu}h^{;\sigma\rho}_{\sigma\rho} - \eta_{\mu\nu}\Box^2 h^{\sigma}_{\sigma}. \tag{8}$$

4. Stelle Gravity and GUP modified GR

The Einstein-Hilbert action describing the most general quadratic gravity theory (Stelle gravity) is[9]

$$S_{Stelle} = \int d^4x\sqrt{-g}[\frac{1}{2\kappa^2}R - \alpha R_{\mu\nu}R^{\mu\nu} + \beta R^2]. \tag{9}$$

By studying static, localized and isotropic solutions in the linear limit, it was shown[9] that the resultant theory contains two extra gauge bosons with masses $\frac{1}{\sqrt{2\alpha}\kappa}$ and

$\frac{1}{\sqrt{4(3\beta-\alpha)}\kappa}$. where $\kappa^2 = 1/8\pi G$. To avoid tachyonic instabilities, α and β must satisfy

$$3\beta \geq \alpha \geq 0. \tag{10}$$

The EOM for Stelle gravity are

$$\frac{1}{2\kappa^2}G_{\mu\nu} + (\alpha - 2\beta)R_{;\mu\nu} - \alpha\Box R_{\mu\nu} - \left(\frac{\alpha}{2} - 2\beta\right) g_{\mu\nu}\Box R - 2\alpha R^{\rho\sigma}R_{\mu\rho\nu\sigma} \tag{11}$$
$$+2\beta R R_{\mu\nu} + \frac{1}{2}g_{\mu\nu}(\alpha R^{\rho\sigma}R_{\rho\sigma} - \beta R^2) = 0.$$

To first order in $h_{\mu\nu} \equiv g_{\mu\nu} - \eta_{\mu\nu}$ (where $\eta_{\mu\nu}$ is the Minkowski metric), we have

$$\frac{1}{2\kappa^2}G^L_{\mu\nu} - (\alpha - 2\beta)(\Box h^{\lambda}_{\lambda,\mu\nu} - h^{\lambda,\rho}_{\rho,\lambda\mu\nu}) + \frac{\alpha}{2}(\Box^2 h_{\mu\nu} + \Box h^{\lambda}_{\lambda,\mu\nu} - \Box h^{\lambda}_{\mu,\lambda\nu} - \Box h^{\lambda}_{\nu,\lambda\mu})$$
$$+ \left(\frac{\alpha}{2} - 2\beta\right)\eta_{\mu\nu}(\Box^2 h^{\lambda}_{\lambda} - \Box h^{\lambda\rho}_{,\lambda\rho}) = 0. \tag{12}$$

It is easy to show that (12) match (7) perfectly when $\alpha = 2\beta = \gamma/\kappa^2$. From (10), this means that we must have $\gamma \geq 0$. Thus, we may claim that $\alpha = 2\beta$ Stelle gravity is a modified gravity theory modelling maximal momentum. Note, however, that it is by no means the *unique* modified gravity theory modelling maximal momentum. This is because the effects of curvature terms of order at least three will not appear in the linear regime. Thus, a more precise statement would be that $\alpha = 2\beta$ Stelle gravity is the *minimally modified, metric-only* theory of gravity which models the effects of maximal momentum.

There are two further points worthy of notice. First, it has been shown[10,11] that Stelle Gravity (and thus GUP modified gravity) does not contain malicious ghosts. Second, when $\alpha = 2\beta$, the additional gauge bosons mentioned earlier have *equal* masses. In this sense, GUP modified GR is a *degenerate* theory.

5. Applications to Cosmology

It is well known that quantum corrections to GR can lead to inflation. A natural question to ask is whether we can obtain inflation from GUP modified GR. To answer this, we compute the EOM for *generic* Stelle gravity (with parameters α and β) in an FRW background. We assume a flat background although the results can be extended. In terms of the Hubble parameter $H(t) \equiv \dot{a(t)}/a(t)$, we have

$$H^2 - 4\lambda[\dot{H}^2 - 2H\ddot{H} - 6H^2\dot{H}] = 0 \tag{13}$$

and

$$3H^2 + 2\dot{H} + \lambda\left[18H^2\dot{H} + 9\dot{H}^2 + 12H\ddot{H} + 2\dddot{H}\right] = 0. \tag{14}$$

where the arguments have been suppressed and $\lambda \equiv (3\beta - \alpha)/\kappa^2$. From these equations, it is clear that the *qualitative* dependence of the solutions is *independent* of

the parameter values. Thus, we can qualitatively study the dynamics of *any* Stelle gravity theory by observing the dynamics of one particular case. Moreover, since Stelle gravity with $\alpha = 0$ corresponds to the Starobinsky action[12] which is a well studied inflationary model, it is clear that *any* Stelle gravity theory and in particular GUP modified GR leads to inflation.

6. Numerics

We can also graphically verify the existence of inflation with exit. To do so, we would like to numerically solve the EOM and study the properties of the resulting solutions. While there are apparently two equations, (13) and (14), the two are completely equivalent as they are related via the Bianchi identities. Therefore, it is preferable to solve (13) as it is second order in time as opposed to (14) which is third order. However, the large scale of H during inflation and the small scale of γ make it difficult to solve (13) numerically. We, therefore, define the following dimensionless variables:

$$s = \frac{t}{\sqrt{\gamma}}; \quad b(s) = \ln\left(\frac{H(s)}{H_{inf}}\right); \quad U = \sqrt{\gamma}\, H_{inf} \tag{15}$$

where H_{inf} is a constant denoting the energy scale during inflation. In terms of the new dynamical variable $b(s)$, (13) is transformed to:

$$1 + 2\dot{b}(s)^2 + 4\ddot{b}(s) + 12Ue^{b(s)}\dot{b}(s) = 0 \tag{16}$$

While γ and H_{inf} are respectively small and large, their composition,U, is not too large or too small. Additionally, since $b(s)$ is clearly $\mathcal{O}(1)$ during inflation, solving (16) is quite tractable. Figure 1a depicts the variation of the scale factor $a(s)$ with s, the rescaled cosmic time, for various values of U. The existence of inflection points graphically demonstrates the existence of inflation with exit. Figure 1b shows the variation of the slow roll parameter $\epsilon(s)$ with s for various values of U. The necessary condition for inflation is $\epsilon < 1$. Such behaviour is evident from the graphs, along with a crossover to $\epsilon > 1$, which shows the exit from inflation.

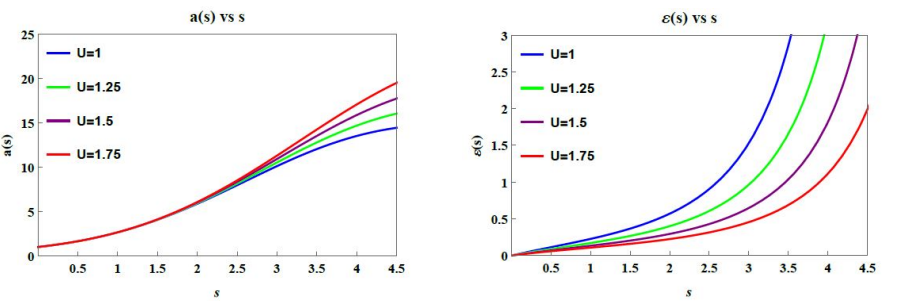

Fig. 1. (a) Variation of a with s. (b) Variation of ϵ with s.

7. Parameter Estimation

The fact that GUP modified GR predicts inflation means that we should able to constrain the GUP parameter γ using the existing constraints on inflation. These constraints stem from theoretical considerations and CMB observations. To do this, we plot the variation of s_0, the exit time (defined as the value of s when $\epsilon = 1$), with U. We see that $s_0 = U$ holds as an order of magnitude relation. This observation can be used to constrain the GUP parameter. Define $t_0 = s_0\sqrt{\gamma}, \gamma_0 = \gamma/l_{Pl}^2$ and $\alpha = t_0/l_{Pl}$. t_0 is simply the exit time is units of cosmic time while α is the exit time in units of Planck time/Planck length (l_{Pl}) and γ_0 is the ratio of two energy scales - the Planck scale and the GUP energy scale. We now have

$$s_0 = \frac{\alpha l_{Pl}}{\sqrt{\gamma}} = \frac{\alpha}{\gamma_0}. \tag{17}$$

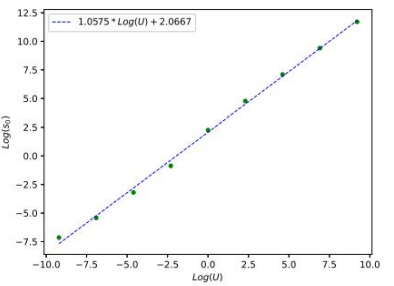

Fig. 2. Variation of s_0 with U.

Since $s_0 \sim U$, we can replace the former with the latter in (17). Simplifying, we get

$$\gamma_0 = \frac{\alpha}{H_{inf} l_{Pl}}. \tag{18}$$

Note that the right hand side is now a function of constants and known parameters. From PLANCK data,[13] we have $H_{inf} \leq 10^{-4} M_{Pl}$. We take $H_{inf} = 10^{-5} M_{Pl}$ which also coincides from the GUT scale. Typically, $\alpha \in (10^9 - 10^{12})$, but we stretch these bounds to $(10^6 - 10^{15})$ to account for errors stemming from the "hand-waving" nature of the argument. Substituting these bounds in (18) and utilizing the additional constraint that the GUP energy scale must exceed the CERN energy scale $\sim 10TeV$, we obtain the following bounds

$$10^{10} \leq \gamma_0 \leq 10^{15} \tag{19}$$

or

$$10^{-28} GeV^{-2} \leq \gamma \leq 10^{-23} GeV^{-2}. \tag{20}$$

In addition to being among the most stringent bounds available (which is expected since, unlike most constraining procedures, the one used above involved inflation and

hence the strong gravity regime), our bounds are double-sided. To our knowledge, this is the first time double-sided bounds have been obtained for GUP parameters.

8. Conclusions and Future Prospects

One expects that the imposition of a maximal momentum scale at the quantum level leads to modifications to GR at the classical level. In this proceeding, we have shown that $\alpha = 2\beta$ Stelle gravity can be regarded as the minimal extension of GR that can model maximal momentum. We have also shown that GUP modified GR leads to inflation and used this feature to obtain some of the best-known bounds on GUP parameters. We reiterate that our bounds possess a unique feature - they are double-sided. Using the GUP-Stelle Gravity correspondence, we can study the effects of maximal momentum scales on gravitational systems by studying these systems using $\alpha = 2\beta$ Stelle gravity. Additionally, we believe that approaches similar to the one outlined in this proceeding can be used to study the effects of other Planck scale phenomena at the classical level.

GUP modified GR is degenerate. It is not clear what the origins or the implications of this degeneracy are. These are currently being looked into. Finally, it is worth pondering over whether we can extend the GUP used above to construct a two-parameter GUP that "corresponds," in the classical limit, to *generic* Stelle gravity.

We study Quantum Gravity effects in cosmology, and in particular that of the Generalized Uncertainty Principle on the Friedmann equations. We show that the Quantum Gravity induced variations of the energy density and pressure in the radiation dominated era provide a viable explanation of the observed baryon asymmetry in the Universe.

Keywords: Quantum Gravity, Quantum Gravity Phenomenology, Minimal Length, Cosmology, Baryon Asymmetry.

1. Introduction

So far there are two successful theories which describe the world around us. Quantum theory, which describes interactions on the smallest scales on one hand and General Relativity, which describes gravitational interactions on large scales on the other hand.[1,2] There is no straightforward way to combine these two theories to describe physics in a regime, where both contribute, which is why we need a theory of Quantum Gravity (QG). Several QG theories have been proposed, but there is no direct experimental evidence yet to verify them. However, phenomenologists have a good intuition what fundamental concepts the regime of QG may imply on physics.[3–11] One such concept is the existence of a minimal measurable length, predicted by all or most models of QG. A natural way to incorporate minimal length in our considerations is to modify the Heisenberg uncertainty principle.[12–30] The modified Heisenberg uncertainty principle is called the Generalized Uncertainty Principle (GUP) and in the commutator form it reads as[21]

$$[x_i, p_j] = i\hbar \left(\delta_{ij} - \alpha \left(p\delta_{ij} + \frac{p_i p_j}{p} \right) + \beta \left(p^2 \delta_{ij} + 3 p_i p_j \right) \right) \tag{1}$$

where $\alpha \equiv \alpha_0/(M_P c)$, $\beta \equiv \beta_0/(M_P c)^2$, α_0, β_0 are the dimensionless linear and quadratic GUP parameters and $M_P = \sqrt{\hbar c/G}$ is the Planck mass. This phenomenological model describes a length scale $\alpha_0\,\ell_P$ and $\sqrt{\beta_0}\,\ell_P$ between the electroweak scale, i.e., $\ell_{EW} \approx 10^{-18}\,\mathrm{m}$, and the Planck scale, i.e., $\ell_P = \sqrt{\hbar G/c^3} \approx 10^{-35}\,\mathrm{m}$. We apply the GUP to quantum quantum mechanical and gravitational systems and predict deviations from standard theory, which we hope experiments can detect now or in the future, or provide explanations for observed phenomena, as in the case of this work, namely the observed baryon asymmetry that is observed in the Universe.

The asymmetry between matter and anti-matter has been an unsolved problem in physics for a long time. Standard theories such as quantum theory and general relativity suggest that there is no reason why the asymmetry between matter and anti-matter in the Universe should exist.[31] This means there should be an equal amount of matter as there is anti-matter in the Universe, while observations show a very large asymmetry. To explain this observed asymmetry we have to satisfy the so-called Sakharov conditions[32]:

1) violation of baryon number B,
2) violation of C and CP symmetries and
3) deviation from thermal equilibrium.

If a proposed mechanism is able to satisfy the above three Sakharov conditions, then it may be possible to explain the origin of the observed baryon asymmetry in the Universe. The mechanism we use is an interaction term from supergravity theories which couples the baryon current and space-time to satisfy the first two Sakharov conditions, and the holographic principle with the thermodynamics of horizons to derive the GUP-modified Friedmann equations, which satisfy the third Sakharov condition. Several proposals how GUP modifies the Friedmann equations have been presented so far.[33–36] In this way we provide a viable explanation of the observed baryon symmetry in the Universe using the GUP.

The paper is structured as follows. In section 2 we modify the Bekenstein-Hawking entropy using GUP, then in section 3, by using the holographic principle we modify the Friedmann equations, and in section 4 by using these modified Friedmann equations we attempt to explain the observed baryon symmetry in the Universe. In section 5 we summarize the work with concluding remarks.

2. Modified Bekenstein-Hawking entropy

In order to modify the Friedmann equations, using the holographic principle, we need to modify the Bekenstein-Hawking entropy formula, since the Friedmann equations can be derived from the first law of thermodynamics, which requires the change in entropy. The holographic principle makes it possible to write a d-dimensional theory on a $d-1$ dimensional boundary.[37,38] We can re-write the GUP from Eq. (1) in the usual form[39] (where $\langle p \rangle = 0$)

$$\Delta x \Delta p \gtrsim \left[1 - \alpha \Delta p + 4\beta \Delta p^2\right] \,, \tag{2}$$

where we have set the numerical prefactor to be $\mathcal{O}(1)$.[40–42]

When a particle with energy E gets absorbed by a horizon, the horizon area changes by $\Delta A_{min} \geq 8\pi\ell_P^2 E\,\Delta x$, where Δx is the uncertainty in position of the absorbed particle.[43,44] To obtain the energy of the particle E, we solve the quadratic equation for Δp from Eq. (2) and obtain the expression

$$E = \Delta p \gtrsim \frac{\Delta x + \alpha}{8\beta}\left(1 - \sqrt{1 - \frac{16\beta}{\Delta x^2 + 2\alpha\Delta x + \alpha^2}}\right), \tag{3}$$

where we chose the negative solution, since we want to obtain the smallest change in area of the apparent horizon and this solution reduces to the standard Heisenberg uncertainty for $\alpha, \beta \longrightarrow 0$. The position uncertainty Δx is the diameter of the observable Universe $\Delta x = 2r_S$, where r_S is the Schwarzschild radius. The square of Δx is then related to the area of the apparent cosmic horizon as $\Delta x^2 = A/\pi$. Plugging all of the above in the change in ΔA_{min}, we get

$$\Delta A_{min} \simeq \lambda\frac{\ell_P^2(A + \alpha\sqrt{\pi}A^{1/2})}{\beta}\left(1 - \sqrt{1 - \frac{16\pi\beta}{A + 2\alpha\sqrt{\pi}A^{1/2} + \alpha^2\pi}}\right), \tag{4}$$

where λ is determined by the Bekenstein-Hawking entropy formula $b/\lambda = 2\pi$. Here $b = \Delta S_{min} = \ln 2$ is the minimal increase in entropy, corresponding to one bit of information.[35]

The Bekenstein-Hawking entropy was first introduced for a black hole, but the holographic principle suggests that it can be used for any horizon. Therefore we can write it for a cosmic horizon in the same way[45,46]

$$S = \frac{A}{4G} = \frac{A}{4\ell_P^2}\ . \tag{5}$$

If we introduce some modification to the Heisenberg uncertainty principle or we modify the entropy in any other way, the only variable in this equation, the area, gets modified.[33] The Bekenstein-Hawking entropy then reads $S = \frac{f(A)}{4\ell_P^2}$. Since the first law of thermodynamics includes a differential of entropy, it useful to calculate its derivative

$$\frac{\mathrm{d}S}{\mathrm{d}A} = \frac{f'(A)}{4\ell_P^2}\ . \tag{6}$$

On the other hand, the above derivative can be written using the minimal change in entropy ΔS_{min} and ΔA_{min}

$$\frac{\mathrm{d}S}{\mathrm{d}A} = \frac{\Delta S_{min}}{\Delta A_{min}} = \frac{\beta^*}{8\ell_P^2\left(A + \alpha^* A^{1/2} - \sqrt{A^2 + 2\alpha^* A^{3/2} + (\alpha^{*2} - \beta^*)A}\right)}\ , \tag{7}$$

where $\alpha^* = \sqrt{\pi}\alpha$ and $\beta^* = 16\pi\beta$. By comparing Eqs. (6) and (7) we can read out what $f'(A)$ is

$$f'(A) = \frac{1}{2}\frac{\beta^*}{\left(A + \alpha^* A^{1/2} - \sqrt{A^2 + 2\alpha^* A^{3/2} + (\alpha^{*2} - \beta^*)A}\right)}\ . \tag{8}$$

To obtain the modified Bekenstein-Hawking entropy we must integrate Eq. (6) over area A, from A to ∞, using $f'(A)$ from Eq. (8). The exact GUP-modified Bekenstein-Hawking entropy then reads

$$S = \frac{1}{8\ell_P^2}\left[A\left(1+\sqrt{1+2\alpha^*\frac{1}{A^{1/2}}+(\alpha^{*2}-\beta^*)\frac{1}{A}}\right)\right.$$
$$+\alpha^* A^{1/2}\left(2+\sqrt{1+2\alpha^*\frac{1}{A^{1/2}}+(\alpha^{*2}-\beta^*)\frac{1}{A}}\right)$$
$$\left.-\beta^*\ln\left(1+\frac{A^{1/2}}{\alpha^*}\left(1+\sqrt{1+2\alpha^*\frac{1}{A^{1/2}}+(\alpha^{*2}-\beta^*)\frac{1}{A}}\right)\right)\right]\ , \tag{9}$$

where we obtain the standard result from Eq.(5) for $\alpha^*, \beta^* \longrightarrow 0$.

3. Modified Friedmann Equations

The Friedmann equations describe the evolution of a dynamical Universe and provide the foundations for the standard model of cosmology. They can be derived in different ways. The most common is by solving the Einstein equations in $(n+1)$-dimensional space-time for a FLRW metric

$$\mathrm{d}s^2 = h_{cd}\mathrm{d}x^c\mathrm{d}x^d + \tilde{r}^2\mathrm{d}\Omega_{n-1}^2\ , \tag{10}$$

where $x^c = (t, r)$, $\tilde{r} = a(t)\, r$, $h_{cd} = \mathrm{diag}(-1, a^2/(1-kr^2))$, $\mathrm{d}\Omega_{n-1}$ is the angular part of the $(n-1)$-dimensional sphere, $a = a(t)$ is the scale factor, r is the comoving radius and k is the spatial curvature constant. Indices c and d only take values 0 and 1. The other way to derive the Friedmann equations is using the holographic principle, which takes advantage of the thermodynamics of horizons.

To generalize the Friedmann equations to include minimum length effects we derive the same from the first law of thermodynamics, with the difference of using the modified Bekenstein-Hawking entropy, derived in the previous section. The first law of thermodynamics for the content inside an apparent horizon is given by[33–36]

$$\mathrm{d}E = T\mathrm{d}S + W\mathrm{d}V\ , \tag{11}$$

where E is the energy contained inside the apparent horizon, given by $E = \rho V$, V is the volume of an n-dimensional sphere, given by $V = \Omega_n\, \tilde{r}_A^{\,n}$, with $\Omega_n = \frac{\pi^{n/2}}{\Gamma(n/2+1)}$ which has an area of $A = n\,\Omega_n\, \tilde{r}_A^{\,n-1}$), T is the Hawking temperature given by[47,48]

$$T = \frac{\kappa}{2\pi} = -\frac{1}{2\pi\tilde{r}_A}\left(1-\frac{\dot{\tilde{r}}_A}{2H\tilde{r}_A}\right)\ , \tag{12}$$

$\mathrm{d}S$ is the differential of the Bekenstein-Hawking entropy given by Eq. (6), and W is the work density which reads as[49]

$$W = -\frac{1}{2}T^{cd}h_{cd} = \frac{1}{2}\left(\rho - p\right)\ . \tag{13}$$

In the above T^{cd} is a projection of the energy-momentum tensor $T_{\mu\nu} = (\rho + p)\, u_\mu u_\nu + p g_{\mu\nu}$ on the $t - r$ subspace. What remains is to differentiate the energy and volume, write everything in terms of $\mathrm{d}A$, and plug the above equations in the first law of thermodynamics from Eq. (11). From here we derive the first Friedmann equation

$$-\frac{8\pi G}{n-1}(\rho + p) = \left(\dot{H} - \frac{k}{a^2}\right) f'(A)\ . \tag{14}$$

By using the continuity equation $\dot{\rho} + nH(\rho + p) = 0$, originating from the conservation of energy $T^{\mu\nu}{}_{;\nu} = 0$, with Eq.(14) and integrating it, one obtains the second Friedmann equation

$$-\frac{8\pi G}{n(n-1)}\rho = \frac{(n\Omega_n)^{\frac{n+1}{n-1}}}{n(n-1)\Omega_n}\int f'(A)\frac{\mathrm{d}A}{A^{\frac{n+1}{n-1}}}\ . \tag{15}$$

By setting $f'(A) = 1$ ($f(A) = A$ in standard theory) we obtain the standard Friedmann equations as we expect. However, to obtain GUP corrections to the Friedmann equations, we plug $f'(A)$ from Eq. (8) in Eqs. (14) and (15). Both of the Friedmann equations have exact solutions in $n = 3$, which read as

$$-4\pi G(\rho + p) = \left(\dot{H} - \frac{k}{a^2}\right) \times \frac{\beta^*}{8\pi}\frac{\left(H^2 + \frac{k}{a^2}\right)}{1 + \frac{\alpha^*}{(4\pi)^{1/2}}\left(H^2 + \frac{k}{a^2}\right)^{1/2} - \sqrt{1 + \frac{2\alpha^*}{(4\pi)^{1/2}}\left(H^2 + \frac{k}{a^2}\right)^{1/2} + \frac{(\alpha^{*2} - \beta^*)}{4\pi}\left(H^2 + \frac{k}{a^2}\right)}} \tag{16}$$

and

$$\begin{aligned}\frac{8\pi G}{3}(\rho - \Lambda) = {} & \frac{1}{2}\left(H^2 + \frac{k}{a^2}\right) + \frac{\alpha^*}{3(4\pi)^{1/2}}\left(H^2 + \frac{k}{a^2}\right)^{3/2} + \frac{2\pi(\alpha^{*2} + 2\beta^*)}{3(\alpha^{*2} - \beta^*)^2} \\ & + \left[\frac{1}{3}\left(H^2 + \frac{k}{a^2}\right) + \frac{(4\pi)^{1/2}\alpha^*}{6(\alpha^{*2} - \beta^*)}\left(H^2 + \frac{k}{a^2}\right)^{1/2} - \frac{2\pi(\alpha^{*2} + 2\beta^*)}{3(\alpha^{*2} - \beta^*)^2}\right] \\ & \times \sqrt{1 + \frac{2\alpha^*}{(4\pi)^{1/2}}\left(H^2 + \frac{k}{a^2}\right)^{1/2} + \frac{(\alpha^{*2} - \beta^*)}{4\pi}\left(H^2 + \frac{k}{a^2}\right)} \\ & + \frac{2\pi\alpha^*\beta^*}{(\alpha^{*2} - \beta^*)^{5/2}}\ln\left[1 + \frac{(\alpha^{*2} - \beta^*)}{(4\pi)^{1/2}(\alpha^* + \sqrt{\alpha^{*2} - \beta^*})}\left(H^2 + \frac{k}{a^2}\right)^{1/2}\right. \\ & + \frac{\sqrt{\alpha^{*2} - \beta^*}}{\alpha^* + \sqrt{\alpha^{*2} - \beta^*}} \\ & \left. \times \left(\sqrt{1 + \frac{2\alpha^*}{(4\pi)^{1/2}}\left(H^2 + \frac{k}{a^2}\right)^{1/2} + \frac{(\alpha^{*2} - \beta^*)}{4\pi}\left(H^2 + \frac{k}{a^2}\right)} - 1\right)\right],\end{aligned} \tag{17}$$

where

$$A = 4\pi\tilde{r}_A^2 = \frac{4\pi}{H^2 + \frac{k}{a^2}} \tag{18}$$

was used. We are interested in the radiation dominated era, since the baryon asymmetry was frozen in at that epoch. In that epoch the small cosmological constant Λ can be ignored, since $\rho \gg \Lambda$ and the curvature constant can be set to $k = 0$, which is consistent with the observations which show a flat Universe. The modified Friedmann equations then get simplified to

$$-4\pi G\,(\rho + p) = \frac{\beta^*\dot{H}}{8\pi}\,\frac{H^2}{1 + \frac{\alpha^*}{(4\pi)^{1/2}}H - \sqrt{1 + \frac{2\alpha^*}{(4\pi)^{1/2}}H + \frac{(\alpha^{*2} - \beta^*)}{4\pi}H^2}} \tag{19}$$

and

$$\begin{aligned}\frac{8\pi G}{3}\rho = {} & \frac{1}{2}H^2 + \frac{\alpha^*}{3(4\pi)^{1/2}}H^3 + \frac{2\pi(\alpha^{*2} + 2\beta^*)}{3(\alpha^{*2} - \beta^*)^2} \\ & + \left[\frac{1}{3}H^2 + \frac{(4\pi)^{1/2}\alpha^*}{6(\alpha^{*2} - \beta^*)}H - \frac{2\pi(\alpha^{*2} + 2\beta^*)}{3(\alpha^{*2} - \beta^*)^2}\right] \\ & \times \sqrt{1 + \frac{2\alpha^*}{(4\pi)^{1/2}}H + \frac{(\alpha^{*2} - \beta^*)}{4\pi}H^2} \\ & + \frac{2\pi\alpha^*\beta^*}{(\alpha^{*2} - \beta^*)^{5/2}}\ln\left[1 + \frac{(\alpha^{*2} - \beta^*)}{(4\pi)^{1/2}(\alpha^* + \sqrt{\alpha^{*2} - \beta^*})}H\right. \\ & \left. + \frac{\sqrt{\alpha^{*2} - \beta^*}}{\alpha^* + \sqrt{\alpha^{*2} - \beta^*}}\left(\sqrt{1 + \frac{2\alpha^*}{(4\pi)^{1/2}}H + \frac{(\alpha^{*2} - \beta^*)}{4\pi}H^2} - 1\right)\right]. \end{aligned} \tag{20}$$

The Taylor expansions of the above modified Friedmann equations up to first order in α^* and β^* turn out to be

$$-4\pi G\,(\rho + p) = \dot{H}\left(1 + \frac{\alpha^*}{2\sqrt{\pi}}H - \frac{\beta^*}{16\pi}H^2\right) \tag{21}$$

and

$$\frac{8\pi G}{3}\rho = H^2\left(1 + \frac{\alpha^*}{3\sqrt{\pi}}H - \frac{\beta^*}{32\pi}H^2\right). \tag{22}$$

The above simplified equations are used to study the breaking of thermal equilibrium in the radiation dominated era, which satisfies one of the Sakharov conditions.

4. Gravitational Baryogenesis

To provide an explanation for the observed baryon asymmetry in the Universe, all Sakharov conditions must be satisfied. Theories of supergravity introduce an extra interaction term to the action which couples the baryon current and space-time[50]

$$\frac{1}{M_*^2}\int \mathrm{d}^4x\sqrt{-g}\,J^\mu\partial_\mu R\,, \tag{23}$$

and thus violates the C, CP and CPT symmetries. In the above M_* is the cutoff scale characterizing the effective theory.[51] The magnitude of M_* is chosen to be in the regime of the Grand Unified Theories (GUT), where interactions which violate the baryon number exist. The term in Eq. (23) therefore satisfies the first two Sakharov conditions. We can see that the integrand from Eq. (23) reduces to

$$\frac{1}{M_*^2} J^\mu \partial_\mu R = \frac{1}{M_*^2}(n_B - n_{\bar{B}})\dot{R} \ , \tag{24}$$

where n_B ($n_{\bar{B}}$) is the baryon (anti-baryon) number density. In the above equation only the time derivative survives, since the spatial derivative of the Ricci scalar vanishes $\nabla R = 0$ for the FLRW metric from Eq. (10). Because the integrand from Eq. (24) corresponds to the energy density term of the grand canonical ensemble, we can read the chemical potential for baryons and anti-baryons from it as

$$\mu_B = -\mu_{\bar{B}} = -\frac{\dot{R}}{M_*^2} \ . \tag{25}$$

To study the baryon asymmetry, we need a suitable variable, which parametrizes this asymmetry. Following Ref.[52], the baryon asymmetry parameter is defined as

$$\eta \equiv \frac{n_B - n_{\bar{B}}}{n_\gamma} \simeq 7\frac{n_B - n_{\bar{B}}}{s} \ , \tag{26}$$

where the photon number density n_γ and the entropy density s are related by a constant factor $n_\gamma \simeq s/7$ since the epoch of $e^\pm$ annihilation. For relativistic particles, the entropy density turns out to be[52]

$$s = \frac{2\pi^2 g_*}{45} T^3 \tag{27}$$

and the baryon number density[52]

$$n_B - n_{\bar{B}} = \frac{g_b}{6}\mu_B T^2 \ . \tag{28}$$

In the above equations $g_* \approx 106$ is the number of degrees of freedom for particles which contribute to the entropy of the universe and $g_b \sim \mathcal{O}(1)$ is the number of intrinsic degrees of freedom for baryons.[52] Plugging Eqs. (25), (27) and (28) in Eq. (26) the baryon asymmetry parameter reads

$$\eta \simeq -\frac{105\, g_b}{4\pi^2 g_*} \frac{\dot{R}}{M_*^2 T}\bigg|_{T_D} \ . \tag{29}$$

The above parameter is evaluated at some decoupling temperature T_D. This decoupling temperature represents the energy scale at which the baryon violating interactions freeze out and go out of equilibrium. The baryon number is conserved below this temperature for all future epochs.

Next, we use the modified Friedmann equations which turn out to break thermal equilibrium. To see that they indeed break thermal equilibrium, we write the energy density and pressure as their equilibrium values plus some small variations

$$\rho = \rho_0 + \delta\rho \, , \qquad p = p_0 + \delta p \ . \tag{30}$$

If there is no variations $\delta\rho = \delta p = 0$, we have thermal equilibrium and no baryon asymmetry is produced due to the third Sakharov condition. We require some variations $\delta\rho, \delta p \neq 0$ to deviate from the thermal equilibrium. To obtain non-vanishing variations we plug the energy density and pressure from Eq. (30) into the modified Friedman equations from Eqs. (21) and (22) to express $\delta\rho$ and δp in terms of the GUP parameters and the equation of state $p_0 = w\rho_0$. The variations then read

$$\delta\rho = \frac{\alpha^*}{3}\sqrt{\frac{8G}{3}}\rho_0^{3/2} - \frac{\beta^*}{12}G\rho_0^2 \tag{31}$$

and

$$\delta p = \frac{\alpha^*}{6}\sqrt{\frac{8G}{3}}(1+3w)\rho_0^{3/2} - \frac{\beta^*}{12}G(1+2w)\rho_0^2 \,, \tag{32}$$

We can see if there is no GUP corrections $\alpha^*, \beta^* = 0$, we get no variations in the energy density and pressure and thermal equilibrium is preserved.

The trace of the Einstein equations give us the Ricci scalar $R = -8\pi G\, T_g = -8\pi G\,(\rho - 3p)$, where we plug in the energy density and pressure from Eq. (30) with their respective variations from Eqs. (31) and (32). We compute its time derivative, use the continuity equation for $n = 3$ and evaluate the whole expression in the radiation-dominated era with $w = 1/3$, where the baryon violating interactions froze out. The time derivative of the Ricci scalar then reads

$$\dot{R} = -\alpha^* \frac{256}{3}\,\pi^{3/2}\,G^2\rho_0^2 + \beta^*\, 8\left(\frac{8\pi}{3}\right)^{3/2} G^{5/2}\rho_0^{5/2} \,. \tag{33}$$

We can see that the above derivative would also vanish if there would be no GUP corrections because every term is proportional to α^* or β^*. We plug Eq. (33) in Eq. (29) and use the equilibrium energy density for relativistic particles[52]

$$\rho_0 = \frac{\pi g_*}{30}T^4 \,, \tag{34}$$

to obtain the expression for the predicted baryon asymmetry

$$\eta = \alpha_0 \frac{112\,\pi^2 g_* g_b}{45}\left(\frac{T_D}{M_P}\right)^7\left(\frac{M_P}{M_*}\right)^2 - \beta_0\frac{896\sqrt{5}\,\pi^3 g_*^{3/2} g_b}{675}\left(\frac{T_D}{M_P}\right)^9\left(\frac{M_P}{M_*}\right)^2 \,, \tag{35}$$

where we expressed the gravitational constant in terms of the Planck mass, i.e., M_P, as $G = 1/M_P^2$. From the above we can see that the baryon asymmetry is dependent on α_0 and β_0 parameters and the scales M_* and T_D.

To compare Eq. (35) to the observed baryon asymmetry we plug in the suggested values for $M_* = M_P/\sqrt{8\pi}$, the reducep Planck mass and $T_D = M_I \sim 2\times 10^{16}\,\text{GeV}$ which corresponds to the tensor mode fluctuations in the inflationary scale.[53] We then obtain

$$\eta = \alpha_0\, 2.08\times 10^{-15} - \beta_0\, 2.16\times 10^{-19} \,, \tag{36}$$

where we can see the baryon asymmetry vanishes for $\alpha_0, \beta_0 \longrightarrow 0$. If $\alpha_0, \beta_0 \neq 0$ the baryon asymmetry is explained by the existence of a minimal length scale.

We compare the predicted baryon asymmetry from Eq. (36) to the observational bounds $5.7 \times 10^{-11} \lesssim \eta \lesssim 9.9 \times 10^{-11}$.[54] By doing this we can fix the GUP parameters to their actual values for different models:

- Only linear GUP ($\beta_0 = 0$): $2.74 \times 10^4 \lesssim \alpha_0 \lesssim 4.76 \times 10^4$
- Only quadratic GUP ($\alpha_0 = 0$): $-4.58 \times 10^8 \lesssim \beta_0 \lesssim -2.64 \times 10^8$
- Linear and Quadratic GUP ($\beta_0 = -\alpha_0^2$): $1.21 \times 10^4 \lesssim \alpha_0 \lesssim 1.71 \times 10^4$ and $-2.92 \times 10^8 \lesssim \beta_0 \lesssim -1.46 \times 10^8$
- Linear and Quadratic GUP: $\alpha_0 \gtrsim 4.81 \times 10^3$ and $\beta_0 \lesssim -1.48 \times 10^8$

We can see that the GUP parameters should have values $\alpha_0 \approx 10^4$ and $\beta_0 \approx -10^8$, which suggest a new length scale of $\ell_{new} = \alpha_0 \ell_P \sim \sqrt{-\beta_0}\ell_P \approx 10^{-31}$ m.

5. Conclusion

With this work we test the fundamental physics of nature. More specifically, how the minimal length can affect phenomena on large scales such as in this case, the baryon asymmetry in the Universe, which is still a problem in physics up to this day. The mechanism which we propose satisfies all Sakharov conditions and thus offers a viable explanation of the observed baryon asymmetry in the Universe. We used an interaction term which couples the baryon current and space-time to satisfy the first two Sakharov conditions, and using the holographic principle we modified the Bekenstein-Hawking entropy and the Friedmann equations to break thermal equilibrium and thus satisfying the third and last Sakharov condition. The modified Friedmann equations can also be used more broadly in cosmology and can provide a very rich phenomenology.

Our findings suggest that minimal length effects could have been the cause for generating the observed baryon symmetry. Our work does not constrain the GUP parameters to an improved upper bound because, but rather fixes the values of the GUP parameters α_0 and β_0 and thus sets the new length scale to be $\ell_{new} = \alpha_0 \ell_P \sim \sqrt{-\beta_0}\ell_P \approx 10^{-31}$ m.

We noticed that the quadratic GUP parameter turns out to be negative. This is consistent with other cosmological studies using quadratic GUP,[55] non-trivial structures of space-time[8,16,55–57] and a crystal lattice considerations with GUP.[56] This can suggest that space-time can have a granular structure at the Planck scale.[27,58–60]

E-mail: dminic@vt.edu, takeuchi@vt.edu

This article summarizes a new approach to quantum gravity based on the concepts of modular spacetime, Born geometry, and metastring theory and their applications to quantum gravity phenomenology. In particular, we discuss a new understanding of dark matter in terms of metaparticles (zero modes of the metastring) and its relation to dark energy (the curvature of dual spacetime) in view of the actual astronomical observations.

Keywords: Quantum Gravity, Quantum Spacetime, Dark Matter, Dark Energy.

1. Introduction and summary

In this paper we review recent work[1–10] on quantum foundations of quantum mechanics (QM), quantum field theory (QFT), and quantum gravity (in the guise of metastring theory) as well as unique implications for the problems of dark matter and dark energy.[11,12] This generic formulation of quantum gravity implies a radiatively stable positive cosmological constant (dark energy)[11] in the observed classical spacetime, and metaparticle quanta (the zero modes of the metastring) representing the natural quanta of dark matter[12] (correlated to dark energy and visible matter). The logic of our story is very similar to the path that leads from the Minkowski geometry of special relativity via relativistic non-gravitational field theory to a dynamical spacetime of general relativity. In this paper, we start with a hidden geometry in quantum theory (Born geometry) and proceed to its dynamical implementation in quantum gravity (formulated as a metastring theory) with implications for QFT (formulated in a way that takes into account the hidden Born geometry) with implications for the observed world: metaparticles as dark matter quanta, and dark energy emerging from the geometry of the dual spacetime. In some sense, this is a sharpening of the modern approaches to non-perturbative quantum physics,[13] using a simple but crucial insight about a completeness of quantum kinematics of discretized physical systems.[14]

In particular, in Ref. 5 we demonstrated that any quantum theory is endowed with a generic quantum polarization associated with modular spacetime.[4] The generic polarization manifestly realizes quantum non-locality, associated with the

quantum superposition principle, that is consistent with causality, and reveals a novel geometry structure, called Born geometry,[1,2] which unifies symplectic (ω), orthogonal (η), and conformal geometries (H). Born geometry is fundamental for a particular quantum theory that consistently propagates in this geometry – this turns out to be string theory formulated in a generalized-geometric and intrinsically non-commutative, doubled, chiral phase-space-like form (called metastring theory).[3,6–8] The zero modes of the metastring correspond to metaparticles that explicitly realize the geometry of modular spacetime,[9] and as such, could be considered as an explicit prediction of the modular representation of quantum theory. The metaparticles[10] are quanta of a modular generalization of quantum fields, the low energy remnants of metastring fields. From this new viewpoint[1–10] quantum gravity is essentially defined as "gravitization of the quantum," that is, as a theory of a dynamical Born geometry. As such it incorporates the concept of Born reciprocity[15] as a covariant implementation of T-duality, the fundamental relation between short and long distance physics in string theory, as well as the new idea of relative (or observer dependent) locality.[16]

In what follows, we start with a discussion of quantum theory via quantum (modular) spacetime and then comment on QFT in this approach, and then move on to quantum gravity and its phenomenology in the context of dark matter and dark energy and the actual astronomical observations.

2. Quantum theory and quantum spacetime

The fundamental reason for the existence of modular polarizations in quantum theory is as follows.[5] If one imagines that a quantum system is formulated on a lattice, as assumed in the modern (Wilsonian) non-perturbative approaches,[13] then a theorem due to Zak[14] states that a complete set of quantum numbers needed to describe any quantum system would require both quantum numbers associated with the lattice and its inverse. This is easy to see by realizing that non-commuting Hermitian operators, such as coordinates and momenta $[\,\hat{q},\,\hat{p}\,] = i\hbar$, when exponentiated, together with the appropriate lattice spacing a and its inverse $2\pi\hbar/a$, commute, that is,

$$\left[\exp\left(\frac{i}{\hbar}\hat{q}\frac{2\pi\hbar}{a}\right),\exp\left(\frac{i}{\hbar}\hat{p}a\right)\right] \,=\, 0\,. \tag{1}$$

Such unitary observables were labeled as "modular" by Aharonov.[17] These variables are purely quantum in the sense that their formal $\hbar \to 0$ limit is singular. Also, even though their commutators are zero, the associated Poisson brackets are non-zero, as these are unitary (phase) variables. Finally, the classical limit is defined by starting with a modular formulation and defining an appropriate "extensification,"[5] with, in principle, many classical limits. These purely quantum variables also appear in the context of QFT.

Thus we concentrate on a complete set of unitary operators as opposed to a complete set of Hermitian operators. Let us examine the simplest example of

the $\hat{q}$ and $\hat{p}$ operators. The commuting subalgebra of the original non-commuting $[\,\hat{q},\,\hat{p}\,] = i\hbar$ algebra can be completely described by self-dual lattices (endowed with the natural symplectic form (ω) coming from the commutator bracket). These in turn represent a discretization of a (covariant) phase space defined by q and p, and when lifted to the original non-commutative algebra, require extra data associated with the lift that is described by a doubly orthogonal ($O(d,d)$, where d denotes the spacetime dimension) metric η (a symmetric counterpart of the antisymmetric ω associated with $Sp(2d)$ transformations). Finally, in order to define the vacuum state on this self-dual lattice, we need a conformal structure $O(2, 2(d-1))$.[5] This triplet of structures defines Born geometry[1,2] associated with the modular representation of quantum theory.[5] Born geometry captures quantum non-locality that is consistent with causality, given the quantum nature of the unitary operators and the fact that the triple intersection of $Sp(2d)$, $O(d,d)$ and $O(2,2(d-1))$ gives the Lorentz group.[6]

Let us formalize these insights about the hidden quantum spacetime geometry of quantization.[5] We start with the Heisenberg (or Weyl-Heisenberg) group, which is generated, on the level of the corresponding algebra, by the familiar position $\hat{q}^a$ and momentum $\hat{p}_b$ operators: $[\,\hat{q}^a,\,\hat{p}_b\,] = i\hbar\delta^a_b$. It will be convenient to introduce a length scale λ and a momentum scale ϵ, with $\lambda\epsilon = \hbar$. Also, let us introduce the notation $\hat{x}^a \equiv \hat{q}^a/\lambda$, $\hat{\tilde{x}}_a \equiv \hat{p}_a/\epsilon$ so that $[\,\hat{x}^a,\,\hat{\tilde{x}}_b\,] = i\delta^a_b$, and let us define

$$\mathbb{X}^A \equiv (x^a, \tilde{x}_a)^T\,, \quad [\,\hat{\mathbb{X}}^a,\,\hat{\mathbb{X}}^b\,] = i\omega^{AB}\,, \quad \text{with} \quad \frac{1}{2}\omega_{AB}dX^A dX^B = \frac{1}{\hbar}dp_a \wedge dq^a, \quad (2)$$

where $\omega_{AB} = -\omega_{BA}$ is the canonical symplectic form on phase space $\mathcal{P}$. The Heisenberg group $H_{\mathcal{P}}$ is generated by Weyl operators[18] $W_{\mathbb{K}} \equiv e^{2\pi i\omega(\mathbb{K},\mathbb{X})}$, where $\mathbb{K}$ stands for the pair $(\tilde{k}, k)$ and $\omega(\mathbb{K},\mathbb{K}') = k\cdot\tilde{k}' - \tilde{k}\cdot k'$. These form a central extension of the translation algebra, $W_{\mathbb{K}}W_{\mathbb{K}'} = e^{2\pi i\omega(\mathbb{K},\mathbb{K}')}W_{\mathbb{K}+\mathbb{K}'}$. The projection $\pi : H_{\mathcal{P}} \to \mathcal{P}$ (where $\pi : W_{\mathbb{K}} \to \mathbb{K}$) defines a line bundle over $\mathcal{P}$ (in principle a covariant phase space of quantum probes). In this formulation, states are sections of degree one, $W_{\mathbb{K}'}\Phi(\mathbb{K}) = e^{2\pi i\omega(\mathbb{K},\mathbb{K}')}\Phi(\mathbb{K}+\mathbb{K}')$.

Using notions of non-commutative algebra and non-commutative geometry[19] (such as the theorem of Gelfand-Naimark[20]), we can say that a Lagrangian submanifold (a half-dimensional submanifold of phase space upon which the symplectic form pulls back to zero) is a maximally commutative subgroup of the Heisenberg group. If we accept this notion of a Lagrangian, then the quantum regime is very different from the classical regime. In particular the vanishing Poisson bracket $\{f(q), g(p)\} = 0$ requires either f or g to be constant. However, the vanishing commutator $[f(\hat{q}), g(\hat{p})] = 0$ requires only that the functions be commensurately periodic :

$$e^{i\alpha\hat{p}}e^{i\beta\hat{q}} = e^{i\hbar\alpha\beta}e^{i\beta\hat{q}}e^{i\alpha\hat{p}}\,, \qquad \alpha\beta = 2\pi/\hbar\,. \quad (3)$$

Similar considerations led Aharonov to introduce *modular variables* to describe purely quantum phenomena such as interference.[21]

Modular variables are described in great detail in Ref. 21, where one can find detailed references on this subject. The modular variables, denoted $[\,\hat{q}\,]$ and $[\,\hat{p}\,]$, are defined modulo a length scale R (the slit spacing being a natural choice) as

$$[\,\hat{p}\,]_{2\pi\hbar/R} = \hat{p} \bmod (2\pi\hbar/R) \ , \qquad [\,\hat{q}\,]_R = \hat{q} \bmod (R) \ . \tag{4}$$

They play a central role in understanding interference in terms of operators (and not states). The shift operator $e^{iR\hat{p}/\hbar} = e^{iR[\,\hat{p}\,]/\hbar}$ shifts the position of a particle state (say an electron in the double-slit experiment) by distance R and is a function of the modular momenta (see also Ref. 22). These modular variables (the main examples being the Aharonov-Bohm and Aharonov-Casher phases[21]) satisfy non-local operator equations of motion. For example, given the Hamiltonian $\hat{H} = \hat{p}^2/2m + V(\hat{q})$, the Heisenberg equation of motion for the shift operator is

$$e^{-iR\hat{p}/\hbar}\,\frac{d}{dt}\,e^{iR\hat{p}/\hbar} \ = \ -\frac{iR}{\hbar}\left(\frac{V(\hat{q}+R)-V(\hat{q})}{R}\right). \tag{5}$$

Modular variables are fundamentally non-local in a non-classical sense, since we see here that their evolution depends on the value of the potential at distinct locations. Remarkably, thanks to the uncertainty principle, this dynamical non-locality does not lead to a violation of causality.[21] One of the characteristic features of these variables is that they do not have classical analogues; indeed, the limit $\hbar \to 0$ of $[\,p\,]_{h/R}$ is ill-defined. Also, modular variables capture entanglement of continuous q, p variables. When exponentiated (*i.e.*, when understood as Weyl operators) the modular variables naturally commute. In other words, given $[\,\hat{x}^a,\,\hat{\tilde{x}}_b\,] = i\delta^a_b$ we find[5] $[\,e^{2\pi i\hat{x}},\,e^{2\pi i\hat{\tilde{x}}}\,] = 0$. Thus, the quantum algebra of modular variables possesses more commutative directions than the classical Poisson algebra, since the Poisson bracket of modular variables does not vanish, $\{\,e^{2\pi ix},\,e^{2\pi i\tilde{x}}\,\} \neq 0$.

2.1. *Modular spacetime as quantum spacetime and Born geometry*

In this view of quantum theory we have a structure analogous to a Brillouin cell in condensed matter physics. The volume and shape of the cell are given by λ and ϵ (i.e. $\hbar$ and G (or α')). The uncertainty principle is implemented in a subtle way: we can specify a point in a modular cell, but if so, we cannot say *which* cell we are in. This means that there is a more general notion of quantization.[5] Instead of selecting a classical polarization L (the arguments of the wave function, or the arguments of a local quantum field) we choose a *modular polarization*. In terms of the Heisenberg group, all that is happening is that in order to have a commutative algebra, we need only $\omega(\mathbb{K},\mathbb{K}') \in 2\mathbb{Z}$, and $W_{\mathbb{K}}W_{\mathbb{K}'} = e^{2\pi i\omega(\mathbb{K},\mathbb{K}')}W_{\mathbb{K}+\mathbb{K}'} = W_{\mathbb{K}'}W_{\mathbb{K}'}$. This defines a lattice Λ in phase space $\mathcal{P}$. Finally, we specify a "lift" of the lattice from the phase space $\mathcal{P}$ to the Heisenberg group $H_{\mathcal{P}}$.

Maximally commuting subgroups $\hat{\Lambda}$ of the Heisenberg group correspond to lattices that are integral and self-dual with respect to ω.[23] Given W_λ, where $\lambda \in \Lambda$, there is a lift to $\hat{\Lambda}$ which defines "modular polarization," $U_\lambda = \alpha(\lambda)W_\lambda$, where $\alpha(\lambda)$

satisfies the co-cycle condition $\alpha(\lambda)\,\alpha(\mu)\,e^{\pi i\omega(\lambda,\mu)} = \alpha(\lambda+\mu)$, with $\lambda, \alpha \in \Lambda$. One can parametrize a solution to the co-cycle condition by introducing a symmetric bilinear from $\eta(\mathbb{K},\mathbb{K}') = k\cdot\tilde{k}' + \tilde{k}\cdot k'$ and setting $\alpha_\eta(\lambda) \equiv e^{i\frac{\pi}{2}\eta(\lambda,\lambda)}$. Finally, when we choose a classical Lagrangian L there exists a special translation-invariant state that we associate with the vacuum, which we interpret as "empty space." In modular quantization there is no such translation-invariant state because of the lattice structure. The best we can do is to choose a state that minimizes an "energy," which requires the introduction of another symmetric bilinear form that we call, again suggestively, H. This means that we are looking for operators such that

$$[\,\hat{\mathbb{P}}_A,\,\Phi\,] = \frac{i}{2\pi}\partial_A\Phi\ , \quad \text{and} \quad \Phi(\hat{\mathbb{X}}+\lambda) = \Phi(\hat{\mathbb{X}})\ , \tag{6}$$

where the modular observables $\Phi(\hat{\mathbb{X}}+\lambda) = \Phi(\mathbb{X})$ are generated by the lattice observables U_λ with $\lambda \in \Lambda$. Translation invariance would be the condition $\hat{\mathbb{P}}\,|0\rangle = 0$. Since this is not possible, the next natural choice is to minimize the translational energy. Therefore, we pick a positive definite metric H_{AB} on $\mathcal{P}$, and we define[5] $\hat{E}_H \equiv H^{AB}\hat{\mathbb{P}}_A\hat{\mathbb{P}}_B$, and demand that $|0\rangle_H$ be the ground state of $\hat{E}_H$. This is indeed the most natural choice and it shows that we cannot fully disentangle kinematics (i.e., the definition of translation generators) from dynamics. In the Schrödinger case, since the translation generators commute, the vacuum state $\hat{E}\,|0\rangle = 0$ is also the translation-invariant state and it carries no memory of the metric H needed to define the energy. In our context, due to the non-commutativity of translations, the operators $\hat{E}_H$ and $\hat{E}_{H'}$ do not commute. Thus, the vacuum state depends on H, in other words $|0\rangle_H \neq |0\rangle_{H'}$, and it also possesses a non-vanishing zero point energy.

Therefore, modular quantization involves the introduction of three quadratic forms (ω,η,H), called *Born geometry*,[1,2] which underlies the geometry of modular variables. As we will see, in the context of metastring theory, a choice of polarization is a choice of a spacetime within $\mathcal{P}$ but the most general choice is a *modular polarization* that we have discussed above. From the foundational quantum viewpoint, Born geometry (ω,η,H) arises as a parametrization of such quantizations, which results in a notion of quantum spacetime, that we call *modular spacetime*. In particular, a one-dimensional modular line is a two-dimensional torus that is compact and not simply connected. Finally, large spacetimes of canonical general relativity (and its extensions, like string theory) result as a "many-body" phenomenon through a process of tensoring (entangling) unit modular cells, which we refer to as "extensification."[5] Note that the Lorentz group (in d spacetime dimensions) lies at the intersection of the symplectic, neutral and doubly orthogonal groups,[5]

$$\mathrm{O}(1,d-1) \ = \ \mathrm{Sp}(2d)\cap\mathrm{O}(d,d)\cap\mathrm{O}(2,2(d-1))\ , \tag{7}$$

which sheds new light on the origin of quantum theory through compatibility of the causal (Lorentz) structure and non-locality captured by the discreteness of quantum spacetime. Note that relative (observer-dependent) locality[16] is needed to resolve

the apparent contradiction between discreteness of quantum spacetime and Lorentz symmetry.

One can pass from a classical polarization (such as the Schrödinger representation) to a modular polarization via the Zak transform.[14] Note that, there is a connection on the line bundle over phase space that has unit flux through a modular cell. (This is very similar to Integer Quantum Hall effect.) A modular wave function is quasi-periodic

$$\Psi(x+a,\tilde{x}) \;=\; e^{2i\pi a\tilde{x}}\Psi(x,\tilde{x})\;, \quad \Psi(x,\tilde{x}+\tilde{a}) \;=\; \Psi(x,\tilde{x})\;. \tag{8}$$

The quasi-periods correspond to the tails of an Aharonov-Bohm[24] potential attached to a unit flux. In particular, vacuum states must have at least one zero in a cell, which leads to theta functions (the Zak transforms of Gaussians).

2.2. *A comment on quantum field theory and quantum spacetime*

A few general comments about QFT in the modular form are in order, following the general modular formulation of any quantum theory. The modular polarization of QFT reveals new structures and sheds new light on both the short distance (UV) and long distance (IR) physics of quantum fields, and the continuum limit of QFTs which is self-dual with respect to the UV and IR properties (resembling some crucial properties of non-commutative field theories[25]). In particular, the modular representation of QFT introduces dual "electric" and "magnetic" variables, which are non-commuting in general. This extends our results in the context of the $2d$ conformal field theory formulation of string theory in which the non-commutativity of such "electric" and "magnetic" variables has been explicitly demonstrated.[7,8]

The general modular representation can be defined in terms of the Zak transform of a Schrödinger representation (*i.e.*, wave functions). Given a square normalizable wave function $\psi(x)$ belonging to a Hilbert space, one defines the modular representation as the lattice Fourier transform (or Zak transform)

$$\psi_a(x,\tilde{x}) \;\equiv\; \sqrt{a}\sum_n e^{-2\pi i n\tilde{x}}\psi(a(x+n))\;, \tag{9}$$

where $x \equiv q/a$, $\tilde{x} \equiv p/b$, with $ab = 2\pi\hbar$. Note that if $\psi(x)$ is a Gaussian, its Zak transform, the modular $\psi_a(x,\tilde{x})$, is given by the doubly-periodic theta function associated with the lattice. (The inverse Zak transform

$$\Phi(x+n) \;\equiv\; \frac{1}{\sqrt{a}}\int_0^1 d\tilde{x}\, e^{2\pi i n\tilde{x}}\Phi_a(a^{-1}x,\tilde{x})\;, \tag{10}$$

illustrates that the usual Schrödinger representation is truly singular, and thus not generic.)

Now if one second quantizes $\psi(x)$, one naturally ends up with a quantum field operator $\phi(x)$. Similarly, the second quantization of the modular $\psi_a(x,\tilde{x})$ would lead to a modular quantum field operator $\phi(x,\tilde{x})$, $\phi(x) \to \phi(x,\tilde{x})$. The excitations of such modular quantum fields are non-local in general, and will be discussed below

as *metaparticles*. Note that the usual wave functional approach to QFT defined in terms of functionals $\Psi\big[\phi(x)\big]$ should be now defined in terms of wave functionals of modular fields $\Psi\big[\phi(x,\tilde{x})\big]$. However, now we have more freedom in the general modular polarization. The dual momenta p and $\tilde{p}$ (to x and $\tilde{x}$ respectively) lead, via the canonical minimal-coupling prescription, not only to the usual fields ϕ but also to their duals $\tilde{\phi}$ (see below). This procedure defines the modular polarization of QFT in terms of the functional Zak transform of the original wave functional, $\Psi\big[\phi(x)\big] \rightarrow \Psi\big[\phi(x,\tilde{x}),\tilde{\phi}(x,\tilde{x})\big]$. For example, the Gaussian wave functionals with non-trivial kernels (such as the ones found in the context of non-trivial interacting theories like 2+1 and 3+1 dimensional Yang Mills theory[26]) would be mapped into functional theta functions.

The non-perturbative formulation is defined in a symmetric, self-dual way with respect to the double RG flows (as in non-commutative field theory[25]) with full spacetime covariance, and should be important not only for quantum non-locality of QFT, but also in the realms of strong coupling and deep infrared.

3. Quantum gravity and dynamical quantum (modular) spacetime

The unexpected outcome of this new view of the foundations of quantum theory is that this fundamental geometry of quantum theory can be realized in the context of metastring theory, in which this Born geometry (given by ω, η and H) is "gravitized" (i.e. dynamical). At the classical level, metastring theory[1–10] can be thought of as a formulation of string theory in which the target space is doubled in such a way that T-duality acts linearly on the coordinates. This doubling means that momentum and winding modes appear on an equal footing. In this formulation, T-duality exchanges the Lagrangian sub-manifold with its image under $J = \eta^{-1}H$. Classical metastring theory is defined by the action[3,27]

$$\hat{S} = \frac{1}{4\pi}\int_{\Sigma} d^2\sigma\Big(\partial_\tau \mathbb{X}^A(\eta_{AB}+\omega_{AB})(\mathbb{X})\partial_\sigma \mathbb{X}^B - \partial_\sigma \mathbb{X}^A H_{AB}(\mathbb{X})\partial_\sigma \mathbb{X}^B\Big)\,, \qquad (11)$$

where $\mathbb{X}^A$ are dimensionless coordinates on phase space and the fields η, H, ω are all dynamical (i.e., in general dependent on $\mathbb{X}$) phase space fields ($\mathbb{X}^A \equiv (x^a, \tilde{x}_a)^T$). In the context of a flat metastring we have constant η_{AB}, H_{AB}, and ω_{AB} :

$$\eta_{AB} \equiv \begin{pmatrix} 0 & \delta \\ \delta^T & 0 \end{pmatrix}, \quad H_{AB} \equiv \begin{pmatrix} h & 0 \\ 0 & h^{-1} \end{pmatrix}, \quad \omega_{AB} = \begin{pmatrix} 0 & \delta \\ -\delta^T & 0 \end{pmatrix}, \qquad (12)$$

where δ^μ_ν is the d-dimensional identity matrix, and $h_{\mu\nu}$ is the d-dimensional Lorentzian metric. The Polyakov string[28] is obtained in a singular limit of zero ω after integrating over $\tilde{x}$. (For a phase space structure of the canonical string see Ref. 29 and references therein.)

3.1. *Non-commutativity and non-associativity in quantum gravity*

The metastring formulation points to an unexpected fundamental non-commutativity of closed string theory, that we address in what follows. The string

commutation relations[7,8] state $[\mathbb{X}^A(\sigma),\mathbb{X}^B(\sigma')] = 2i\lambda^2\big[\pi\omega^{AB} - \eta^{AB}\theta(\sigma-\sigma')\big]$, where $\theta(\sigma)$ is the staircase distribution, i.e., a solution of $\theta'(\sigma) = 2\pi\delta(\sigma)$; it is odd and quasi-periodic with period 2π. Following standard practice, all indices are raised and lowered using η and η^{-1}. The momentum density operator is given by

$$\mathbb{P}_A(\sigma) \;=\; \frac{1}{2\pi\alpha'}\,\eta_{AB}\,\partial_\sigma\mathbb{X}^B(\sigma)\,, \tag{13}$$

and the previous commutation relation implies that it is conjugate to $\mathbb{X}^A(\sigma)$. The two-form ω appears when one integrates this canonical commutation relation to include the zero-modes, the integration constant being uniquely determined by worldsheet causality. Denoting by $(\,\hat{\mathbb{X}},\hat{\mathbb{P}}\,)$ the zero mode components of the string operators $\mathbb{X}(\sigma)$ and $\mathbb{P}(\sigma)$, we have $\big[\,\hat{\mathbb{P}}_A,\hat{\mathbb{P}}_B\,\big]=0$, $\big[\,\hat{\mathbb{X}}^A,\hat{\mathbb{P}}_B\,\big] = i\hbar\delta^A{}_B$, and $\big[\,\hat{\mathbb{X}}^A,\hat{\mathbb{X}}^B\,\big] = 2\pi i\lambda^2\omega^{AB}$. This is a deformation of the doubled Heisenberg algebra involving the string length λ as a deformation parameter. Note that under a constant B-field transformation $\mathbb{X}=(x^a,\tilde{x}_a)\mapsto(x^a,\tilde{x}_a+B_{ab}x^b)$, the trivial symplectic form $\omega(\mathbb{K},\mathbb{K}')=k\cdot\tilde{k}'-\tilde{k}\cdot k'$ is mapped onto $\omega(\mathbb{K},\mathbb{K}')=k_a\tilde{k}'^a-k'_a\tilde{k}^a-2B_{ab}\tilde{k}^a\tilde{k}'^b$, and the commutators read

$$\big[\,\hat{x}^a,\hat{x}^b\,\big]=0\,,\quad \big[\,\hat{x}^a,\hat{\tilde{x}}_b\,\big]=2\pi i\lambda^2\delta^a{}_b\,,\quad \big[\,\hat{\tilde{x}}_a,\hat{\tilde{x}}_b\,\big]=-4\pi i\lambda^2B_{ab}\,. \tag{14}$$

We see that the effect of the B-field is to render the dual coordinates non-commutative (and that the B-field originates from the symplectic structure ω). This implies a new view of the axion in four spacetime dimensions. The β-transformation on the other hand corresponds to the map $(x^a,\tilde{x}_a)\mapsto(x^a+\beta^{ab}\tilde{x}_b,\tilde{x}_a)$. Equivalently, it has the effect of mapping the symplectic structure to $\omega(\mathbb{K},\mathbb{K}') = k_a\tilde{k}'^a-k'_a\tilde{k}^a+2\beta^{ab}k_ak'_b$, and yields commutation relations

$$\big[\,\hat{x}^a,\hat{x}^b\,\big]=4\pi i\lambda^2\beta^{ab}\,,\qquad \big[\,\hat{x}^a,\hat{\tilde{x}}_b\,\big]=2\pi i\lambda^2\delta^a{}_b\,,\qquad \big[\,\hat{\tilde{x}}_a,\hat{\tilde{x}}_b\,\big]=0\,. \tag{15}$$

Dramatically, the coordinates that are usually thought of as the spacetime coordinates have become themselves non-commutative. Since this is the result of an $O(d,d)$ transformation it can be thought of in similar terms as the B-field; these are related by T-duality. We are familiar with the B-field background because we have, in the non-compact case, a fixed notion of locality in the target-space theory. However, in the non-geometric β-field background, we do not have such a notion of locality but we can access it through T-duality. However, this background does lead to non-commutative field theory, and one can place a bound on the minimal length λ of $O(10\,\mathrm{TeV})$, which is the current high-energy limit for probing the continuum structure of spacetime. (Similarly, this background can be used to argue for an effective minimal-length extension of commutation relations.[30] For astrophysical probes of the minimal length, see Ref. 31.)

Note that the dilaton can be understood as coming from the volume of phase space.[32] In general, for varying B-backgrounds we encounter non-associativity as well,[33] and the proper closure of such non-commutative and non-associative structure is ensured by the equations of motion. Here we remark that fundamental non-associativity can be related to the robustness of the Standard Model (SM) gauge

group.[34] Similarly, fundamental non-commutativity can be related to the underlying non-commutative nature of the SM and its phenomenology.[19,35]

3.2. *Non-perturbative formulation of quantum gravity*

The metastring offers a new view on the fundamental question of a non-perturbative formulation of quantum gravity.[1–10] The worldsheet can be made modular in our formulation, with the doubling of τ and σ, so that $\mathbb{X}(\tau,\sigma)$ can be in general viewed as an infinite-dimensional matrix (the matrix indices coming from the Fourier components of the doubles of τ and σ). Then the corresponding metastring action reads as

$$\int \mathrm{Tr}\Big[\,\partial_\tau \mathbb{X}^A \partial_\sigma \mathbb{X}^B(\omega_{AB}+\eta_{AB}) - \partial_\sigma \mathbb{X}^A H_{AB}\partial_\sigma \mathbb{X}^B\,\Big] d\tau d\sigma\ , \tag{16}$$

where the trace is over the matrix indices. One can associate partonic degrees of freedom with matrix entries. A non-perturbative quantum gravity follows by replacing the σ-derivative with a commutator involving one extra $\mathbb{X}^{26}$:

$$\partial_\sigma \mathbb{X}^A \to \big[\,\mathbb{X}^{26},\,\mathbb{X}^A\big]\ , \tag{17}$$

with $A = 0,1,2,\ldots,25$. The resulting matrix-model form of the above metastring action is

$$\int \mathrm{Tr}\Big(\partial_\tau \mathbb{X}^a\big[\mathbb{X}^b,\mathbb{X}^c\big]\eta_{abc} - H_{ac}\big[\mathbb{X}^a,\mathbb{X}^b\big]\big[\mathbb{X}^c,\mathbb{X}^d\big]H_{bd}\Big) d\tau\ , \tag{18}$$

with $a,b,c = 0,1,2,\ldots,25,26$, where the first term is of a Chern-Simons form and the second of the Yang-Mills form. η_{abc} contains both ω_{AB} and η_{AB}. This defines a non-perturbative quantum gravity viewed as "a gravitization of the quantum."[10]

This formulations invokes the IIB matrix model,[36] which describes N D-instantons (and is by T-duality related to the Matrix model of M-theory[37]). Given our new viewpoint we suggest a new covariant non-commutative matrix-model formulation of string theory as a theory of quantum gravity, by writing in the large N limit $\partial_\sigma \mathbb{X}^C = [\mathbb{X},\mathbb{X}^C]$ (and similarly for $\partial_\tau \mathbb{X}^B$) in terms of commutators of two (one for $\partial_\sigma \mathbb{X}^C$ and one for $\partial_\tau \mathbb{X}^C$) extra $N\times N$ matrix-valued chiral $\mathbb{X}$'s. Notice that, in general, we do not need an overall trace, and so the action can be viewed as a matrix, rendering the entire non-perturbative formulation as purely quantum in the sense of the original matrix formulation of QM:

$$\mathbb{S}_{\mathrm{ncF}} = \frac{1}{4\pi}\big[\mathbb{X}^a,\mathbb{X}^b\big]\big[\mathbb{X}^c,\mathbb{X}^d\big]f_{abcd}\ , \tag{19}$$

where instead of 26 bosonic $\mathbb{X}$ matrices we have 28, with supersymmetry emerging in 10(+2) dimensions from this underlying bosonic formulation. (This is a non-commutative matrix-model formulation of F-theory.) By T-duality, the new covariant M-theory matrix model is

$$\mathbb{S}_{\mathrm{ncM}} = \frac{1}{4\pi}\int_\tau \Big(\partial_\tau \mathbb{X}^i\big[\mathbb{X}^j,\mathbb{X}^k\big]g_{ijk} - \big[\mathbb{X}^i,\mathbb{X}^j\big]\big[\mathbb{X}^k,\mathbb{X}^l\big]h_{ijkl}\Big), \tag{20}$$

with 27 bosonic $\mathbb{X}$ matrices, with supersymmetry emerging in 11 dimensions. In this approach, holography[38] (such as AdS/CFT[39] or dS/CFT[40]), which can be viewed as a "quantum Jarzynski equality on the space of geometrized RG flows,"[41] is emergent in a particular "extensification" of quantum spacetime. The relevant information about ω_{AB}, η_{AB}, and H_{AB} is now contained in the new dynamical backgrounds f_{abcd} in F-theory, and g_{ijk} and h_{ijkl} in M-theory. This offers a new formulation of covariant Matrix theory in the M-theory limit,[42] which is essentially a partonic formulation; strings emerge from partonic constituents in a certain limit. This new matrix formulation is fundamentally bosonic (*i.e*, supersymmetry is emergent only in a specific limit) and thus it is reminiscent of bosonic M-theory.[43] The relevant backgrounds g_{ijk} and h_{ijkl} should be determined by the matrix RG equations. Also, there are lessons here for the new concept of "gravitization of quantum theory" as well as the idea that dynamical Hilbert spaces, or 2-Hilbert spaces (here represented by matrices), are fundamentally needed in quantum gravity.[44]

This matrix-like formulation should be understood as a general non-perturbative formulation of string theory. In this partonic formulation closed strings are collective excitations, in turn constructed from the product of open string fields. The observed classical spacetime emerges as an "extensification"[1–10] in a particular limit, out of the basic building blocks of quantum spacetime. Their remnants can be found in the low energy bi-local quantum fields, with bi-local (metaparticle) quanta, to which we now turn.

4. Quantum gravity, metastrings, metaparticles and dark matter

The above manifestly T-duality covariant formulation of closed strings (i.e. metastring theory) implies intrinsic non-commutativity of zero-modes. It is thus instructive to formulate a particle-like limit of the metastring that we call the *metaparticle*.[7–9] The theory of metaparticles (the low energy remnants of the metastring, and as such, the low energy remnants (predictions) of quantum gravity) is defined by the following world-line action[7–9]

$$S \equiv \int_0^1 d\tau \left[p\dot{x} + \tilde{p}\dot{\tilde{x}} + \lambda^2 p\dot{\tilde{p}} - \frac{N}{2}\left(p^2 + \tilde{p}^2 + m^2\right) + \tilde{N}\left(p\tilde{p} - \mu\right) \right] . \qquad (21)$$

Here the signature $(+,-,\cdots,-)$ and the contraction of indices are implicitly assumed. At the classical level, theory of metaparticles is a worldline theory with the usual reparameterization invariance and two additional features.[9] The first new feature is the presence of an additional local symmetry, which from the string point of view corresponds to the completion of worldsheet diffeomorphism invariance. From the particle worldline point of view, this symmetry is associated with an additional local constraint. The second new feature is the presence of a non-trivial symplectic form on the metaparticle phase space, also motivated by string theory.[7,8] Because of its interpretation as a particle model on Born geometry, associated with the modular representation of quantum theory, the spacetime on which the metaparticle propagates is ambiguous, with different choices related by T-duality. The attractive

feature of this model include worldline causality and unitarity, as well as an explicit mixing of widely separated energy-momentum scales. The metaparticle propagator follows from the world line path integral defined by the above action and it has the following form in momentum space[9]:

$$G(p,\tilde{p};p_i,\tilde{p}_i) \;\sim\; \delta^{(d)}(p-p_i)\,\delta^{(d)}(\tilde{p}-\tilde{p}_i)\,\frac{\delta(p\cdot\tilde{p}-\mu)}{p^2+\tilde{p}^2+m^2-i\varepsilon}\;. \tag{22}$$

The canonical particle propagator is a highly singular $\tilde{p}\to 0$ (and $\mu\to 0$) limit of this expression. This propagator also predicts the following dispersion relation (in a particular gauge[9]) that can be tested in various experiments and with various probes: $E_p^2+(\mu^2/E_p^2)=\vec{p}^{\,2}+m^2$. This formulation is fully compatible with Lorentz covariance, and is a direct consequence of the consistency of quantum theory and a minimal length (and thus Born geometry). In a cosmological context, one can use this dispersion relation to put a bound on μ for the case of neutrinos, which turns out to be close to the energy scale of dark energy.[45] In general, for each particle at energy E there exists a dual particle at energy μ/E. This is in complete analogy of the well-known prediction of antiparticles in the union of special relativity and quantum theory.

Note that the usual particle limit is obtained, at least classically, by taking $\mu\to 0$ and $\tilde{p}\to 0$. Given the form of the above Lagrangian, the metaparticle looks like two particles that are entangled through a Berry-phase-like $p_\mu\,\dot{\tilde{p}}^\mu$ factor. The metaparticle is fundamentally non-local, and thus it should not be associated with effective local field theory. In particular, by looking at the metaparticle constraints $p^2+\tilde{p}^2=m^2$ and $p\tilde{p}=\mu$, we note that the momenta p and $\tilde{p}$ can be, in principle, widely separated. For example, if m is of the order of the Planck energy, and μ of the order of TeV^2 (which can be considered a characteristic particle physics scale), then the p can be of the order of the Planck energy, and the $\tilde{p}$ of the vacuum energy scale. Thus metaparticle theory can naturally relate widely separated scales, which transcends the usual reasoning based on Wilsonian effective field theory (and should be relevant for the naturalness and hierarchy problems).

We can also discuss the background fields that couple to the metaparticle quanta. Following the well-known procedure of introducing background fields in the case of particles, by shifting the canonical momentum by a gauge field we may try to extend the gauging procedure to the metaparticle counterpart. There is a possible ambiguity in this gauging which depends on which configuration variables one decides to work with. If one takes $(x,\tilde{x})$ as configuration variables, one obtains a gauging which could also be motivated by the presence of a "stringy gauge field" in metastring theory,[3] $p_\mu\to p_\mu+A_\mu(x,\tilde{x})$ and $\tilde{p}^\mu\to\tilde{p}^\mu+\tilde{A}^\mu(x,\tilde{x})$. The generic prediction here is the existence of a dual field $\tilde{A}$, which is correlated (entangled), with the original A field. Thus the entire SM would have a dual SM (which we propose, describes the dark matter sector).

We expect that the correct field theoretic description of the metaparticle is in terms of the above general non-commutative (modular) field theory $\Phi(x,\tilde{x})$ limit of

the metastring.[1–10] Such an effective non-commutative field theory is similar in spirit to Ref. 25. Also, we note that the concept of metaparticles might be argued from the compatibility of the quantum spacetime that underlies the generic representations of quantum theory, as discussed in Ref. 5, and thus the metaparticle might be as ubiquitous as the concept of antiparticles which is demanded by the compatibility of relativity and quantum theory. The metaparticles also provide a natural route to the problem of dark matter. To lowest (zeroth) order of the expansion in the non-commutative parameter λ, the effective action for the SM matter Lagrangian (L_m) and their duals (that could be interpreted as the dark matter Lagrangian L_{dm}) takes the form

$$S_{\text{eff}} = -\iint \sqrt{g(x)\tilde{g}(\tilde{x})}\big[L_m(A(x,\tilde{x})) + \tilde{L}_{dm}(\tilde{A}(x,\tilde{x})) + \cdots\big] \,, \tag{23}$$

where we have included the non-dynamical gravitational background. Note that after integrating over the "hidden variable" parameters $\tilde{x}$, we obtain an effective theory of visible and dual (dark) matter in the observed spacetime x :

$$S_{\text{eff}} = -\int \sqrt{g(x)}\,\Big[L_m(A(x)) + \tilde{L}_{dm}(\tilde{A}(x)) + \cdots\Big] \,. \tag{24}$$

Thus, the metaparticle can be understood as a generic message of string theory/quantum gravity for low energy physics. Like their visible particle cousins, dark matter quanta should be detectable through their particular metaparticle correlation/entanglement to visible matter. This is a Berry-phase-like effect that comes from a fully covariant description, and is uniquely different from the usual effective field theory interaction terms between visible and dark matter particles. We will discuss the observable consequences of this view of dark matter in the last section.

5. Quantum gravity, dark matter and dark energy

We now explain how the generalized geometric formulation of string theory discussed above provides for an effective description of dark energy that is consistent with de Sitter spacetime. This is essentially due to the theory's chirally and non-commutatively doubled realization of the target space, and the stringy effective action on the doubled non-commutative spacetime $(x^a, \tilde{x}^a)$:

$$S^{nc}_{\text{eff}} = \iint \text{Tr}\sqrt{g(x,\tilde{x})}\,\big[R(x,\tilde{x}) + L_m(x,\tilde{x}) + \cdots\big] \,, \tag{25}$$

where the ellipses denote higher-order curvature terms induced by string theory, and L_m is the matter Lagrangian. S^{nc}_{eff} clearly expands into numerous terms with different powers of λ, which upon $\tilde{x}$-integration and from the x-space vantage point produce various effective terms. To lowest (zeroth) order of the expansion in the non-commutative parameter λ of S^{nc}_{eff} takes the form:

$$S_d = -\iint \sqrt{-g(x)}\sqrt{-\tilde{g}(\tilde{x})}\big[R(x) + \tilde{R}(\tilde{x})\big] \,, \tag{26}$$

a result which was first obtained almost three decades ago, effectively neglecting ω_{AB} by assuming that $[\hat{x}^a, \hat{\tilde{x}}_b] = 0$.[46] In this leading limit, the $\tilde{x}$-integration in the first term defines the gravitational constant G, and in the second term produces a *positive* cosmological constant $\Lambda > 0$. In particular, we are lead to the following low-energy effective action valid at long distances of the observed accelerated universe (focusing on the relevant 3+1-dimensional spacetime X, of the $+---$ signature):

$$S_{\text{eff}} = \frac{-1}{8\pi G}\int_X \sqrt{-g}\big(\Lambda + \tfrac{1}{2}R + \mathcal{O}(R^2)\big)\ , \tag{27}$$

with Λ the positive cosmological constant (corresponding to the scale of 10^{-3} eV) and the $\mathcal{O}(R^2)$ denote higher order corrections (which are also required by the sigma model of string theory[47]).

It also follows from this construction that the weakness of gravity is determined by the size of the canonically-conjugate dual space, while the smallness of the cosmological constant is given by its curvature. Given this action, we may proceed reinterpreting Ref. 46. Integrate out the dual spacetime coordinates and write the effective action as

$$\overline{S} \sim \tilde{V}\int_X \sqrt{-g(x)}R(x) + \cdots\ , \quad \text{where} \quad \widetilde{V} = \int_{\tilde{X}}\sqrt{-\tilde{g}(\tilde{x})}\ , \tag{28}$$

and then relate the dual spacetime volume to the observed spacetime volume as $\widetilde{V} \sim V^{-1}$ (T-duality). This produces an "intensive" effective action[46] :

$$\overline{S} = \frac{\int_X \sqrt{-g(x)}\,(R(x) + L_m(x))}{\int_X \sqrt{-g(x)}} + \cdots\ . \tag{29}$$

By concentrating on the classical description first (we discuss below quantum corrections and the central role of intrinsic non-commutativity in string theory) we obtain the Einstein equations[46]

$$R_{ab} - \frac{1}{2}Rg_{ab} + T_{ab} + \frac{1}{2}\overline{S}\,g_{ab} = 0\ , \quad \text{with} \quad T_{ab} \stackrel{\text{def}}{=} \frac{\partial L_m}{\partial g^{ab}} - \frac{1}{2}L_m\,g_{ab}\ . \tag{30}$$

We emphasize that our reinterpretation of Ref. 46 does not follow the original presentation and intention. In particular, we directly relate the intensive action to the cosmological constant, $\overline{S} \sim \Lambda$. Note that this new approach to the question of dark energy (viewed as a cosmological constant) in quantum gravity is realized in certain stringy-cosmic-string-like toy models,[48] which can be viewed as illustrative of a generic non-commutative phase of F-theory.[49] In particular, a "see-saw" formula is directly realized in Ref. 48 as $M_\Lambda \sim M^2/M_P$, where M_Λ is the dark energy scale, M_P the Planck scale, and M an intermediate scale coming from the matter sector (such as the Higgs scale).

Note that, in general, to lowest (zeroth) order of the expansion in the non-commutative parameter λ, S^{nc}_{eff} takes the following form (that also includes the matter sector and its dual)[50] :

$$S_d = -\iint \sqrt{g(x)\tilde{g}(\tilde{x})}\,\Big[R(x) + \tilde{R}(\tilde{x}) + L_m(A(x,\tilde{x})) + \tilde{L}_{dm}(\tilde{A}(x,\tilde{x}))\Big]\ . \tag{31}$$

Here, A denotes the usual SM fields, and $\tilde{A}$ denotes their duals. Note that after integrating over the dual spacetime, and after taking into account T-duality, the intensive action now reads

$$\overline{S} = \frac{\int_X \sqrt{-g(x)}\big(R(x) + L_m(x) + \tilde{L}_{dm}(x)\big)}{\int_X \sqrt{-g(x)}} + \cdots \,. \tag{32}$$

The proposal here is that the dual sector (as already indicated in the previous section) should be interpreted as the dark matter sector, which is correlated to the visible sector via the dark energy sector, as discussed in Ref. 12. (The radiative stability of this construction has been discussed in Ref. 50, which also addresses the hierarchy problem.) We emphasize the unity of the description of the entire dark sector based on the properties of the dual spacetime. Note that one can also discuss statistical effects in this view of dark energy and, in particular, provide an explicit formula for a dynamical form of dark energy[51] that can be compared to cosmological observations.

6. Coda: Quantum gravity phenomenology and the real world

In conclusion, we discuss the implications of our new view on dark matter and dark energy in the context of actual astronomical observations.

6.1. *Observational issues*

The above metaparticle-like dark matter quanta are by construction correlated to visible matter and have been discussed in the literature as Modified dark matter (MDM).[12] MDM is, at the moment, a phenomenological model of dark matter inspired by gravitational thermodynamics. For an accelerating Universe with positive cosmological constant Λ, certain phenomenological considerations lead to the emergence of a critical acceleration parameter related to Λ. This "fundamental acceleration" is just the value of Λ expressed as acceleration $\sim cH_0$, where H_0 is the Hubble constant, and thus, is of the order of $10^{-10}\mathrm{m/s}^2$. Appearance of this acceleration scale in the data is an expected manifestation of MDM, and its existence is observationally supported as discussed below. The resulting MDM mass profiles, which are sensitive to Λ, are consistent with observational data at both the galactic and cluster scales. In particular, the same critical acceleration appears both in the galactic and cluster data fits based on MDM.[12] Furthermore, using some robust qualitative arguments, MDM appears to work well on cosmological scales. If the quanta of MDM are metaparticles, this may explain why, so far, dark matter detection experiments have failed to detect dark matter particles. In particular, the natural model for MDM quanta could be provided by the metaparticle realizations of the SM particles, associated with bi-local extensions of all SM fields. Thus the baryonic matter described by the SM fields (the A backgrounds in the above discussion) would have natural cousins (the $\tilde{A}$ backgrounds in the above discussion) in the

dark matter sector, which in turn would be sensitive to the dark energy modeled by the cosmological constant $\Lambda \sim 1/H_0^2$, that is, the curvature of the dual spacetime, which is radiatively stable and related to the Planck energy and the characteristic energy scale of the visible sector $M_\Lambda \sim M^2/M_P$.

The importance of the fundamental acceleration $10^{-10}\mathrm{m/s}^2$ is manifest in the empirically established baryonic Tully-Fisher[53] (BTF), and baryonic Faber-Jackson[54] (BFJ) relations. The BTF relation refers to the observed correlation between the total baryonic mass of spiral galaxies M_{bar} and the rotational velocity in the flat part of the rotation curve v_{flat} of the form $M_{\mathrm{bar}} \sim v_{\mathrm{flat}}^4$. The slope of the BTF relation gives the fundamental acceleration $v_{\mathrm{flat}}^4/(GM_{\mathrm{bar}}) \sim 10^{-10}\mathrm{m/s}^2$. The relation for elliptical galaxies and other pressure supported systems that parallels the BTF for spirals is the BFJ relation between M_{bar} and the line-of-sight velocity dispersion σ of the form $M_{\mathrm{bar}} \sim \sigma^n$. When fit to data of various pressure supported systems, the best fit to the power n was found to be anywhere from about 3 to 5 depending on the scale of the systems considered. However, when the data for globular clusters, elliptical galaxies, galaxy clusters, etc. are all analyzed together, the preferred power is $n = 4$, though the data does show considerable scatter around this line.[52,55,56] Furthermore, the slope of the $n = 4$ BFJ fit again gives the fundamental acceleration $\sigma^4/(GM_{\mathrm{bar}}) \sim 10^{-10}\mathrm{m/s}^2$.

According to the ΛCDM model of cosmology, our Universe started out with almost uniform distributions of cold dark matter (CDM) and baryonic matter. Consequently, a correlation between the total dark matter and total baryonic matter in a region surrounding a galaxy is to be expected in the ΛCDM model. However, given that galaxies are thought to have gone through various phases including starbursts, emission of gasses, and multiple mergers during their evolutionary histories, a dynamic correlation such as the BTF and BFJ relations involving the fundamental acceleration scale is surprising. The question is: what do these correlations imply on the nature of dark matter? What type of dark matter would be able to explain these relations?

6.2. *Analogy with turbulence*

Given that the temperature fluctuations in the Cosmic Microwave Background have been observed to be scale invariant,[57] and assuming that dark matter (whether traditional or metaparticle) is collisionless, then an analogy with Kolmogorov's theory of turbulence may be instructive.[58]

In the so-called inertial range of the turbulent fluid, *i.e.* at length scales L where the viscosity of the fluid can be neglected, the dynamics of vortices is determined solely by the rate of energy dissipation ε, and if one writes $\langle \mathrm{KE} \rangle = \int dk\, E(k)$, where $\langle \mathrm{KE} \rangle$ is the mean turbulent kinetic energy of the flow and $k = 2\pi/L$ is the wave number, simple dimensional analysis yields the famous Kolmogorov scaling relation $E(k) \propto \varepsilon^{2/3} k^{-5/3}$, which has been confirmed experimentally. The length scale η

below which viscous effects become important, called the Kolmogorov microscale, is the boundary of the inertial region. Again, from dimensional analysis, it is argued that $\eta \propto (\nu^3/\varepsilon)^{1/4}$, where ν is the kinematic viscosity. Essentially, the scale η is determined by the competition between ε and ν. Note that this argument assumes that there is no other dimension-ful scale in the problem other than these two parameters.

In the case of structure formation in a statistically self-similar (*i.e.* scale invariant) Universe, the two competing effects would be attraction due to gravity, parametrized by G, and the speed of the expansion of the Universe $H(z) = \dot{a}/a$, where z is the redshift. The scale of the structures that form at redshift z should be determined by G and $H(z)$. Now, consider the size $R_{\rm vir}$ of a virialized structure of total mass M. We expect $\langle v^2 \rangle \sim \sigma^2 \sim GM/R_{\rm vir}$. The gravitational acceleration at the edge of this structure is $a_{\rm vir} = GM/R_{\rm vir}^2 \sim \sigma^4/(GM)$. Thus, the scale of the structure $R_{\rm vir}$ can be characterized by this acceleration scale $a_{\rm vir}$. From dimensional analysis a la Kolmogorov we expect $a_{\rm vir} \sim \sigma^4/(GM) \propto cH(z)$, which is analogous to the $n = 4$ FJ relation except 1) M is the sum of the dark matter mass and the baryonic mass, 2) dark matter halos are not necessarily virialized, 3) the proportionality constant may not be order one, 4) the z dependence of $H(z)$ suggests that $\sigma^4/(GM)$ will depend on the redshift z at which the structures formed, and 5) in actuality, there are many other scales present. Nevertheless, this simple handwaving argument does suggest a possible path toward the BFJ, or a BFJ-like relation. Note also that metaparticle quanta are sensitive to both the UV (G, the Planck scale) and the IR ($H(z)$), suggesting that they may provide the linchpin connecting those scales, and the crucial ingredient in constructing a dark matter model that could realize this scenario.

One intriguing prediction of the above discussion is the possible z-dependence of $\sigma^4/(GM)$. Replacing M by $M_{\rm bar}$ should not erase this dependence. Dimensionally, $\sigma^4/(GM_{\rm bar})$ should scale as $(1 + z)$. Galaxy clusters have formed recently ($z < 1$), galaxies have started to form at around $z \sim 10$, and globular clusters at around $z \sim 10^2$.[59] So if $\sigma^4/(GM_{\rm bar})$ is around $10^{-10}\,{\rm m/s^2}$ for galaxy clusters, it should be around $10^{-9}\,{\rm m/s^2}$ for galaxies, and $10^{-8}\,{\rm m/s^2}$ for globular clusters. In Fig. 1 we plot $\sigma^4/(GM_{\rm bar})$ for a variety of structures. As can be seen, the galaxy cluster data points are clustered around $10^{-10}\,{\rm m/s^2}$, while the galaxy data points are spread out in both directions and go up as far as $\sim 10^{-9}\,{\rm m/s^2}$, and the globular cluster data are spread out even further and go up as far as $\sim 10^{-8}\,{\rm m/s^2}$. One interpretation of this result is that galaxies and globular clusters started out with characteristic accelerations of $O(10^{-9}\,{\rm m/s^2})$ and $O(10^{-8}\,{\rm m/s^2})$, respectively, but have migrated to lower values as they went through various stages of evolution, resulting in distributions centered around $10^{-10}\,{\rm m/s^2}$ (in the log scale). This possibility had not been manifest in previous BFJ analyses which had always plotted σ^4 against $M_{\rm bar}$, demonstrating that a simple change of perspective can open up new vistas.

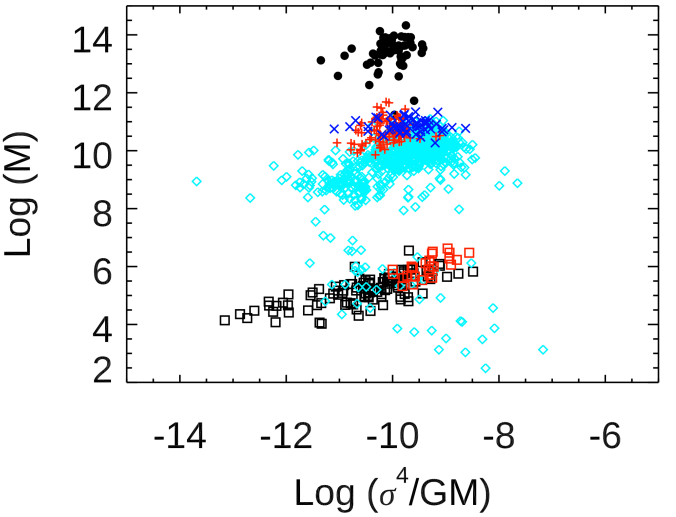

Fig. 1. The virial acceleration for structures spanning about 10 decades of scale $M/M_{\odot} = 10^{4\sim14}$. The data points are: • galaxy clusters,[60] + elliptical galaxies,[61,62] × elliptical galaxies,[63,64] ◇ elliptical, dwarf elliptical, and dwarf spheroidal galaxies,[65] □ Milky Way globular clusters,[66] □ M31 (Andromeda) globular clusters.[67]

6.3. *Closing remarks*

In this paper, we propose that the BFJ relation could be explained by metaparticle-based, or similar MDM models. We are, however, mindful that it could well be explained by more conventional means. Indeed, Kaplinghat and Turner[68] have provided a scenario on how the BTF relation may emerge from ΛCDM, though we are unaware of a similar work on the BFJ relation. MDM models, though suggestive, are lacking in similar concrete scenarios that would connect the models to the BFJ relation; a direction of research we intend to pursue.

This concludes our presentation of the new approach to quantum gravity (based on modular spacetime, Born geometry and metastring theory) and quantum gravity phenomenology in the context of dark matter and dark energy and actual astronomical observations.

The problem of time emerging in the canonical quantization procedure of gravity signals a necessity to properly define a relational time parameter. Previous approaches, which are here briefly discussed, make use of the dependence of the quantum system on semi-classical gravitational variables in order to define time. We show that such paths, despite the following studies, lead to a non-unitary evolution. We propose a different model for the quantization of the gravity-matter system, where the time parameter is defined via an additional term, i.e. the kinematical action, which acts as a clock for quantum matter. The procedure here used implements a Born-Oppenheimer-like separation of the system, which maintains covariance under the foliation of the gravitational background and keeps the correct classical limit of standard quantum field theory on a fixed background. It is shown with a WKB expansion that quantum gravity corrections to the matter dynamics arise at the next order of expansion, and such contributions are unitary, signaling a striking difference from previous proposals. Applications to a cosmological model are presented and the analogies of the kinematical term with an incoherent dust are briefly discussed.

Keywords: Quantum Gravity; Quantum Field Theory; Born-Oppenheimer approach; Cosmology.

1. Introduction

A suitable quantum description of the gravity-matter system is necessary in order to describe the Universe and its early phases. An important requirement for this purpose is the quantization of the gravitational field, which has opened a debate leading to many approaches and outcomes. The first candidate for this procedure is the Dirac prescription,[1] which leads however to the problem of time[2]: the Universe wave function does not evolve on time, hence a probabilistic interpretation is not clear. For this reason a different clock must be introduced[2,3]: essentially, we have to define a *relational time*[4] in order to describe the quantum system dynamics, adopting a subpart of the system as a clock through carefully chosen boundary conditions.

A first step in this path was proposed in,[5] by separating the system into a semiclassical component and the purely quantum sector due to their different energy scales, in analogy with the Born-Oppenheimer approximation.[6] The external time

was introduced via the dependence of the quantum subsystem on the semiclassical variables and, with a Wentzel-Kramer-Brillouin expansion[7] (WKB) in the Planck constant, the limit of standard quantum field theory on curved background was recovered at the first order, together with a positive-semidefinite probability density under certain conditions (see the original article[5] for such discussion).

Other models,[8–10] which differ for the choice of expansion parameter and initial conditions, have been studied focusing on the next order of expansion. The work[8] in particular dealt with computing quantum gravity induced corrections to the quantum matter dynamics, finding that non-unitary terms emerge. The workaround,[10] proposed to avoid such troublesome feature, cannot be applied in many contexts due to the strict initial requirements (see discussion in[11]). The work[9] followed more closely a Born-Oppenheimer approach on the problem, in order to define a conserved probability density; also in this case, however, it can be shown via the WKB expansion that the Hamiltonian operator describing the system dynamics is not unitary at the next order.[11]

Here we shall present a different implementation of the gravity-matter system, that ensures the standard limit of quantum field theory on curved background, with an expansion parameter proportional to the squared Planck mass (symbolizing the energy scale of gravity). The time parameter will not be linked to the dependence of the quantum sector on the semiclassical variables, but instead arise from an additional Hamiltonian term, i.e. the *kinematical action*,[12] that reinstates covariance of the theory in Arnowitt-Deser-Misner (ADM) variables[13] for assigned foliations. This term, together with the definition of the deformation vector, will allow us to obtain a functional Schrödinger equation for the quantum matter sector and, at the next order, a unitary dynamics including quantum gravity corrections.

An application will be shown for the case of the homogeneous free massless scalar field in a spatially flat Friedmann-Lemaitre-Robertson-Walker background, representing the inflaton field during the de Sitter phase; in this case such quantum gravity corrections indeed modify the Hamiltonian spectrum, with non-vanishing but small contributions due to the perturbative nature of the approach.

An important analogy is also discussed, linking the introduction of the *kinematical action* to the frame fixing procedure using Gaussian coordinates,[14] that emerge as a fluid term (more specifically, an incoherent dust) in the action, and showing how the two procedures are related.

The structure of the paper is the following. In Sec. 2 we will briefly introduce the WKB expansion of the gravity-matter system, discussing the mentioned approaches in literature and their outcomes. In Sec. 3 we propose a model constructing the time parameter from the kinematical action and show that its WKB expansion gives a unitary dynamics for the quantum matter sector at the order next to standard quantum field theory. In Sec. 4 the procedure is applied to a case representing the homogeneous inflaton field, in order to analyze the outcome in a cosmological view. In Sec. 5 the analogy of such construction with the frame-fixing procedure is presented. Sec. 6 contains the conclusive remarks.

2. Main features of the WKB expanded gravity-matter system

The starting point for the study of quantum gravity effects is the quantization of the gravitational field. It is known that, following the Dirac prescription,[1] one finds a time-independent Schrödinger equation which describes no evolution in time: the equation, known as the Wheeler-DeWitt[3] equation, is the essence of the so-called problem of time.[2] Then, in order to overcome such problem, one has to define a relational time parameter,[4] meaning that a selected subsystem must be chosen as a new, different clock to describe the evolution.

Let us briefly recall how this critical result emerges. We start with the foliation of space-time proposed by Arnowitt, Deser and Misner[13]: we identify 3d hypersurfaces immersed in the 4d spacetime environment by using some parametric equations, and derive the induces properties of such hypersurfaces from the environment ones. We label the induced 3d metric with the tensor h_{ij}, and the normal vector field with n^{μ}. Using these variables, one can compute the Hamiltonian formalism of the gravitational field, finding primary and secondary constraints on the wave function of the system.[15] It follows that the wave function depends only on the equivalence class of the induced geometries $\{h_{ij}\}$, and on the matter fields ϕ_a if present. Due to the superHamiltonian constraint, the action of the superHamiltonian on the system wave function must vanish:

$$H\Psi = \left(-\frac{2\hbar^2\kappa}{\sqrt{h}}\nabla_g^2 - \frac{\sqrt{h}\,R^{(3)}}{2\kappa} - \frac{\hbar^2}{2\sqrt{h}}\nabla_m^2 + u(h_{ij},\phi_a) \right)\Psi = 0 \tag{1}$$

where h refers to the determinant of the induced metric, $R^{(3)}$ to its curvature, κ is the Einstein coefficient $\kappa = 8\pi G/c^3$ and $u(h_{ij},\phi_a)$ is the total potential energy of the matter fields. The gradients ∇_g and ∇_m indicate respectively the derivatives with respect to the gravitational and matter variables.

This result is troublesome since it implies the problem of time,[2] where the associated Schrödinger equation states that the Universe wave function does not evolve in time at all. It follows that another time parameter[4] should be implemented in order to describe a non-trivial, meaningful dynamics.

A semiclassical approach can be implemented in this sense. By following the Wentzel-Kramer-Brillouin expansion,[7] we write the system wave function as the complex exponential $\mathrm{e}^{\mathrm{i}S/\hbar}$ and expand it with a chosen parameter, examining the dynamics order by order. The choice of parameter will determine the range of validity: it can be chosen as the Planck constant $\hbar$, or related to the inverse of the Einstein coefficient κ, i.e. proportional to the square of the reduced Planck mass (here labeled m_{Pl}):

$$M \equiv \frac{1}{4c^2\kappa} = \frac{c\,(m_{\mathrm{Pl}})^2}{4\hbar}. \tag{2}$$

Although different parameters can be implemented, these two cases present interesting results and therefore will be discussed in this paper.

The works under examination[5,8] differ from each other in few but fundamental starting hypotheses; let us briefly discuss them in the following.

2.1. *Expansion in* $\hbar$

In the $\hbar \to 0$ expansion,[5] the variables are separated into semiclassical c and quantum ones q, so that Eq. (1) reads

$$\left(-\hbar^2\nabla_c^2 + U_c(c) - \hbar^2\nabla_q^2 + U_q(c,q)\right)\Psi(c,q) = 0, \tag{3}$$

where the operator H_c is obtained neglecting all the quantum variables and U_c, U_q are respectively the semiclassical and quantum sector potentials.

The first assumption states that the action of the quantum Hamiltonian on the system wave function Ψ is small with respect to the semiclassical one:

$$\frac{\hat{H}_q\Psi}{\hat{H}_c\Psi} = \mathcal{O}(\hbar). \tag{4}$$

Secondly, it is assumed that the semiclassical and quantum subspaces are orthogonal; stronger requirements are needed in order to perform the expansion after the quantum mechanical order $\mathcal{O}(\hbar)$ (see discussion in[11]).

These assumptions allow a clean factorization of the action, which is implemented at each order of expansion after the first one:

$$S_n = \sigma_n(c) + \eta_n(c,q), \quad n \geq 1 \tag{5}$$

so that

$$S = S_0 + P + Q \quad \text{with} \quad P(c) = \sum_{n=1}^{\infty}\hbar^n\sigma_n, \quad Q(c,q) = \sum_{n=1}^{\infty}\hbar^n\eta_n, \tag{6}$$

being the term S_0 at lowest order $\mathcal{O}(\hbar^0)$ purely classical. This factorization is reflected in the wave function:

$$\Psi(c,q) = \psi(c)\chi(c,q) = \mathrm{e}^{\mathrm{i}(S_0+P)/\hbar}\,\mathrm{e}^{\mathrm{i}Q/\hbar}, \tag{7}$$

where the background part $\psi(c)$ is assumed to satisfy the semiclassical part of the Wheeler-DeWitt equation:

$$\left(-\hbar^2\nabla_c^2 + U_c\right)\psi(c) = 0. \tag{8}$$

Expanding up to order $\hbar$, a functional Schrödinger equation is recovered for the quantum subsystem χ_q in the background given by the semiclassical variables:

$$\mathrm{i}\hbar\frac{\partial\chi_1}{\partial\tau} = \hat{H}_q\chi_1, \tag{9}$$

with the following definition of time derivative

$$\frac{\partial}{\partial\tau} = 2\,\nabla_c S_0 \cdot \nabla_c\,. \tag{10}$$

This implementation describes a non-trivial dynamics (Eq. (9)) and allows the definition of a positive-semidefinite probability density, with suitable requirements on the background foliation, so that the standard interpretation of the wave function for a small subsystem of the Universe is recovered.

It shall be noted that in this process the semiclassical variables, from which the time parameter is constructed, have been essentially treated as classical ones. At the next order of expansion $\mathcal{O}(\hbar^2)$, not present in the original work, the quantum properties of the background should start to influence the quantum subsystem. By continuing the calculation,[11] it can be seen that some correction terms to the quantum dynamics emerge:

$$\mathrm{i}\hbar\frac{\partial\chi_2}{\partial\tau} = \hat{H}_q\chi_2 - \left(2\mathrm{i}\hbar^2\,\nabla_c\sigma_1\cdot\nabla_c + \hbar^2\,\nabla_c^2\right)\chi_2. \tag{11}$$

It is straightforward to prove that these additional terms, which are attributed to the non-purely classical behavior of the background, are not unitary, thus presenting us a crucial point of discussion.

2.2. *Expansion in $M \propto G$*

The work[8] uses the parameter M defined in Eq. (2) for the expansion. Being it representative of the Planck scale, this choice implies that the lowest order will only see gravity and not the matter sector, describing a vacuum Universe in the limit $M \to \infty$. Eq. (1) becomes then:

$$\left(-\frac{\hbar^2}{2M}\nabla_g^2 + MV(g) + H_m\right)\Psi(g,m) = 0 \tag{12}$$

where H_m contains all the matter terms. The wave function is factorized in a similar matter (see Eqs. (5),(6)) into a gravitational function and a matter one, each expanded with the WKB method:

$$\Psi(g,m) = \psi(g)\chi(m;g) = \mathrm{e}^{\mathrm{i}(MS_0+P)/\hbar}\,\mathrm{e}^{\mathrm{i}Q/\hbar}\,, \tag{13}$$

where the action at the lowest order (pure gravity) is of order M.

Similarly, a time-dependent non-trivial Schrödinger equation (see Eq. (9)) for the matter sector is obtained, defining again time from the dependence on the semiclassical gravitational variables:

$$\frac{\partial}{\partial\tau} = \nabla_g S_0\cdot\nabla_g. \tag{14}$$

The authors also investigate the next order of expansion, finding that the quantum matter dynamics is described by:

$$\mathrm{i}\hbar\frac{\partial\chi_2}{\partial\tau} = \hat{H}_q\chi_2 - \left(\frac{\mathrm{i}\hbar}{M}\nabla_g\sigma_1\cdot\nabla_g + \frac{\hbar^2}{2M}\nabla_g^2\right)\chi_2, \tag{15}$$

presenting non-unitary terms.

Cosmological implications of such a result were presented in.[16] A possible workaround for the issue developed by the authors in,[10] which eliminated the non-Hermitian part of the matter Hamiltonian by suitable redefinitions of the wave functions in the product $\Psi = \psi\chi$, is not applicable to many cases (see discussion in[11]) due to the basic assumptions implemented, thus leaving the problem of how to deal with non-unitarity. We stress that both definitions of time (see Eqs. (10), (14)) make use of the dependence of the quantum subsystem on the background semiclassical variables.

It is essential to cite the work,[9] which applied a procedure more similar to the Born-Oppenheimer method, by subtracting to the initial Eq. (1) its average over the quantum function χ. However, once WKB expanded in the M parameter, with a similar time definition as in Eqs. (10), (14), the total quantum Hamiltonian operator still presents a non-unitary morphology.[11]

3. A different definition of time via the kinematical action

We have seen that the previously mentioned definitions of relational time, using the dependence on the semiclassical variables, give a non-unitary matter Hamiltonian operator due to quantum gravitational corrections (Eqs. (11), (15)). This result seems a direct consequence of such construction, even with different expansion parameters (we refer for this point to Ssec. 4.1 of the mentioned article[11]).

For this reason we here propose a different construction, which implements the kinematical action[12] into the theory as a clock for quantum matter.

3.1. *The kinematical action*

The kinematical action, first introduced in,[12] is an additional action term used to ensure some constraint equations of a quantum system, in analogy with a Lagrangian multiplier. We remind that, in the Hamiltonian formalism, gravity presents both primary and secondary constraints[15]; the components of the deformation vector of the ADM splitting[13]

$$N^\mu = \partial_t y^\mu = N n^\mu + N^i b_i^\mu \tag{16}$$

play the role of the Lagrangian multipliers for the secondary constraints.

When a specific splitting is assigned, however, the components N and N^i still appear in the action of the quantum field theory as multipliers, but their initial meaning as components of the four-vector N^μ is not evident. To recover this, the kinematical action in ADM variables can be inserted:

$$S_k = \int d^4x (p_\mu \partial_t y^\mu - N^\mu p_\mu), \tag{17}$$

where $y^\mu = y^\mu(x^i; x^0)$ are the coordinates defining the parametric equations of the hypersurfaces, and p^μ are the conjugate momenta. Inserting this term into the action, some additional equations of motion appear by variations of y^μ, p_μ and N^μ:

these equations ensure[12] that the momenta p_μ are trivial and recover the physical meaning of the deformation vector N^μ as in Eq. (16).

Additional contributions also emerge in the Hamiltonian formalism to the superHamiltonian and supermomentum functions:

$$\mathcal{H}^k = n^\mu p_\mu \,, \tag{18a}$$

$$\mathcal{H}_i^k = b_i^\mu p_\mu \tag{18b}$$

which are linear in the conjugate momenta, a feature which is crucial in order to construct the time parameter of the theory.

3.2. *Basic hypotheses and conditions*

Let us now start with a Born-Oppenheimer-like separation of the wave function:

$$\Psi(h_a, \phi, y^\mu) = \psi(h_a)\chi(\phi, y^\mu; h_a) \tag{19}$$

where ψ is the slow gravitational sector, and χ the fast quantum one. We are considering the kinematical action as a matter term, regarding its variables as fast. This choice ensures the correct limit at the order of standard quantum theory on curved background.

As stated in,[5] since the matter fields live at an energy scale much lower than the Planck scale, we can reasonably assume that the slow function satisfies the semiclassical Wheeler-DeWitt equation, as in Eq. (8). For the sake of generality, we will not work in the minisuperspace, so that supermomentum constraints are not automatically satisfied. With the same reasoning we assume that the slow function satisfies the gravitational supermomentum constraint:

$$\left[-\frac{\hbar^2}{2M}\left(\nabla_g^2 + g\cdot\nabla_g\right) + MV\right]\psi = 0\,, \tag{20}$$

$$2\mathrm{i}\hbar\, h_i \mathrm{D}\cdot\nabla_g\psi = 0\,. \tag{21}$$

By insertion of the kinematical action, the equations satisfied by the total wave function Ψ are:

$$\left[-\frac{\hbar^2}{2M}\left(\nabla_g^2 + g\cdot\nabla_g\right) + MV - \hbar^2\nabla_m^2 + U_m\right]\Psi = \mathrm{i}\hbar\, n^\mu \frac{\delta}{\delta y^\mu}\Psi\,, \tag{22}$$

$$\left(2h_i\,\mathrm{D}\cdot\nabla_g - \partial_i\phi\cdot\nabla_m\right)\Psi = \mathrm{i}\hbar\, b_i^\mu \frac{\delta}{\delta y^\mu}\Psi\,. \tag{23}$$

We implement M, defined in Eq. (2), as the expansion parameter, so that the perturbative approach will be valid for fields with small associated energy with respect to the Planckian one. Formally, this property can be stated as the smallness of the ratio

$$\frac{\hat{H}\chi(\phi, y^\mu; h_a)}{\hat{H}\psi(h_a)} = \mathcal{O}\left(\frac{1}{M}\right) \tag{24}$$

and the adiabatic approximation also implies the smallness of the variation of the fast wave function with respect to the slow variables:

$$\frac{\delta}{\delta h_a}\chi(\phi, y^\mu; h_a) \simeq \mathcal{O}\left(\frac{1}{M}\right). \tag{25}$$

3.3. *Emerging dynamics for the gravity-matter system*

The model can now be expanded following the WKB method. At the first order $\mathcal{O}(M^1)$, it is clear that only gravitational terms survive, recreating the gravitational Hamilton-Jacobi equation

$$\frac{1}{2}\nabla_g S_0 \cdot \nabla_g S_0 + V = 0 \tag{26}$$

which ensures the classical limit of General Relativity. This is an intrinsic property of the expansion due to the choice of parameter, which selects the Planck scale.

Following the expansion, at $\mathcal{O}(M^0)$ both the gravitational and the matter sector are present. Making use of the gravitational constraints (20), (21), the equation for the matter wave function at this order (here labeled χ_0) is found:

$$\mathrm{i}\hbar\frac{\delta}{\delta\tau}\chi_0 \equiv \mathrm{i}\hbar\int_\Sigma d^3x \left(Nn^\mu + N^i b_i^\mu\right)\frac{\delta}{\delta y^\mu}\chi_0 = \hat{H}\chi_0 \tag{27}$$

where the operator $\hat{H}$ is the matter Hamiltonian up to this order, defined combining both the matter superHamiltonian and supermomentum functions:

$$\hat{H}(\bullet) = \int_\Sigma d^3x \left(N\hat{\mathcal{H}}^m + N^i\hat{\mathcal{H}}_i^m\right)(\bullet). \tag{28}$$

Eq. (27) has been rewritten as a functional Schrödinger equation through an integration over the spatial hypersurfaces and an appropriate definition of the time derivative, using the definition of the deformation vector (16). The striking difference from previous works is that, in this case, time comes from the kinematical action which plays the role of clock in the theory, instead of the dependence from the slow gravitational variables.

The next order of expansion $\mathcal{O}(\frac{1}{M})$ gives for the matter wave function χ, now enclosing the contributions up to this order, the following:

$$\mathrm{i}\hbar\frac{\delta}{\delta\tau}\chi = \hat{H}\chi + \int_\Sigma d^3x \left[N\nabla_g S_0 \cdot (-\mathrm{i}\hbar\nabla_g\chi) - 2N^k h_k \mathrm{D}\cdot\left(\frac{1}{\chi}(-\mathrm{i}\hbar\nabla_g\chi)\right)\chi\right]. \tag{29}$$

It can be shown[11] that the additional terms in Eq. (29) are unitary. This property, together with the smallness of such contributions coming from the initial adiabatic assumption (25), make this model an acceptable one for investigating quantum gravity effects on the matter dynamics.

4. Dynamics of a cosmological scalar field

Let us now consider an homogeneous Universe filled with a free massless homogeneous scalar field, and with a cosmological constant $\Lambda > 0$, a setup similar to.[16] This model reproduces the inflationary scheme during the de Sitter phase, since the kinetic term of the scalar field stands for the kinetic term of the inflaton one, which can become important towards the Planck scale, and the cosmological constant accounts for the almost constant potential during that phase. We now apply the model described in the previous section to this simple case in order to infer the effect of the corrections computed in Eq. (29) to the Hamiltonian spectrum of the scalar matter field.

The background is given by a Robertson-Walker metric:

$$ds^2 = N^2 dt^2 - a(t)^2 \left(dx^2 + dy^2 + dz^2\right) \tag{30}$$

with Ricci scalar:

$$R = \frac{6}{c^2}\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right) \tag{31}$$

where a is the cosmic scale factor. The shift vector N^i (see Eq. (16)) cannot be included in the metric since it would violate isotropy of the model.

Since we are considering the homogeneous case, choosing the ADM foliation such that the normal vector field is $n^\mu = (1, 0, 0, 0)$, it is easy to see that the only surviving contribution of the kinematical conjugate momenta is

$$\hat{p}_0 = \mathrm{i}\hbar \frac{\delta}{\delta T} \tag{32}$$

where the constructed time parameter, here labeled as T, coincides with the synchronous time[17] hence $N = 1$.

Following the steps in Sec. 3, the total wave function of the system will satisfy the gravitational superHamiltonian constraint (20) and the total superHamiltonian constraint (22). The second one, after integration over a proper portion of space, i.e. the fiducial volume V_0, gives:

$$(H_{grav} + H_\phi + H_{kin})\Psi = \left(\frac{1}{2V_0 a^3}\pi_\phi^2 - \frac{2\pi G c^2}{3V_0\, a}\pi_a^2 + \frac{V_0}{8\pi G}\,\Lambda a^3 + p_0\right)\Psi \tag{33}$$

and analogously for the gravitational constraint. The contribution of the supermomentum is canceled due to the condition $N^i = 0$.

In order to proceed with the expansion, the Einstein constant has to be rewritten in terms of the chosen parameter M defined in Eq. (2). Then, the system composed of the two constraints can be expanded order by order as presented in Sec. 3.

The gravitational constraint equation gives solutions for the functions S_0, P_1, P_2 of the gravitational wave function up to order $\mathcal{O}(1/M)$, following the separation in Eq. (13). Implementing these solutions, the total constraint gives at order $\mathcal{O}(M^0)$

the ordinary Schrödinger equation for the scalar field:

$$\mathrm{i}\hbar\frac{\delta}{\delta T}\chi = \hat{H}\chi \tag{34}$$

where we have taken $V_0 = 1$.

The corrections emerge at the next order $\mathcal{O}(1/M)$. After plugging the gravitational solutions into the total constraint equation, we switch to the time parameter τ such that $d\tau = \frac{dT}{a^3}$ and we pass to the Fourier space, so that the dynamical equation for the scalar field becomes:

$$\mathrm{i}\hbar\frac{\delta\tilde{\chi}}{\delta\tau} = -\frac{\hbar^2}{2}\frac{\delta^2\tilde{\chi}}{\delta\phi^2} + \hbar\,\frac{k_a\,(-\tau)^{7/3}}{3(3\Lambda)^{1/6}}\,\tilde{\chi}, \tag{35}$$

where the matter Hamiltonian (given by the standard kinetic term of the free field) is indeed corrected by the additional term related to k_a, which is the eigenvalue of the conjugate momentum π_a of the scale factor a.

The solution for the matter wave function is

$$\tilde{\chi} = e^{-\mathrm{i}\frac{\hbar p^2}{2}\tau + \mathrm{i}\frac{k_a\,(-\tau)^{7/3}}{7(3\Lambda)^{1/6}}}\,, \tag{36}$$

where p is the conjugate momentum with respect to the scalar field ϕ.

The solution (36) can be used to construct a wave packet and infer the magnitude of the spectrum modifications. It is important to stress that, passing from Eq. (33) to Eq. (35), the momentum k_a and hence the cosmic scale factor maintain their quantum nature: for this reason we do not insert the classical limit $a(T)$ of the background metric, but we leave a as an intrinsic quantum variable. We also remind that, due to the initial assumptions (see in particular Eq. (24)), the range of validity of the expansion is $-\frac{1}{M} < k_a < \frac{1}{M}$.

Numerical analysis of the corrected Hamiltonian spectrum has been computed by considering a Gaussian wave packet in a, ϕ constructed with the solution in Eq. (36). The results of the analysis show small corrections as expected from the hypotheses of the theory, since the quantum contributions are considered of order $\mathcal{O}(1/M)$.

5. Analogy with the frame fixing procedure

An interesting observation should be made regarding the procedure we followed. In a later paper,[14] the authors fix the reference frame of a gravity-matter system by inserting an additional term to the action, which resonates with the kinematical action insertion developed years before from one of the authors.[12] We do not show the detailed calculations here, reporting only the key points of such procedure and why it is connected to this work.

The chosen coordinates for their procedure are the Gaussian ones $g^{00} = 1$, $g^{0i} = 0$, implemented with Lagrange multipliers $\mathcal{M}$, $\mathcal{M}_i$ into the action with an

additional term, that is written in a parametrized form as:

$$S^F = \int_\Sigma d^4x \left[-\frac{1}{2}\mathcal{M}\sqrt{-g}(g^{\alpha\beta}\partial_\alpha T\partial_\beta T - 1) + \mathcal{M}_i\sqrt{-g}(g^{\alpha\beta}\partial_\alpha T\partial_\beta X^i) \right], \quad (37)$$

where X^i, T are the Gaussian coordinates and x^α are the new variables ("parameters") associated to the metric $g_{\alpha\beta}$, so that coordinate transformations on the x^α are allowed.

The authors prove that such term (37), corresponding to the choice of reference system, materializes into the theory as a fluid, more precisely as an incoherent dust with energy tensor:

$$T^{\alpha\beta} = \mathcal{M}\, U^\alpha\, U^\beta \qquad \text{with } U^\alpha = g^{\alpha\beta}\partial_\beta T \quad (38)$$

and with positive-definite energy as long as $\mathcal{M} \geq 0$.

Again, going to the order of quantum matter, a Schrödinger equation emerges with time coinciding with the parameter T of the Gaussian frame. This means that the emergent fluid plays the role of clock for quantum matter, in a way which is very similar to the kinematical action implementation.

Starting from the action with the "emergent fluid term", we can implement the same WKB expansion as explained in Sec. 3. We obtain that, in the minisuperspace, such procedure gives at the order $\mathcal{O}(1/M)$ quantum gravity corrections which are isomorphic to those of Eq. (29).

This result has an immediate explanation. In the minisuperspace, one can choose the ADM foliation such that $n^\mu = (1, \vec{0})$, consequently the parametric equations in (17) give $y^0 = T$, $y^i = X^i$; this means that their time derivative becomes

$$\partial_t y^\mu \to \partial_t y^0 = \dot{T} = \frac{\delta T}{\delta t} \quad (39)$$

It is clear that, in the minisuperspace and with a specific foliation, the kinematical action exactly reduces to the "reference fluid" emerging from the Gaussian reference frame fixing of Eq. (37). In this sense, the two implementations are equivalent.

6. Concluding remarks

The semiclassical WKB expansions of the gravity-matter system presented in the works here cited[5,8–10] encounter some problems when the canonical quantization procedure is applied and a time parameter is recovered from the dependence of the quantum system on the semiclassical variables. We have shown that the expansion performed in[5] with parameter $\hbar$ describes a non-unitary quantum matter dynamics at the next order, as seen in Eq. (11). A similar result already emerged in the work,[8] see Eq. (15), which was later modified with an *ad-hoc* procedure[10]; however the basic assumptions of that workaround cannot be satisfied in many cosmological models, thus requiring a different procedure.

Even dealing with an approach more similar to the Born-Oppenheimer one,[9] after the WKB expansion, it seems that non-unitary terms for the matter sector

dynamics do not emerge, but the theory cannot be set by means of a general Hilbert product (see discussion in[11]).

The previous results signal a necessity to define the relational time in a different way, not using the dependence from the gravitational variables, which have an intrinsic quantum component due to the WKB limit. For this reason a different construction of the gravity-matter system has been implemented, where both the WKB expansion and the adiabatic approximation have been used, but with the core difference that time has been constructed from the the kinematical action. The utility of such term, defined in Eq. (17), in quantum field theory on a given background is to recover covariance under ADM foliation, since the deformation vector is assigned due to an *a priori* choice of the reference system.

Thanks to the additional contributions (see Eqs. (18a)-(18b)) coming from the kinematical action, we have recovered a dynamics described by linear constraints in the conjugate momenta (Eqs. (22), (23)) and covariant under choice of an ADM foliation. The momenta p_μ associated to the kinematical variables y^μ, after the quantization procedure, are a strong candidate for the definition of a time parameter.

By performing the WKB expansion in the parameter M defined in (2), we have obtained at the highest order the Hamilton-Jacobi equation (26) for gravity, which is equivalent to the Einstein equations in vacuum.[15] At the next order, with the definition in Eq. (27), we have recovered at the zero-th order a functional Schrödinger equation which corresponds standard quantum field theory. Finally, at order $\mathcal{O}(1/M)$, the corrections arising from quantum gravity to the quantum matter sector dynamics have been computed, showing that the additional terms in Eq. (29) are unitary. Although the obtained corrections are small by construction, they suggest a new investigation tool to evaluate how a non-standard dynamics of quantum field theory behaves, when examining energies small with respect to the Planck scale. We have shown in Sec. 4 that such modifications give a non-zero contribution to the Hamiltonian spectrum of the scalar matter field in a cosmological setting.

We have shown in Sec. 5 the comparison between the kinematical action insertion and the reference frame fixing procedure.[14] Setting the problem in the minisuperspace and choosing a specific ADM foliation, the parametric equations giving the kinematical variables directly correspond to the Gaussian coordinates of the frame fixing procedure. Then, it is clear that the kinematical action in this case is equivalent to the choice of the reference system, that clearly emerges as a fluid in the theory. This analogy provides a starting point for a deeper understanding and future analysis on the presented model.

Noncommutative geometry is one of the quantum gravity theories, which various researchers have been using to describe different physical and astrophysical systems. However, so far, no direct observations can justify its existence, and this theory remains a hypothesis. On the other hand, over the past two decades, more than a dozen overluminous type Ia supernovae have been observed, which indirectly predict that they originate from white dwarfs with super-Chandrasekhar masses $2.1 - 2.8\,\mathrm{M}_{\odot}$. In this article, we discuss that considering white dwarfs as squashed fuzzy spheres, a class of noncommutative geometry, helps in accumulating more mass than the Chandrasekhar mass-limit. The length-scale beyond which the effect of noncommutativity becomes prominent is an emergent phenomenon, which depends only on the inter-electron separations in the white dwarf.

Keywords: Noncommutative geometry, white dwarfs, type Ia supernova, mass-limit.

1. Introduction

Noncommutative geometry, a theory of quantum gravity, has been used for many decades to explain physical systems. Riemann quoted in 1854 that "*... it seems that empirical notions on which the metrical determinations of space are founded, the notion of a solid body and a ray of light cease to be valid for the infinitely small. We are therefore quite at liberty to suppose that the metric relations of space in the infinitely small do not conform to hypotheses of geometry; and we ought in fact to suppose it, if we can thereby obtain a simpler explanation of phenomena ...*". In 1930s, Bronstein, using Heisenberg uncertainty principle and the features of Einstein's general relativity (GR), first argued that gravitational dynamics does not allow to measure arbitrarily small spacetime distances, concluding that the notions of classical Riemmanian geometry should be duly modified. The formalism of a fuzzy sphere, first introduced in 1992,[1] was later modified to show equivalence between noncommutativity (NC) and Landau levels in the presence of magnetic fields.[2] Moreover, NC alters the spacetime metric,[3] which results in shifting the

event horizon and removing the essential singularity at the center of a black hole.[4] etc. Unfortunately, there is no direct way to confirm the existence of NC like most of the other quantum gravity formalism, which compels it to remain a hypothesis.

In astrophysics, a white dwarf (WD) is the end state of a star with mass $\lesssim (10 \pm 2)\,\mathrm{M}_\odot$. Chandrasekhar showed that the maximum mass of a carbon-oxygen non-magnetized and non-rotating WD is about $1.4\,\mathrm{M}_\odot$.[5] Above this mass-limit, they burst out to produce type Ia supernovae (SNe Ia) with nearly similar luminosities. However, observations of various peculiar over-luminous SNe Ia, such as SN 2003fg, SN 2006gz, SN 2007if, SN 2009dc, and many more, suggested that they were originated from super-Chandrasekhar WDs with mass $2.1-2.8\,\mathrm{M}_\odot$.[6,7] Over the years, different models including rotation, magnetic fields, modified gravity, ungravity effects, generalized Heisenberg uncertainty principle, to name a few, have been proposed to explain these massive WDs. However, since these super-Chandrasekhar WDs have not been observed directly, no one can single out the correct theory so far.

This article shows that the squashed fuzzy sphere algebra can quantize the energy dispersion relation, which further alters the equation of state (EoS) of the degenerate electrons present in a WD, resulting in the increase in mass of the WD beyond the Chandrasekhar mass-limit. It also discusses that the length-scale below which NC is prominent depends on the inter-electron separation. Hence, the inference of super-Chandrasekhar WDs can indirectly predicts the existence of NC in high-density regimes.

2. Squashed fuzzy sphere and equation of state

The formalism of a fuzzy sphere is analogous to the angular momentum algebra in ordinary quantum mechanics, where the position coordinates mimic the angular momentum variables. In an N-dimensional irreducible representation of $\mathtt{SU}(2)$ group, the commutation relation for the coordinates of fuzzy sphere, X_i (i=1,2,3), is given by[1]

$$[X_i, X_j] = i\frac{k\hbar}{r}\epsilon_{ijk}X_k, \tag{1}$$

where $k = 2r^2/\hbar\sqrt{N^2-1}$, $\hbar = h/2\pi$, h is the Planck constant and r the radius of the fuzzy sphere.

A squashed fuzzy sphere is a simple geometrical construction obtained from the fuzzy sphere by projecting all the points to an equatorial plane as shown in Figure 1. The equatorial plane can be in any direction, and for illustration, we show the $X_1 - X_2$ plane. Using the above relation, the commutation relation for this squashed fuzzy sphere is given by[2]

$$[X_1, X_2] = \pm i\frac{k\hbar}{r}\sqrt{r^2 - X_1^2 - X_2^2}. \tag{2}$$

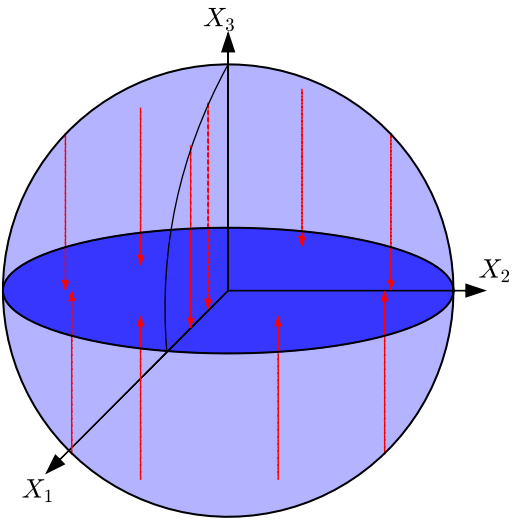

Fig. 1. An illustrative diagram of a squashed fuzzy sphere which is obtained by projecting all the points of the fuzzy sphere on an equatorial plane.

Note that NC vanishes at the surface of the sphere. The square of the quantized energies in a squashed fuzzy sphere, obtained from the Dirac operator, is given by[8]

$$E^2_{l,m} = \frac{2\hbar c^2}{k\sqrt{N^2-1}}\left\{l(l+1) - m(m\pm 1)\right\}, \tag{3}$$

where c is the speed of light and l, m are the quantum numbers with l taking all the integer values from 0 to $N-1$ and m taking all the integer values from $-l$ to l. Moreover, the relations between the Cartesian and spherical polar coordinates are $X_1 = r\sin\theta\cos\phi$ and $X_2 = r\sin\theta\sin\phi$. Therefore, from Equation (2), the squashed fuzzy sphere algebra in spherical polar coordinates is given by

$$[\sin\theta\cos\phi, \sin\theta\sin\phi] = \pm i\frac{k\hbar}{r^2}\cos\theta. \tag{4}$$

A squashed fuzzy sphere is such that it actually provides a NC between its azimuthal and polar coordinates at the surface of the fuzzy sphere. This is because the squashed plane in a fuzzy sphere can be any of its equatorial planes and there is no particular direction for it, which means that the squashed fuzzy sphere has a rotational symmetry about the equatorial plane. There is no NC along the r-direction and an electron with mass m_e does not experience NC along the radial direction. Defining p_r to be the momentum of the electron in r-direction, considering Equation (3), we obtain the total energy dispersion relation in the squashed fuzzy sphere as[8]

$$E^2 = p_r^2c^2 + m_\mathrm{e}^2c^4\left[1 + \left\{l(l+1) - m(m\pm 1)\right\}\frac{2\hbar}{m_\mathrm{e}^2c^2k\sqrt{N^2-1}}\right]. \tag{5}$$

In the large N limit, this expression reduces to[8]

$$E^2 = p_r^2 c^2 + m_{\rm e}^2 c^4 \left(1 + 2\nu \frac{2\hbar}{m_{\rm e}^2 c^2 k}\right), \qquad \nu \in \mathbb{Z}^{0+}. \tag{6}$$

It is evident that $1/k$ behaves as the strength of NC. Note that a similar dispersion relation occurs in the case of a planar NC.[9] We can assume a series of concentric squashed fuzzy spheres, such that at the surface of each spheres, the above relation is valid. Nevertheless, $k \propto r^2$ and hence $1/k$ decreases from center to the surface. Now, applying simple statistical mechanics techniques, we obtain the EoS for the degenerate electrons present in a WD, given by[8,10]

$$\text{pressure} \quad \mathcal{P} = \frac{2\rho^{2/3}}{\xi h \mu_{\rm e}^{2/3} m_{\rm p}^{2/3}} \sum_{\nu=0}^{\nu_{\max}} g_\nu \left\{ p_{\rm F} E_{\rm F} - \left(m_{\rm e}^2 c^3 + 2\nu \frac{2\hbar c}{k}\right) \ln\left(\frac{E_{\rm F} + p_{\rm F} c}{\sqrt{m_{\rm e}^2 c^4 + 2\nu \frac{hc^2}{\pi k}}}\right)\right\}, \tag{7}$$

$$\text{density} \quad \rho = \frac{64 \mu_{\rm e} m_{\rm p} \left(2\nu_{\max} + 1\right)^3 p_{\rm F}^3}{\xi^3 h^3}, \tag{8}$$

where $\xi = kh\left(\rho/\mu_{\rm e} m_{\rm p}\right)^3$, $m_{\rm p}$ is the mass of the proton, $\mu_{\rm e}$ is the mean molecular weight per electron, g_ν is the degeneracy factor, and $p_{\rm F}$ and $E_{\rm F}$ are respectively the Fermi momentum and Fermi energy of the electron gas. ξ needs to be chosen appropriately such that at the low-density limit, EoS is same as the Chandrasekhar's EoS, where NC is almost negligible. Figure 2 shows EoS for the degenerate electrons when they occupy different energy levels. It is evident that if the electrons occupy more levels, it tends to the Chandrasekhar's EoS and NC is not prominent in that density regime.

3. Stellar structure model

To obtain the stellar structure of any compact object in GR, one needs to solve the Tolman-Oppenheimer-Volkoff or TOV equations along-with EoS of the constituent particles. The TOV equations for a non-rotating and non-magnetized star are given by[11]

$$\begin{aligned} \frac{{\rm d}\mathcal{M}}{{\rm d}r} &= 4\pi r^2 \rho, \\ \frac{{\rm d}\mathcal{P}}{{\rm d}r} &= -\frac{G}{r^2}\left(\rho + \frac{\mathcal{P}}{c^2}\right)\left(\mathcal{M} + \frac{4\pi r^3 \mathcal{P}}{c^2}\right)\left(1 - \frac{2G\mathcal{M}}{c^2 r}\right)^{-1}, \end{aligned} \tag{9}$$

where $\mathcal{M}$ is the mass of the star inside a volume of radius r and G is Newton's gravitational constant. Note that NC affects the microscopic physics, while TOV equations describe the pressure and mass balances, which are macroscopic physics. Hence, in a semi-classical approach, TOV equations remain unchanged to that for the classical GR formalism. Figure 3 shows the mass–radius relation for the WDs

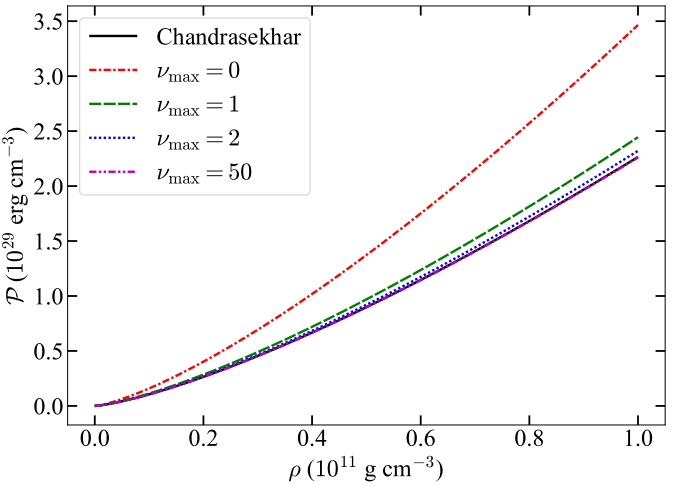

Fig. 2. EoS for degenerate electrons in a squashed fuzzy sphere with various $\nu_{\max}$ along with the Chandrasekhar's EoS. $\nu_{\max} = 0$ means electrons occupy only the ground energy level, $\nu_{\max} = 1$ means they occupy both ground and first energy levels, and so on. Chandrasekhar's EoS corresponds to $\nu_{\max} \to \infty$.

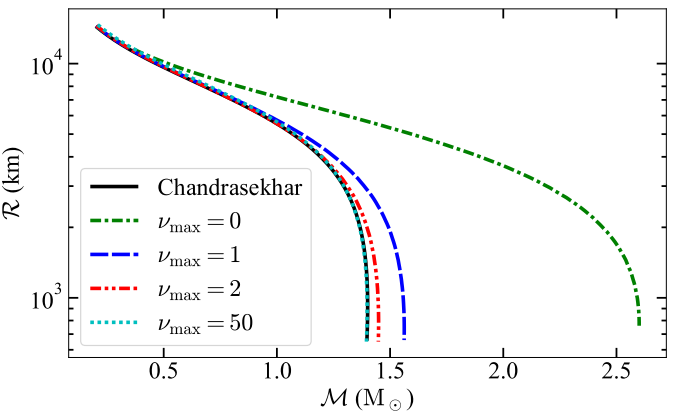

Fig. 3. Mass–radius relations of the WDs in the presence of NC when various energy levels are occupied.

in the presence of NC for various $\nu_{\max}$ along with the Chandrasekhar's mass–radius relation, which corresponds to $\nu_{\max} \to \infty$. It is evident from the figure that a non-rotating and non-magnetized WD can have a limiting mass of about $2.6\,M_\odot$ if all the electrons occupy the ground level. The mass-limit decreases when more energy levels are filled, and finally coincides with the Chandrasekhar's original mass–radius curve when many levels are occupied furnishing a limiting mass of about $1.4\,M_\odot$.

3.1. *Length scale in noncommutative geometry*

It is understood from Equation (6) that NC is prominent if $2\hbar \gtrsim m_e^2 c^2 k$, which implies that the system length-scale $\mathcal{L} \lesssim \mathcal{L}_{\rm eff} = \lambda_e/\sqrt{\pi\xi}$ with λ_e being the Compton wavelength of the electron.[8] In the case of degenerate electrons, $\mathcal{L}$ is the inter-electron separations. It is evident from this expression that for the prominence of NC, $\mathcal{L}$ does not need to be the Planck scale $\mathcal{L}_P$ as opposed to the general belief. Rather it depends upon the system's length-scale. Indeed Salecker and Wigner showed that the new uncertainty in length-scale for a system has to be $\delta \sim \left(\mathcal{L}\mathcal{L}_P^2\right)^{1/3}$, and one needs to consider δ as the quantum measurement of length.[12] Hence, for a WD, one can expect to observe a significant NC effect depending on the inter-electron separation, even though it is far from the Planck scale. In extremely high densities with inter-electron distance much less than the Compton wavelength, one can expect certain features of NC becomes prominent. One such feature is the notion of statistics, which needs localization of particles, gets distorted and can affect physical systems, such as the mass-limit of the WD.

4. Conclusions

We have demonstrated that NC may have a prominent effect in a system whose length-scale is greater than $\mathcal{L}_P$. Whether NC has a significant effect or not depends upon the system's length-scale, and we show that it is an emergent phenomenon. We have used the formalism of a squashed fuzzy sphere where NC is at the surface of the sphere, i.e., between the azimuthal and polar coordinates. We have obtained the energy dispersion relation for this formalism and found that it is very similar to that for the Landau levels in the presence of magnetic fields. Hence, one may assume that NC mimics the internally generated magnetic field. It has a significant effect in a WD if the inter-electron separation is nearly less than one-tenth of the Compton wavelength of electrons. Such prominent NC may provide a super-Chandrasekhar limiting mass $2.6\,M_\odot$ and it can explain the formation of peculiar over-luminous SNe Ia. In the future, if gravitational wave detectors detect these massive WDs directly, it can confirm the existence of NC more firmly.[13]

We propose a polymer quantization scheme to derive the effective propagation of gravitational waves on a classical Friedmann-Lemaitre-Robertson-Walker (FLRW) spacetime. These waves, which may originate from a high energy source, are a consequence of the dynamics of the gravitational field in a linearized low-energy regime. A novel method of deriving the effective Hamiltonian of the system is applied to overcome the challenge of polymer quantizing a time-dependent Hamiltonian. Using such a Hamiltonian, we derive the effective equations of motion and show that (i) the form of the waves is modified, (ii) the speed of the waves depends on their frequencies, and (iii) quantum effects become more apparent as waves traverse longer distances.

Keywords: Quantum gravity, gravitational waves

1. Introduction

Recent discovery of gravitational waves (GWs) and the rapid increase in the sensitivity of GWs observatories has opened up a great opportunity in connecting theory and phenomenology with experiment in precision cosmology, black hole

physics and quantum gravity among other fields. In particular we are now becoming more hopeful about the observation of signatures of quantum gravity in GWs emitted from black hole mergers and high redshift regions of the cosmos.

There have been numerous studies connecting theories of quantum gravity with potential observations regarding the structure of quantum spacetime. In particular, in Loop Quantum Gravity (LQG),[1] there have been studies to understand the consequence of nonpertubative quantization in propagation of Gamma Ray Bursts (GRBs), other matter fields, and GWs on cosmological or black holes spacetimes (for some examples see, Refs. [2–31] and references within).

In this work we consider GWs as effective perturbations propagating on a classical FLRW cosmological spacetime. The effective form of such waves is derived by applying the techniques of polymer quantization[32–36] to the classical perturbations. Such a quantization is a representation of the classical algebra on a Hilbert space that is unitarily inequivalent to the usual Schrödinger representation. In it, operators are regularized and written in a certain exponential form. In such theories, the infinitesimal generators corresponding to some of the operators do not exist on the Hilbert space. As a consequence, the conjugate variables to those operators only admit finite transformations. Thus, the dynamics of the theory leads to the discretization of the spectrum of the conjugate operators (for more details and some examples of polymer quantization applied to particles and path integral formulation of black holes, see Refs. [34, 35, 37–39]).

In the model we present in this paper, the Hamiltonian is time-dependent and directly polymer quantizing it proves to be quite challenging. Hence, we apply a novel method based on the use of extended phase space, to overcome this issue (see Ref. [40]). The Hamiltonian in the extended phase space is rendered time independent by applying a certain canonical transformation and then polymer quantized using some of techniques developed in the literature.[35,41,42] After that, the effective version of this quantum Hamiltonian is made time-dependent again by applying the inverse of the above-mentioned canonical transformation. Finally the system is re-expressed in the usual non-extended phase space. Using this modified Hamiltonian, we derive the effective equations of motion of polymerized GWs and show that i) the form of the waves is modified, ii) the speed of the waves depends on their frequencies, and iii) the quantum effects are amplified by the distance/time the waves travel.

This paper is organized as follows: in Sec. 2, we derive the classical Hamiltonian of perturbations on an FLRW classical background. In Sec. 3, this time-dependent Hamiltonian is turned into a polymer effective time-dependent Hamiltonian by applying a certain method that is inspired by an approach used to deal with time-dependent Harmonic oscillators. Using this Hamiltonian, we then derive the effective equations of motion. In Sec. 4, we study the behavior of the solutions in both nonperturbative and perturbative regimes and show that quantum gravitational effects induce certain imprints on the waveform, frequency, and speed of GWs. Finally, in Sec. 5 we present our concluding remarks.

2. Hamiltonian formalism for GWs

We start with a spacetime manifold $M = \mathbb{T}^3 \times \mathbb{R}$ with a spatial 3-torus topology[a], equipped with coordinates $x^j \in (0, \ell)$ and a temporal coordinate $x^0 \in \mathbb{R}$. The background metric $\mathring{g}_{\mu\nu}$ is then perturbed by a small perturbation $h_{\mu\nu}$ such that the full metric $g_{\mu\nu}$ can be written as

$$g_{\mu\nu} = \mathring{g}_{\mu\nu} + h_{\mu\nu}. \tag{1}$$

GWs are the result of the weak-field approximation to the Einstein field equations for the above metric. As is well-known, a wave traveling along, say, the x^3 direction, can be separated into two polarization scalar modes $h_+(x)$ and $h_\times(x)$ as

$$h_{ij}(x) \;=\; h_+(x)e^+_{ij} + h_\times(x)e^\times_{ij}\,, \tag{2}$$

where

$$e^+ = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad \text{and} \qquad e^\times = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}. \tag{3}$$

We would like to study the dynamics of the perturbations on a homogeneous, isotropic universe described by the FLRW metric

$$\mathring{g}_{\mu\nu}dx^\mu dx^\nu = -N^2(x^0)\, d(x^0)^2 + a^2(x^0)d\mathbf{x}^2, \tag{4}$$

where x^0 is an arbitrary time coordinate, $N(x^0)$ is the lapse function which depends on the choice of x^0, and $d\mathbf{x}^2 = \sum_i^3 d(x^i)^2$ is a unit 3-sphere. To obtain a Hamiltonian which resembles the Hamiltonian of a Harmonic oscillator, we introduce a new field

$$h_\sigma\left(x^0, \mathbf{x}\right) = \frac{a^2\sqrt{\kappa}}{\ell^{3/2}} \sum_{\mathbf{k}} \mathcal{A}_{\sigma,\mathbf{k}}\left(x^0\right) e^{i\mathbf{k}\cdot\mathbf{x}} \tag{5}$$

which together with its conjugate momentum $\mathcal{E}_{\sigma,\mathbf{k}}$ constitute a canonically conjugate pair

$$\left\{\mathcal{A}_{\lambda,\mathbf{k}}, \mathcal{E}_{\lambda',\mathbf{k}'}\right\} = \delta_{\mathbf{k}\mathbf{k}'}\delta_{\lambda\lambda'}. \tag{6}$$

Here ℓ is the result of our quantization on a lattice which corresponds to an upper limit on the momenta involved. The above canonical pair allow us to write the Hamiltonian of the system as

$$H = \frac{N}{2a^3} \sum_{\sigma=+,\times} \sum_{\mathbf{k}} \left[\mathcal{E}^2_{\sigma,\mathbf{k}} + k^2a^4\mathcal{A}^2_{\sigma,\mathbf{k}}\right] =: \sum_{\sigma=+,\times} \sum_{\mathbf{k}} H_{\sigma,\mathbf{k}}\left(x^0\right), \tag{7}$$

where N is the lapse. It is clear that this last equation represents the Hamiltonian of a set of decoupled harmonic oscillators with a time-dependent frequency $\omega^2 = k^2a^4$, due to time dependence of $a(t)$.

At this point, we choose the harmonic time gauge where $N(x^0 = \tau) = a^3(\tau)$ to get rid of the factor a^{-3} in front of Eq. (7). Hence, the Hamiltonian of the

[a]To avoid a discussion of boundary conditions on fields (generated by perturbations), we will assume that the spatial 3-manifold is $\mathbb{T}^3$.

perturbations (for a fixed mode $\mathbf{k}$ and a fixed polarization σ) over the FLRW background in harmonic time becomes

$$H_{\sigma,\mathbf{k}}(\tau) = \frac{1}{2}\left[\mathcal{E}^2_{\sigma,\mathbf{k}} + k^2 a^4 \mathcal{A}^2_{\sigma,\mathbf{k}}\right]. \tag{8}$$

3. Polymer quantization and the effective Hamiltonian

The time-dependence of this Hamiltonian (8) makes deriving its effective polymer corrections quite complicated. This is because its polymer quantization will yield a time-dependent quantum pendulum-type system whose solutions are mathematically difficult to treat. In order to circumvent this issue, we will apply a procedure based on the extended phase space formalism (more details in Ref. [40]). The idea is to first lift the (action of the) system

$$S = \int \left\{ p\frac{dq}{dt} - H(t) \right\} dt, \tag{9}$$

with time-dependent Hamiltonian of the form

$$H(t) = \frac{1}{2m}p^2 + \frac{1}{2}m\omega(t)^2 q^2, \tag{10}$$

to the extended phase space (EPS). In accordance with Dirac's formalism, the system is now described by the extended action

$$S = \int \left\{ p\frac{dq}{d\tau} + p_t\frac{dt}{d\tau} - \lambda\phi \right\} d\tau, \tag{11}$$

where

$$\phi = p_t + H(t) \approx 0, \tag{12}$$

is a first class constraint ensuring the compatibility of the two actions (9) and (11) on the constrained surface $\phi = 0$, λ is a Lagrange multiplier, and p_t is the momentum conjugate to t. This is step (1) in Fig. 1. In step (2) in Fig. 1, we apply a canonical transformation

$$Q = \frac{1}{\rho(t)}q, \tag{13}$$

$$T = \int \frac{1}{\rho^2(t)}\, dt, \tag{14}$$

$$P = \rho(t)p - m\dot{\rho}(t)q, \tag{15}$$

$$P_T = \rho^2(t)p_t + \rho(t)\dot{\rho}(t)\, q\, p - \frac{m}{2}q^2\left[\dot{\rho}^2(t) + \frac{W^2}{\rho^2(t)} - \omega^2(t)\rho^2(t)\right], \tag{16}$$

in the extended phase space which removes the time dependency of the Hamiltonian $H(t)$in ϕ. Here, W is the time-independent frequency of the time-independent

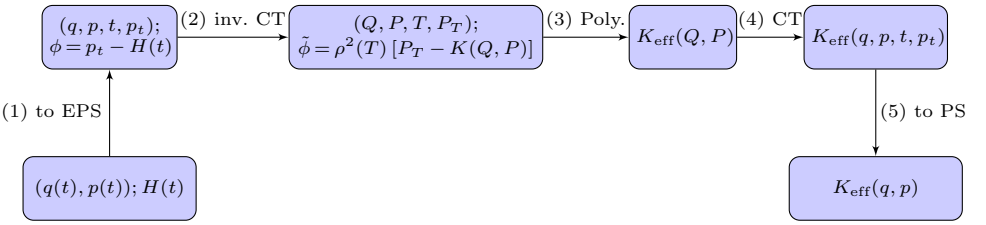

Fig. 1. Schematics of the derivation of a time-dependent effective Hamiltonian constraint. Here "EPS" means extended phase space, "inv. CT" denotes inverse canonical transformation, "Poly." means the process of polymer quantization and getting an effective polymer Hamiltonian from there, "CT" denotes the canonical transformation, and "PS" means the nonextended phase space. The lower row corresponds to the usual phase space, while the upper row corresponds to the extended phase space.

system and ρ is an auxiliary variable to be determined by the specific properties of the system, more precisely by ω and W. After this step the action becomes

$$S = \int \left\{ P\frac{dQ}{d\tau} + P_T\frac{dT}{d\tau} - \lambda\tilde{\phi} \right\} d\tau, \tag{17}$$

where, the first class constraint now reads

$$\tilde{\phi} = \rho^2(T)\,[P_T + K] \approx 0, \tag{18}$$

and the corresponding Hamiltonian K appearing in it is

$$K = \frac{1}{2m}P^2 + \frac{1}{2}mW^2Q^2. \tag{19}$$

Moreover, the auxiliary equation used to fix $\rho(t)$ becomes

$$\ddot{\rho}(t) + \omega^2(t)\rho(t) = \frac{W^2}{\rho^3(t)}. \tag{20}$$

This time-independent harmonic oscillator can now be polymer quantized[35,41,42] as in step (3) of Fig. 1. We then perform the inverse canonical transformations above in step (4) of Fig. 1. Finally, in step (5) of Fig. 1, we apply the inverse of the canonical transformations above and solve the constraint. This yields the polymer effective Hamiltonian on the usual phase space, where now the Hamiltonian is not just effective but also time-dependent.

By applying this method to our Hamiltonian (7), we obtain an effective polymer Hamiltonian with polymer $\mathcal{E}_{\sigma,\mathbf{k}}$ and discrete spectra for $\mathcal{A}_{\sigma,\mathbf{k}}$ as

$$H_{\rm eff}^{(\mathcal{E})} = \sum_{\sigma=+,\times}\sum_{\mathbf{k}\in\mathscr{L}} \left\{ \frac{2}{\mu^2\rho^2}\sin^2\left(\frac{\mu\left(\rho\mathcal{E}_{\sigma,\mathbf{k}} - \dot{\rho}\mathcal{A}_{\sigma,\mathbf{k}}\right)}{2}\right) + \frac{\dot{\rho}\mathcal{A}_{\sigma,\mathbf{k}}\,\mathcal{E}_{\sigma,\mathbf{k}}}{\rho} + \frac{\mathcal{A}_{\sigma,\mathbf{k}}^2}{2}\left[\omega^2 - \frac{\dot{\rho}^2}{\rho^2}\right] \right\}, \tag{21}$$

where μ is called the polymer parameter that sets the scale for which the quantum gravity effects become important, and we have set $\hbar = 1$. The corresponding

equations of motion read

$$\frac{d\mathcal{A}_{\sigma,\mathbf{k}}}{dt} = \frac{1}{\rho}\frac{\sin\left(\mu\left(\rho\mathcal{E}_{\sigma,\mathbf{k}} - \dot{\rho}\mathcal{A}_{\sigma,\mathbf{k}}\right)\right)}{\mu} + \frac{\dot{\rho}}{\rho}\mathcal{A}_{\sigma,\mathbf{k}}, \tag{22}$$

$$\frac{d\mathcal{E}_{\sigma,\mathbf{k}}}{dt} = \frac{\dot{\rho}}{\rho^2}\frac{\sin\left(\mu\left(\rho\mathcal{E}_{\sigma,\mathbf{k}} - \dot{\rho}\mathcal{A}_{\sigma,\mathbf{k}}\right)\right)}{\mu} + \left(\frac{\dot{\rho}}{\rho}\right)^2\mathcal{A}_{\sigma,\mathbf{k}} - \omega^2\mathcal{A}_{\sigma,\mathbf{k}} - \frac{\dot{\rho}}{\rho}\mathcal{E}_{\sigma,\mathbf{k}}. \tag{23}$$

These equations are nonlinear in both $\mathcal{A}_{\sigma,\mathbf{k}}$ and $\mathcal{E}_{\sigma,\mathbf{k}}$, and their $\mu \to 0$ limit matches the classical equations of motion as expected. Also notice that in our case, ρ controls the background geometry such that a time-dependent ρcorresponds to a time-dependent background geometry and a constant ρ corresponds to the flat spacetime.

4. Perturbative and nonperturbative numerical solutions

We will now solve Eqs. (22)–(23) for specific field-space configurations, both perturbatively, and numerically and nonperturbatively for both time-dependent and time-independent backgrounds.

4.1. *Time-independent background*

For a time-independent background, for which $\rho = 1$ and $\dot{\rho} = \ddot{\rho} = 0$, we can obtain full nonpertubative numerical solutions for $\mathcal{A}(t)$ as seen in Fig. 2. We can also obtain a perturbative solution

$$\begin{aligned}\mathcal{A}(t) \simeq\ & \mathcal{E}_I \sin\left[(1-(\mathcal{E}_I k\mu)^2/16)kt\right] \\ & - \frac{\mathcal{E}_I^3 k^2\mu^2}{16}\sin^2\left[(1-(\mathcal{E}_I k\mu)^2/16)kt\right]\cos\left[(1-(\mathcal{E}_I k\mu)^2/16)kt\right]\,.\end{aligned} \tag{24}$$

This solution can exhibits a frequency shift of order μ^2, and a cubic correction term. The cubic term can also be rewritten, and thought of, as an introduction of higher harmonics using angle identities. In observations, the frequency shift may be more important to account for than the excited harmonics. This is because the frequency shift can manifest as a phase shift that has considerable time to develop as the wave traverses cosmological distances. In Fig. 2 we demonstrate this, comparing the perturbative solution to the exact and classical ones for the time-independent case.

We can also analyze the above perturbative solutions and obtain some insight into the speed of propagation of the waves. For that, we note that the dominant contributions to Eq. (24) can be written as

$$\mathcal{A}(t) \simeq \mathcal{E}_I \sin\left[\left(1-\left(\frac{\mathcal{E}_I k\mu}{4}\right)^2\right)kt\right]. \tag{25}$$

Comparing with the classical solution where we identify $ka^2 = \omega_c$, with ω_c being the classical angular speed, we notice that up to first order the polymer angular

speed is

$$\omega_{\mu}^{(\mathcal{E})} \simeq \omega_c \left[1 - k^2 \left(\frac{\mathcal{E}_I \mu}{4}\right)^2\right]. \tag{26}$$

Although this is a perturbative and approximate result and even though we have neglected higher harmonics in Eq. (24), the above equation reveal a curious phenomenon. Noting that $\omega_c = ka^2$ and with the group velocity being

$$v = \frac{d\omega_{\text{poly}}}{d\,(ka^2)} \tag{27}$$

with ω_{poly} being either $\omega_{\nu}^{(\mathcal{A})}$ or $\omega_{\nu}^{(\mathcal{E})}$, we obtain

$$v_{\mu}^{(\mathcal{E})} \simeq 1 - k^2 \left(\frac{\mathcal{E}_I \mu}{4}\right)^2. \tag{28}$$

where $v_{\mu}^{(\mathcal{E})}$ is the velocity of the effective waves. One can see from Eq. (28) that the group velocity of the waves is slower than the speed of light by a factor of $k^2 \left(\frac{\mathcal{E}_I \mu}{4}\right)^2$, and it also depends on the initial momentum $\mathcal{E}_I$ of the waves and the polymer parameter μ due to the factor $k^2 \left(\frac{\mathcal{E}_I \mu}{4}\right)^2$. More importantly, the deviation from the speed of light also depends on the modes k. Hence, waves with larger k (i.e., larger energies) have a lower speed compared to the ones with smaller k and are more affected by the quantum structure of spacetime. Also, notice that this case leads to the violation of Lorentz symmetry as can be seen by squaring both sides of Eq. (26). Of course, due to the sheer smallness of the expected value of μ, and the appearance of their squares in the above expressions, these effects are very small, but a highly energetic phenomenon with a large $\mathcal{E}_I$ may help to amplify it to an extent that future observatories can detect it. We should emphasize that the presence of the violation of the Lorentz symmetry in this case, as seen from the above results, is a consequence of the polymer quantization and, in particular, this model, and is not a direct consequence of LQG.

4.2. *Time-independent background*

For the case of a time-dependent background, we can obtain a solution in one of two ways: directly integrating the EOMs, or using the canonical transformation in Eqs. (13)–(16). In either case, we will need to obtain a solution for ρ by solving Eq. (20). In general, this choice determines whether the mode amplitude will be purely decaying or will contain oscillatory behavior. Here we will seek purely growing solutions for ρ, choosing initial conditions such that oscillatory behavior is minimized; in our case, simply choosing $\rho = 1$ and $\dot{\rho} = 0$ is sufficient. Choosing a different initial amplitude for ρ is in any case equivalent to rescaling of the scale factor a, polymer scale, momentum, and time coordinate. The full nonperturbative

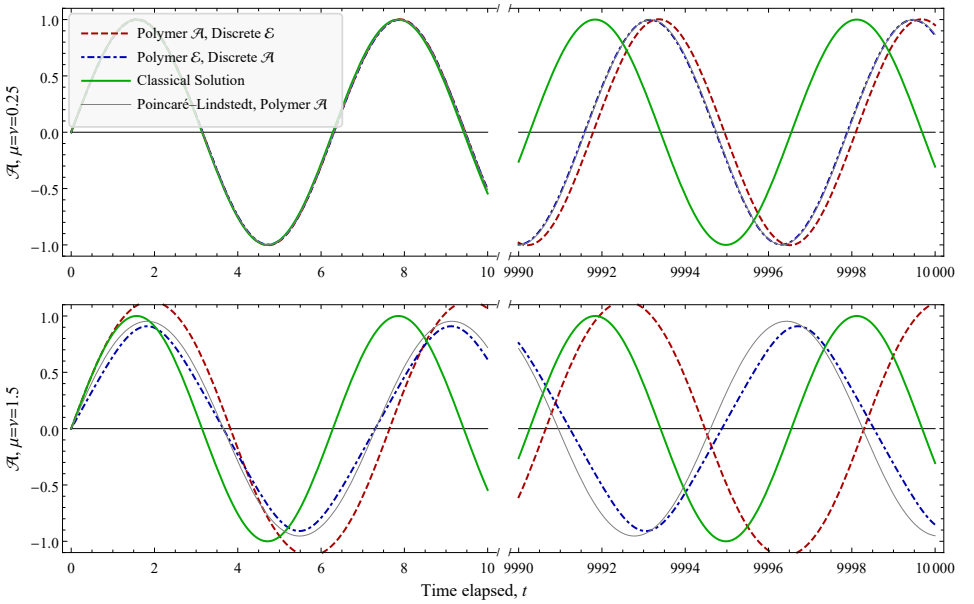

Fig. 2. Time evolution of $\mathcal{A}$ with $\mathcal{A}_I = 0$, $\mathcal{E}_I = 1$, and $k = 1$ for two different choices of μ in the case of a time-independent background spacetime, i.e., $\rho =$ const. Here ν refers to another representation of the polymer quantization in which the momentum $\mathcal{E}$ is discrete, which can be found in our original paper.[31] The solutions are shown at early times, and the axis is broken to show the behavior at a much later time. Solutions can be mapped to different choices of k and $\mathcal{E}_I$, while changing $\mathcal{A}_I = 0$ can be viewed as a phase shift.

solutions are plotted in Fig. 4. We can also obtain a perturbative solution

$$\mathcal{A}(t) \simeq \mathcal{E}_I \rho \sin\left[(1-(\mathcal{E}_I k\mu)^2/16)kT(t)\right] - \frac{\mathcal{E}_I^3 k^2 \mu^2}{16}\rho \sin^2\left[(1-(\mathcal{E}_I k\mu)^2/16)kT(t)\right]\cos\left[(1-(\mathcal{E}_I k\mu)^2/16)kT(t)\right], \tag{29}$$

where

$$T(t) = \int_{t_I}^{t} dt' \frac{1}{\rho(t')^2} \tag{30}$$

For GWs emitted at a time much greater than the characteristic wave time scale, i.e., $t_I \gg k^{-1}$, where T_I is the initial time, and for nonoscillatory solutions of ρ, the second-derivative term is small, and solutions to the auxiliary equations are well approximated by a simple power law, $\rho = 1/a$. In Fig. 3 we show the behavior of ρ for several sets of initial conditions, and for a universe with a cosmological constant with $w = -1$, $a \propto t^{1/3}$, and $t_I = 10^3$ (in units of k^{-1}). In subsequent plots we will use initial conditions that do not result in oscillatory behavior.

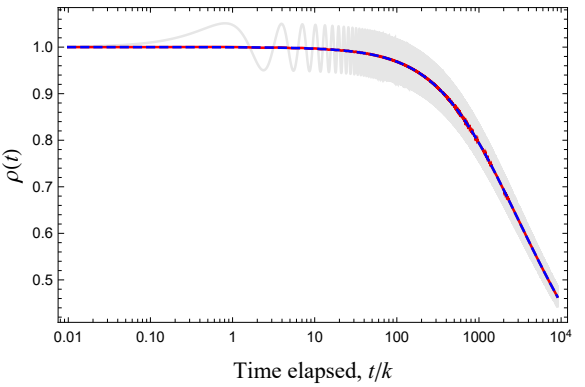

Fig. 3. Evolution of the auxiliary variable $\rho(t)$. The full numerical nonoscillatory solution is shown in solid red, an approximate power-law solution is shown in dashed blue, and a solution with initial conditions that result in oscillatory behavior is shown in light grey.

From the canonical transformation (13)–(15) (or, rather, its inverse), we see that the time-dependent waveform amplitude will pick up an overall factor of ρ relative to the time-independent one, the time coordinate will be altered, and the momentum will be similarly rescaled but will also pick up an additional factor proportional to the wave amplitude. Due to the monotonically decreasing nature of ρ and the smallness of its derivative, this additional factor will be a strongly subdominant contribution. In Fig. 4 we show the final solution for the field $\mathcal{A}(t)$ for this time-dependent background. Somewhat counterintuitively, the frequency is seen to increase at later times; more commonly the frequency is considered to decrease (redshift) with cosmological expansion. This is due to the choice of harmonic slicing we have made, with $N = a^3$ instead of the more commonly used $N = 1$ (synchronous) or $N = a$ (comoving) time coordinate.

5. Discussion and conclusion

In this work we have studied a certain effective form of GWs, considered as quantized perturbations propagating over a classical FLRW spacetime, in order to derive observational signatures to be compared with the results of experiments conducted by GW observatories. We have considered the Hamiltonian of classical gravitational perturbations, a time-dependent Hamiltonian, and have applied the techniques of polymer quantization to it. This polymer quantization was applied to each of the Fourier modes of the GW. A feature of this quantization is that the one-particle Hilbert space is modified and the Lorentz symmetry is no longer present.[38] This modification is "encoded" on the polymer scale μ, which is usually considered to be very small (of the order of the Planck scale). However, our intuition in the present case is that the propagation of the GWs may capture some insights about these modifications despite the small values of the polymer scales.

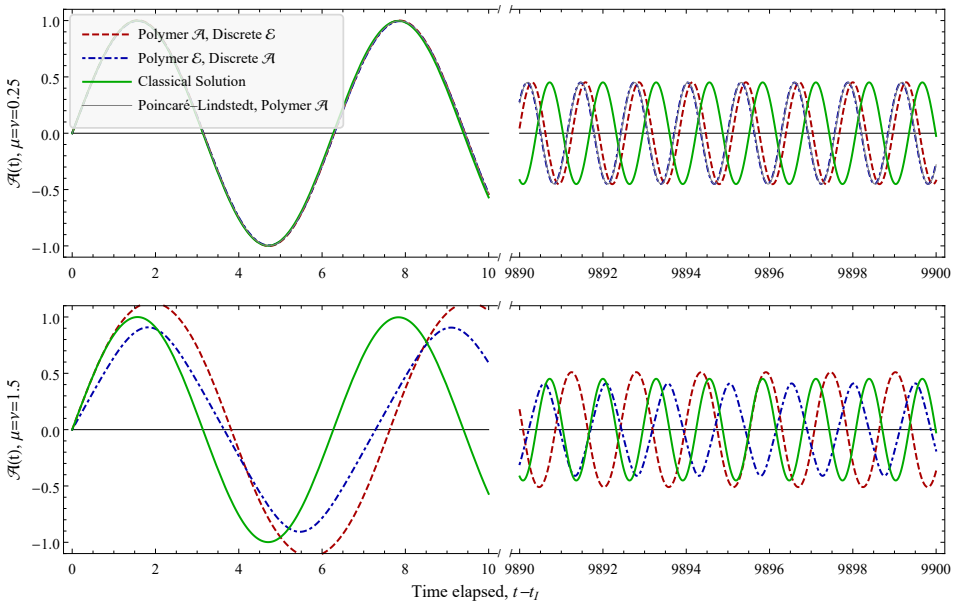

Fig. 4. Time evolution of $\mathcal{A}$ (as in Fig. 2) for two different choices of μ, for the case of a time-dependent background, i.e., $\rho(t)$ as described in the text. The axis is broken to show the behavior at a later time. Again, ν refers to another representation of the polymer quantization in which the momentum $\mathcal{E}$ is discrete, which can be found in our original paper.[31]

After deriving a tine-dependent effective polymer Hamiltonian using a novel approach, we derived both nonperturbative and perturbative analytical expression for the solutions and analyzed them to obtain further insight into the behavior of such waves. As a result, we found the following:

i) The form of the waves is modified. More precisely, there is a phase shift with respect to the classical case. Furthermore, small-amplitude harmonics are excited.
ii) The speed of the waves turns out to be smaller than the speed of light by a factor $k^2\left(\frac{\mathcal{E}_I\mu}{4}\right)^2$. This factor not only depends on the polymer scale μ and the initial momentum of the perturbations $\mathcal{E}_I$, but also on the wave vector k or, equivalently, the frequency of the waves. Thus, the higher-energy waves show a greater deviation from the classical behavior compared to the low-energy waves.
iii) The modifications to the classical behavior due to quantum effects become increasingly visible as the waves travel: the corrections result in an effective phase shift, which can become of order unity when $\mathcal{E}_I\mu^2k^3D_s$ is of order unity for a distance D_s traveled.

In a future work, we will proceed to apply our method to the case where both the background spacetime and the perturbations are effective.

The general matter bounce scenario, including an Ekpyrotic field to avoid anisotropic instabilities, is studied in a loop quantized isotropic and homogeneous FLRW setting. The matter bounce scenario provides a convenient way to include quantum corrections from the bounce in the perturbations originating in the far past, which also produce a scale invariant power spectrum. LQC provides the right setting for studying quantum corrections in a matter bounce scenario as the bounce in LQC occurs entirely due to quantum geometrical effects without needing any exotic matter fields to avoid the singularity. A detailed exploration of this general matter-Ekpyrotic scenario in spatially flat FLRW spacetime in LQC filled with minimally coupled dust and Ekpyrotic scalar field is studied with the help of numerical simulations. Various features of the background dynamics are shown to be robust under variations in initial conditions and choice of parameters. We use the dressed metric approach for the perturbations and obtain a scale invariant power spectrum for modes exiting the horizon in the dust dominated contracting phase. In contrast to previous studies considering a constant equation of state for the Ekpyrotic field, we found that the magnitude of the power spectrum changes during the evolution. The scale invariant section of the power spectrum also undergoes a rapid increase in its magnitude in the bounce regime, while its scale invariance is unaffected. We argue that apart from increasing the magnitude, the bounce regime may only substantially affect the modes outside the scale invariant regime. However, the spectral index is found to be too close to unity, thus inconsistent with the observational constraints, necessitating further modifications of the model.

Keywords: Loop quantum cosmology; bouncing cosmology; primordial power spectrum.

1. Introduction

Early universe cosmology provides one of the most promising avenues to search for signatures of quantum gravity. Singularity free bouncing cosmologies of LQC provide a convenient setting for this. Inflation being the leading model has been studied widely with LQC backgrounds. Since there is no singularity, it is possible to extend the inflationary scenario further back in time upto the Planck regime of the quantum bounce to include quantum gravity signatures. These studies have led to predictions that are in excellent agreement with standard inflation and CMB observations at small angular scales but are closer to observations at larger scales than standard inflation.[2] The quantum bounce which lies to the past of this inflationary regime is a cataclysmic event which changes the course of the evolution of the universe, thus is expected to contribute significantly to the quantum gravity signatures in

the early universe. In this regard, it's natural to consider alternatives such as the matter-bounce scenario where the perturbations start out in the far past in the contracting branch, hence getting imprinted by the highly quantum phenomena as they pass through the quantum bounce. Due to a duality between inflation and matter-bounce, a scale invariant spectrum of perturbations is obtained in both of them.[3] An Ekpyrotic field is generally also included to guard against a potential BKL instability which may occur due to unchecked growth of anisotropies during the contracting phase.[4] An Ekpyrotic field is a scalar field with a negative-definite potential, thus having an equation of state larger than unity. As the bounce is approached in the contracting phase, the Ekpyrotic field having an equation of state larger than unity is expected to dominate the anisotropies which evolve as a^{-6}, where a denotes the scale factor.[5] Thus combining these two ingredients we obtain the the matter-Ekpyrotic scenario,[6] in which a scale invariant spectrum is produced by matter perturbations which exit the horizon during the contracting phase.

An important ingredient of the matter-Ekpyrotic scenario is a non-singular bounce which allows the scale invariant perturbations to pass through without changing them substantially. This is where LQC provides an advantageous framework. In LQC, the quantum bounce arises purely due to quantum geometry effects without requiring any exotic matter content violating the weak energy conditions.[7] Thus the marriage of the matter-Ekpyrotic scenario with an LQC bouncing background provides a compelling model for obtaining quantum gravity signatures in the early universe. Using effective dynamics of LQC, a nonsingular model with an Ekpyrotic potential was obtained[8,9] but it was found that a viable cyclic model cannot be realized unless another matter field or anisotropies are present.[10] Previous studies of the matter-Ekpyrotic model in LQC have either restricted to a special case of a constant equation of state for the Ekpyrotic field,[11] or when the general case has been considered,[12] the analysis has been limited to qualitative predictions due to difficulties associated with the deformed algebra approach used for perturbations in dealing with ultraviolet modes near the bounce. Thus a detailed study of the general matter-Ekpyrotic scenario in LQC analyzing the impact of the Ekpyrotic phase and the bounce on the perturbations has been lacking so far. Our work aims to fill this gap and provide a basis for further exploration.

2. Background dynamics of the matter-Ekpyrotic scenario in LQC

LQC uses the techniques of non-perturbative canonical quantization of LQG on symmetry reduced cosmological models such as the isotropic and homogeneous FLRW model. The canonical quantization of gravity in LQG is carried out in terms of the Ashtekar-Barbero connection and their conjugate triads instead of metric variables. The discrete quantum dynamics obtained in LQC is found to be well approximated by a continuum effective description in terms of differential equations on a smooth manifold, giving modified versions of Friedmann and Raychaudhuri equations that

include quantum corrections that lead to a singularity free evolution in which the big bang is replaced by a bounce. The effective Hamiltonian describing the dynamics of loop quantized spatially flat FLRW model in terms of symmetry-reduced Ashtekar-Barbero connection and its conjugate triad, namely c and p, is given by[7]

$$\mathcal{H} = -\frac{3v}{8\pi G\gamma^2\lambda^2}\sin^2(\lambda b) + \mathcal{H}_{\rm m}, \tag{1}$$

where $\lambda = \sqrt{\Delta}$. Here $\Delta = 4\sqrt{3}\pi\gamma\ell_{\rm Pl}^2$ is the minimum area eigenvalue in LQG. The matter Hamiltonian $\mathcal{H}_{\rm m}$ is given by

$$\mathcal{H}_{\rm m} = \frac{{p_\phi}^2}{2v} + vU(\phi) + \mathcal{E}_{\rm dust}, \tag{2}$$

and the Ekpyrotic potential $U(\phi)$ is taken to be,

$$U(\phi) = \frac{-2u_o}{e^{-\sqrt{\frac{16\pi}{p}}\phi} + e^{\beta\sqrt{\frac{16\pi}{p}}\phi}}, \tag{3}$$

which has the shape of an asymmetric exponential well. Here u_o, p and β are parameters taking positive values. The potential (3) is negative definite. The width of the potential increases with an increasing p, and the degree of asymmetry is controlled by β.

We obtain the following Hamilton's equations from the above Hamiltonian constraint,

$$\dot{b} = -\frac{3\sin^2(\lambda b)}{2\gamma\lambda^2} - 4\pi G\gamma P, \tag{4}$$

$$\dot{v} = \frac{3\sin(2\lambda b)}{2\gamma\lambda}v, \tag{5}$$

$$\dot{\phi} = \frac{p_\phi}{v}, \qquad \dot{p}_\phi = v\,U_{,\phi}, \tag{6}$$

where $U_{,\phi}$ stands for the differentiation of the potential with respect to the Ekpyrotic field and P is the isotropic pressure $P = -\frac{\partial\mathcal{H}_{\rm m}}{\partial v}$. It can be shown that the above equations lead to a following modified Friedmann equation of the form

$$H^2 = \frac{8\pi G}{3}\rho\left(1 - \frac{\rho}{\rho_c}\right), \tag{7}$$

where $\rho_c = 3/(8\pi G\gamma^2\lambda^2) \approx 0.41\rho_{\rm Pl}$ is called the critical energy density in LQC. The Hubble rate is generically bounded, and vanishes and turns around when the energy density reaches a maximum ρ_c. This is when the bounce occurs. The matter content satisfies the continuity equation $\dot{\rho} + 3H(\rho + P) = 0$, where ρ and P are given respectively by

$$\rho = \frac{\dot{\phi}^2}{2} + U(\phi) + \frac{\mathcal{E}_{\rm dust}}{v}, \quad P = \frac{\dot{\phi}^2}{2} - U(\phi). \tag{8}$$

We use the above set of equations along with suitable initial conditions provided at the bounce to numerically analyze the background dynamics of this model. We

also carry out simulations to study the effect of changes in the potential parameters and the relative proportion of the initial dust energy density compared to the Ekpyrotic field energy density. We find that LQC leads to a non-singular bounce in all cases. Although there can be multiple bounces, we restrict ourselves to the cases with a single bounce to study the evolution of curvature perturbations. As an example, we show here the evolution for the choice of parameters $u_o = 0.75, p = 0.10$ and $\beta = 5.0$ with the following initial conditions:

$$\phi_B = 0, \qquad \mathcal{E}_{dust} = 2.00 \times 10^{-5}, \qquad p_{\phi_B} = 1.50. \tag{9}$$

The volume at bounce is taken to be unity, while we choose $b_B = \pi/2\lambda$ in order to have the correct classical limit on either side of the bounce. The dust energy density is chosen such that the energy density at the bounce is dominated by the Ekpyrotic field. The initial conditions are taken to satisfy the Hamiltonian constraint which has to be satisfied throughout the evolution. The evolution of the energy densities and the equation of state for these initial conditions is shown in Fig. 1. We note that the contracting phase starts in a dust dominated phase where the total energy density is very small and the universe is classical. Eventually it transitions to a phase dominated by the Ekpyrotic field which lasts through the bounce. Thus we find the equation of state at the bounce is $w_B \approx 5.76$. Thus a distinct phase where $w > 1$ is obtained near the bounce, which is very important to avoid the BKL instability as envisaged. The $w > 1$ regime is obtained only when the scalar field is traversing the very bottom of the potential, and is obtained only for a short duration during the scalar field dominated phase near the bounce. After the bounce the equation of state quickly drops below unity and decreases monotonically as the Ekpyrotic field moves away from the bottom of the potential. We did extensive simulations to study the robustness of the qualitative features of the background dynamics obtained above by varying the parameters of the potential and taking different proportions of the initial dust energy density while still keeping the bounce dominated by Ekpyrotic field. We found that the effect of reducing the proportion of the dust energy density

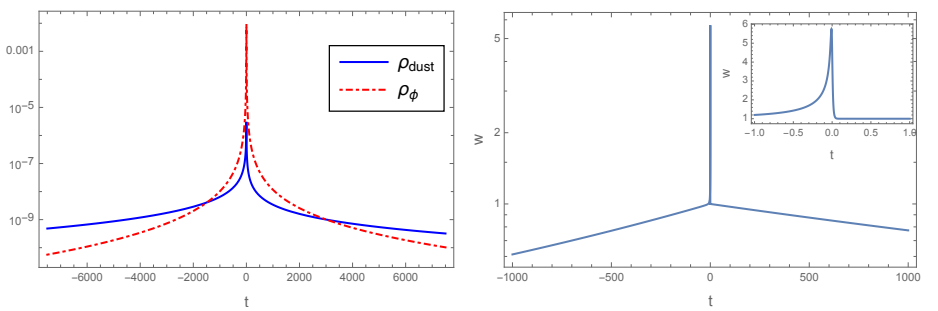

Fig. 1. In the left panel, we see that the energy density of the Ekpyrotic field dominates over the dust energy density in the bounce regime. The right panel shows the behavior of the equation of state when the Ekpyrotic field is dominant and the inset plot depicts the details of the change in the equation of state near the bounce point.

at the bounce has the obvious effect of increasing the duration of Ekpyrotic field dominated regime and the $w > 1$ regime near the bounce. The $w > 1$ regime can also be elongated by widening the potential by increasing p, making it less steep due to which the field takes longer to traverse the bottom of the well. Further, increasing the parameter u_o has effect of increasing both the depth and steepness of the potential. If we increase u_o while keeping the rest of the conditions same, this has the effect of numerically increasing both the kinetic and potential energy of the scalar field at the bounce while keeping the total the same (since the potential is negative-definite, the total energy density is the difference of the numerical values of kinetic and potential energies). Higher kinetic energy means the field climbs out of the well faster, i.e. the duration of the Ekpyrotic field dominated phase is reduced. But a deeper well means that $w > 1$ for most of the duration of this climb. Thus increasing u_o has the effect of decreasing the Ekpyrotic field dominated phase while increasing the $w > 1$ regime. This is illustrated in the following table showing durations of different regimes in the contracting branch (in Planck seconds):

u_o	Ekpyrotic field dominated phase	$w > 1$ regime
1	8.70×10^4	100
0.75	1.50×10^5	65
0.03	3.00×10^5	11
0.008	3.04×10^5	6.5

3. Scalar power spectrum using the dressed metric approach

In this section, we study perturbations around the background spacetime studied in the previous section. As mentioned above, due to the duality with the inflationary epoch,[3] the perturbations in dust matter that exit the horizon during the contracting phase yield a scale invariant spectrum. The dust dominated phase in our background dynamics occurs in the far past, away from the bounce when the universe is classical. Thus we must start perturbations in the far past and then evolve them through the Ekpyrotic phase and the bounce upto the expanding branch.

Since the Ekpyrotic field contributes negligibly to the total energy density in the far past and the equation of state $w \approx 0$, thus we ignore it while considering perturbations in this phase. In this regime the total energy density is far below the Planck density and quantum gravity modifications are negligible. Thus the perturbation equation in terms of the Mukhanov-Sasaki variable also takes its classical

form in this phase,

$$\nu_k'' + \left(k^2 - \frac{z''}{z}\right)\nu_k = 0, \tag{10}$$

where the prime represents the differentiation with respect to the conformal time. And we choose initial conditions such that, the above state corresponds to the Bunch-Davies vacuum in the asymptotic past:

$$\lim_{\eta\to-\infty} \nu_k = \frac{e^{-ik\eta}}{\sqrt{2k}}. \tag{11}$$

The above equations are only valid in the matter dominated phase. As perturbations evolve towards the bounce, the Ekpyrotic field starts dominating and the energy density starts increasing towards the Planck scale. Since the Ekpyrotic field dominated phase overlaps with the bounce regime, we cannot use classical equations to describe the perturbations in the Ekpyrotic field dominated phase. Of the various approaches in LQC that consider perturbations in the quantum spacetime, we work with the dressed metric approach.[13] This avoids the Jeans instability encountered near the bounce in the previous study based on deformed algebra approach.[12] In the dressed metric approach, the quantum spacetime is approximated by a differential manifold with a dressed metric for sharply peaked semi-classical states. The effective description of the quantum perturbations is then provided by a Mukhanov-Sasaki variable with an evolution equation of the form

$$\nu_k'' + \left(k^2 + \Omega^2 - \frac{a''}{a}\right)\nu_k = 0, \tag{12}$$

where Ω^2 can be written in terms of the background variables as

$$\Omega^2 = 3\kappa\frac{p_\phi^2}{a^4} - 18\frac{p_\phi^4}{a^6\pi_a^2} - 12a\frac{p_\phi}{\pi_a}U_{,\phi} + a^2U_{,\phi\phi}. \tag{13}$$

Here $\kappa = 8\pi G$ and π_a is the conjugate momentum of the scale factor. The required background quantities in the above equations are to be calculated using the effective background dynamics described in section 2. The power spectrum is given by

$$\mathcal{P}_\mathcal{R} = \frac{k^3}{2\pi^2}\frac{|\nu_k|^2}{z^2}, \tag{14}$$

with $z = a\dot{\phi}/H$. The modes that exit the horizon in the matter-dominated phase of contraction are scale invariant, and it is these modes that will be observable today. However, numerical simulations are important to study the impact of the Ekpyrotic field dominated phase and the bounce on the spectrum of these perturbations. In particular, the scale invariance of spectrum is to be preserved in order to be consistent with observations. Fig. 2 shows the evolution of scalar power spectrum at different stages.

It is clear from the plots that a scale invariant spectrum is already generated at the end of the dust dominated phase during contraction. However, in contrast to previous studies relying on constant equation of state for the Ekpyrotic field,[11] the

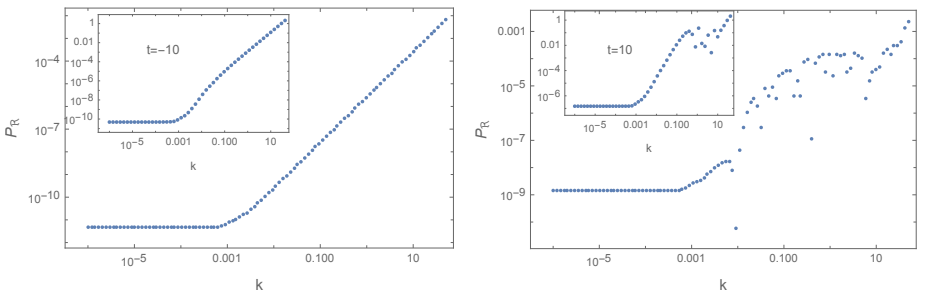

Fig. 2. The power spectra at different times are depicted: in the left panel, the power spectra are evaluated at the transition time from dust dominated to Ekpyrotic field dominated regime in the contracting phase ($t \approx -1.49 \times 10^3$) and at $t = -10$ (in the inset plot); while in the right panel, the power spectra are evaluated at the transition time in the expanding phase ($t \approx 3.02 \times 10^3$) from Ekpyrotic field domination to dust domination and at $t = 10$ (in the inset plot).

magnitude of the scale invariant power spectrum changes over time. Although the scale invariance is preserved through the bounce, a rapid increase in the magnitude of the power spectrum is observed from before the bounce to after the bounce seen by comparing the inset plots. Further, an oscillatory regime reminiscent of inflationary scenarios is seen for $k \geq 10^{-2}$. A comparison of the oscillatory regime at different times as seen in the right panel of Fig. 2 shows that different modes become oscillatory as they exit the horizon in the expanding phase. In contrast to earlier works on the matter-Ekpyrotic scenario in LQC dealing with special cases as well as in contrast to inflationary scenarios, the magnitude of the spectrum in the scale invariant regime gradually decreases as the universe expands. The qualitative behavior of the spectrum remains the same when we vary the proportion of the initial dust energy density relative to the Ekpyrotic field density. However, the range of modes that show scale invariance may get shifted. When the dust energy proportion is decreased, that leads to a shorter duration of dust dominated phase during contraction. Since only those modes that exit during the dust dominated contraction show a scale invariant spectrum, range of modes that show scale invariance is decreased. This may be used to put a constraint on the duration of Ekpyrotic field allowed by observed range of scale invariant modes.

Lastly, in order to compare with observations, we compute the spectral index of the spectrum given by:

$$n_s = 1 + \frac{\mathrm{d} \ln P_{\mathcal{R}}}{\mathrm{d} \ln k}. \tag{15}$$

The spectral index is plotted in Fig. 3. We find that the spectral index is larger than unity in the scale invariant regime and is unfavored by recent CMB observations that put tight constraints on the spectral index: $n_s = 0.9649 \pm 0.0042$ (68%CL).[14] We find that this cannot be ameliorated by either changing the parameters of the scalar field potential or changing the proportion of initial dust density to Ekpyrotic field density. Thus making further modifications of this model necessary.

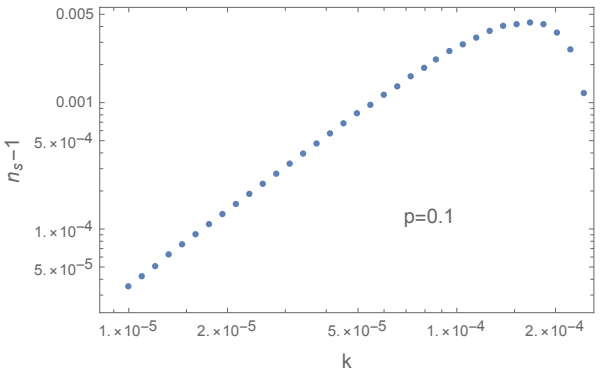

Fig. 3. For the power spectrum displayed in Fig. 2, we evaluate the spectral index n_s at the transition point $t \approx 3.02 \times 10^3$ in the expanding branch and find n_s is larger than unity in the scale invariant regime of the power spectrum.

4. Conclusion

In this paper, we study a general matter-Ekpyrotic scenario in an isotropic and homogeneous FLRW universe in LQC. Using extensive numerical simulations, we establish some general features of the background dynamics and the scalar power spectrum, some of which were not seen in earlier works that either dealt with special cases or were limited to qualitative analysis. A bouncing background cosmology, characteristic of LQC, is obtained where a contracting and an expanding branch connected through a bounce. We find that the background dynamics in each branch is characterized in general by two distinct phases. It starts out in the far past with dust domination and transitions to Ekpyrotic field dominated phase which overlaps with the high energy quantum regime at the bounce. After the bounce there is another transition back to dust dominated universe in the expanding branch. Further we find that the Ekpyrotic field dominated phase generally also contains a phase of ultrastiff equation of state ($w > 1$) leading up to the bounce, which is essential in avoiding the BKL instability. We varied the parameters of the potential and also varied the relative proportion of initial dust density (while keeping it sub-dominant at the bounce), and found the above mentioned features of the background dynamics to hold in general.

We found that the duration of the Ekpyrotic field dominated phase and the $w > 1$ phase can be increased by increasing the width of the Ekpyrotic field potential or by decreasing the relative proportion of initial dust density. In contrast, increasing the depth of the potential has the effect of shortening the Ekpyrotic field dominated phase while increasing the $w > 1$ phase at the same time.

For the study of comiving curvature perturbations, we give our initial conditions in the far past in the dust-dominated classical phase of the contracting branch in order to include the full effect of the quantum bounce on the power spectrum. We employ the classical Mukhanov-Sasaki equation for the dust-dominated contraction

phase as the universe is large and classical in this phase. Since the Ekpyrotic field dominated phase overlaps with the quantum bounce regime, we have employed the dressed metric approach to obtain the effective evolution equation for quantum perturbations on a quantum spacetime in this regime. This is a deliberate choice as previous studies employing the deformed algebra approach have faced difficulty in analyzing ultraviolet modes near the bounce. Using the dressed metric approach for the bounce regime has allowed us to fully explore the scalar power spectrum in the bounce regime.

We found that the perturbation modes exiting the horizon during dust dominated phase have a scale invariant spectrum. These modes then maintain their scale invariance as they pass through the Ekpyrotic field dominated phase, the $w > 1$ phase and the bounce, until they start re-entering the horizon in the expanding branch after which they become oscillatory. However, unlike previous studies considering a constant equation of state for the Ekpyrotic field, the magnitude of the scale invariant modes gradually increases during the Ekpyrotic-field dominated contraction, then rapidly increases during the bounce regime and then gradually decreases as the universe expands. This is also in contrast to inflationary scenarios where the magnitude is frozen after the modes exit the horizon during inflation. Further, the duration of the Ekpyrotic field dominated not only impacts the magnitude of the scale invariant power spectrum, but also impacts the range of comoving modes that lie in the scale invariant part of the spectrum.

We also studied the spectral index of the scale invariant part of the spectrum and found that it is inconsistent with current observational bounds. This is due to the fact that perturbation originating in a purely dust-dominated phase of contraction have an exactly scale invariant spectrum, while the observed spectrum has a slight red tilt. Thus changing potential parameters of the Ekpyrotic field potential has no effect on this feature.

Based on our results, further studies are needed to fully explore the possibilities presented by the matter-Ekpyrotic scenario in LQC. In particular, a lower bound on the minimum number of e-foldings required of the $w > 1$ phase needs to be rigorously established by studying the Ekpyrotic scenario in more general anisotropic spacetimes. Further, a suitable extension of the matter-Ekpyrotic scenario needs to be developed where the perturbations finally exit to a radiation-dominated universe. Bounds on the duration of the Ekpyrotic field dominated phase also needs to be established by employing its impact on the range of scale invariant modes and their magnitude. The issue of the inconsistent spectral index can addressed if instead of sourcing perturbations from a purely dust-dominated phase, we have a matter field with slightly negative equation of state. Although, preliminary studies following these lines have been carried out in the literature in various bouncing cosmologies including those of LQC, but rigorous and extensive studies taking the most general matter-Ekpyrotic scenario need to be done.

We review recent developments in the primordial power spectra of two modified loop quantum cosmological models (mLQCs) which originate from the quantization ambiguities while loop quantizing the spatially-flat Friedmann-Lemaître-Robertson-Walker (FLRW) universe. The properties of the background dynamics and the primordial scalar power spectra in two modified models, namely mLQC-I and mLQC-II, are reported. In both models, the inflationary scenario can be naturally extended to the Planck regime when a single scale field is minimally coupled to gravity with an inflationary potential and the big bang singularity is replaced with a quantum bounce. The qualitative difference lies in the behavior of the contracting phase where a quasi de Sitter phase emerges in mLQC-I. When applying the dressed metric approach and the hybrid approach to mLQCs, we find the most distinguishable differences between these models and the standard loop quantum cosmology (LQC) occur in the infrared and intermediate regimes of the power spectra.

Keywords: Loop quantum cosmology; bouncing cosmology; primordial power spectrum.

1. Introduction

Loop quantum cosmology (LQC)[1,2] provides an elegant resolution to the big bang singularity in the standard big bang cosmology by replacing it with a quantum bounce and also naturally extends the inflationary paradigm into the Planck regime. The loop quantization of the spatially flat FLRW spacetime in LQC is based on the homogeneity and isotropy of the spacetime. It has been found that the dynamics of the resulting quantum theory can be well described by the effective dynamics for the states which are sharply peaked around the classical trajectories at late times.[3] However, as is common in any quantum theory, different regularizations of the classical Hamiltonian may give rise to different quantum theory and finally result in distinct physical consequences. So it is important to check the robustness of the theoretical predictions from standard LQC by studying its variants originating from quantization ambiguities. The modified LQC models initially proposed in[4] provide a good platform to investigate the impacts of the quantization prescriptions on the dynamics and the observations.

In standard LQC, when quantizing a spatially flat FLRW universe, the Lorentz term was initially treated in the same way as the Euclidean term since they are

proportional to each other at the classical level due to the homogeneity and isotropy of the background spacetime.[5] A separate treatment of these two terms was first implemented in[4] where two modified LQC models, namely mLQC-I and mLQC-II, were proposed due to different regularizations of the Lorentz term. Later, mLQC-I was rediscovered by computing the expectation value of the Hamiltonian constraint in LQG with complexifier coherent state.[6] The right Friedmann and Raychauduri equations of these two models were first reported in,[7,8] and it was found that after taking into account an inflaton field in mLQCs, the inflationary phase turns out to be an attractor in both models.[8] As a result, the inflationary scenario can also be naturally extended to the Planck regime in both models. In the following, assuming the validity of the effective dynamics in mLQCs, we first summarize the main features of the background dynamics of these two mLQCs and their similarities and differences with/from standard LQC. Then we report the results on the numerical simulations of the power spectra in both mLQCs in the dressed metric and the hybrid approaches.

2. The background dynamics in the modified LQC

Although the big bang singularity is resolved and replaced with a quantum bounce in both mLQCs, the differences in the background dynamics between these models are still distinct. Similar to standard LQC, the evolution of the background dynamics in mLQC-II is symmetric with respect to the bounce when gravity is coupled to a massless scalar field. The maximum energy density in mLQC-II is about $1.73m_{\rm pl}^4$ which is larger than the maximum energy density ($\approx 0.41m_{\rm pl}^4$) in LQC. It turns out that the evolution of the universe in mLQC-II is similar to that in LQC when gravity is coupled to the same matter content. In contrast, in mLQC-I, the contracting and the expanding phases are no longer symmetric with respect to the bounce point which takes place at the maximum energy density ($\approx 0.097m_{\rm pl}^4$). A characteristic quasi de Sitter phase quickly emerges in the contracting phase when the universe is evolved backwards from the bounce point. This de Sitter phase is dominated by a Planck-sized effective cosmological constant and the asymptotic forms of the Friedmann and Raychauduri equations reveal a rescaled Newton's constant in the contracting phase as well.[7] As a result, when filled with an inflaton field, the classical universe can only be recovered in the expanding phase of mLQC-I while in the contracting phase, the universe remains quantum with a Planck-scale Hubble parameter.

Meanwhile, the numerical simulations of the background dynamics shows qualitatively similar behavior of the universe in the expanding phase of mLQCs and standard LQC.[9] The initial conditions of the background dynamics which are relevant to CMB data are those dominated by the kinetic energy of the inflaton field at the bounce. For these initial conditions, three distinct phases can be observed in the expanding phase: the bouncing phase with $w \approx 1$ which lasts only a few number of e-foldings, the transient transition phase where the equation of state quickly

decreases from positive unity to near negative unity and the slow-roll inflationary phase. These generic features of the background dynamics shared by mLQCs and LQC imply the robustness of the preinflationary dynamics in loop quantizations of the spatially flat FLRW universe and the different regularizations of the Lorentz term in the classical Hamiltonian constraint leave imprints only in the contracting phase.

3. The primordial power spectra in the modified LQC

To compute the primordial power spectra in the mLQCs, one can appeal to the techniques developed in standard LQC where several distinct approaches are widely studied. Among them the most popular ones are the dressed metric approach[10–12]and the hybrid approach.[13–16] We have applied both these approaches to mLQCs and numerically obtained the resulting scalar power spectrum.[17,18] Irrespective of specific model and approach, the power spectrum can be generally divided into three distinctive regimes: the infrared (IR) regime, the intermediate regime and the ultraviolet (UV) regime.

The behavior of the IR regime sensitively depends on the initial states, the specific model and the applied approach. For example, when the fourth-order adiabatic states are employed as the initial states in the contracting phase, the magnitude of the power spectra remains almost constant in LQC and mLQC-II in both dressed metric and hybrid approaches. In contrast, when the second-order adiabatic states are used as the initial states, the magnitude of the power spectra keeps increasing with the comoving wavenumber in LQC and mLQC-II in both approaches. In mLQC-I, the power spectrum in the IR regime strongly relies on the approach we use. In the dressed metric approach, due to the emergent de Sitter phase, the preferred choice of the Bunch-Davies (BD) vacuum state yields a Planck-sized magnitude of the power spectrum in the IR regime. While in the hybrid approach, the effective mass changes so drastically as compared with the one in the dressed metric approach that the adiabatic states can be again chosen as the initial states of the scalar perturbations, leading to a power spectrum whose magnitude is comparable to that of LQC and mLQC-II in the IR regime. From our numerical results, we find the relative difference between LQC and mLQC-II in the IR regime turns out to be less than 40% in the dressed metric approach and less than 50% in the hybrid approach. Due to the similar background dynamics between the LQC and mLQC-II, the relative difference between LQC and mLQC-II is much less than that between LQC(mLQC-II) and mLQC-I.

The power spectrum keeps oscillating throughout the intermediate regime in all of the three models with the dressed metric and the hybrid approaches. This oscillatory behavior is believed to be associated with the bouncing regime where adiabatic conditions are violated for the modes whose comoving wavenumbers are close to the characteristic wavenumber in each model and thus particle creations become appreciable.[19] For the adiabatic initial states and in particular the BD

vacuum state in the dressed metric approach of mLQC-I, the magnitude of the power spectrum in this regime is amplified as compared with that in the UV regime. Moreover, the relative difference of the power spectra between different models turns out to be larger than that in the IR regime due to the oscillatory behavior of the power spectra. In particular, the relative difference of the power spectra between LQC and mLQC-II in the intermediate regime can be up to 100% in both approaches and the relative difference between LQC and mLQC-II is also smaller than that between LQC(mLQC-II) and mLQC-I.

Finally, regardless of the initial states, the specific model and approach used to compute the power spectra, we always observe a scale-invariant UV regime whose magnitude agrees with the observations. The relative difference between the magnitudes of the power spectra from three models turns out to be less than 1%. As a result, only the IR and intermediate regimes are mostly affected by the different regularizations of the classical Hamiltonian constraints, there is little impact on the UV regime due to the quantization ambiguities as it should be.

4. Summary

We have studied the background dynamics and the primordial power spectra in mLQCs and compare the results with those from LQC. The background dynamics in mLQC-II is qualitatively similar to that in LQC with a symmetric evolution with respect to the bounce when gravity is minimally coupled to a massless scalar field. An asymmetric evolution is observed only in mLQC-I where the classical limit can only be recovered in the expanding phase and there shows up an emergent de Sitter spacetime in the contracting phase. The difference between the background dynamics also affects the power spectrum in the IR and intermediate regime. From our numerical results, we find the relative difference of the power spectra between LQC and mLQC-II in these two regimes is much smaller than the relative difference between LQC(mLQC-II) and mLQC-I in the dressed metric and hybrid approaches. Moreover, mLQC-I also serves as a good example to explicitly show the differences between the dressed metric and hybrid approaches. In particular, a Planck scale magnitude of the power spectrum in the IR regime of mLQC-I with the dressed metric approach is observed while in the hybrid approach the magnitude of the power spectrum is suppressed in the IR regime of mLQC-I. This difference is completely due to the distinct construction of the Mukhanov-Sasaki equation in each approach which leads to different effective masses. Finally, the power spectrum in the UV regime is found to be consistent with the CMB data in all three models regardless of the approach and the initial states.

There is an increasing interest in very early stages of the Universe in which the energy density of the inflaton could be dominated by its kinetic part. This includes classical inflationary scenarios with deviations from slow-roll regimes that can introduce modifications to the power spectra of the primordial fluctuations. Another example are certain quantum bouncing cosmologies. For instance, this is the typical situation in loop quantum cosmology if quantum corrections may leave observable traces in the power spectra. In models of this type, we discuss the leading-order effects of an inflaton potential on the primordial perturbations. These effects are of two kinds, referred to the case without potential. First, there are changes in the background-dependent mass appearing in the dynamical equations of the perturbations in conformal time. Second, away from conventional slow roll, a Bunch-Davies vacuum may no longer be natural, and possible new choices depend on the potential.

Keywords: Loop Quantum Cosmology, Kinetically Dominated Inflation, Primordial Perturbations

1. Introduction

We live in an era of precision cosmology, in which the technological progress has allowed us to obtain more accurate observations and determine a number of cosmological parameters with a precision of a few percent.[1] This new era opens the possibility of confronting predictions with observations, falsifying cosmological models and gravitational theories that may suggest corrections to general relativity (GR). Although the standard cosmological model, based on GR and an inflationary phase in slow-roll regime, has proved extremely succesful to explain the observations, there exist some anomalies that, at least, point towards the statistical exceptionality of our universe.[2–6] Namely, cosmological data such as those imprinted in the spectrum of anisotropies of the cosmic microwave background (CMB) or the lensing amplitude are not statistically favored within this standard model. These anomalies may be a sign of new physics that modifies in part the paradigms of the model.

A possibility that has attracted a lot of attention lately is the occurrence of kinetically dominated regimes in the very early epochs of the expansion of the Universe, i.e. regimes in which the scalar field that is going to drive the inflationary

mechanism displays a period in its evolution in which its energy density is dominated by the kinetic contribution, rather than by a potential. This kinetic dominance would have taken place before slow roll, and the transition between both regimes may cover a part of the inflationary era. Typically, the situations of interest combine this kinetic dominance with a short lived inflation, because it is then that the frequencies that are most affected by the dynamics away from slow roll can overlap at present with the band that is observed in the CMB fluctuations.[7,8] This change in the early dynamics of the primordial fluctuations can leave traces in their amplitude and modify the predictions about their power and other measurable quantities, mostly for modes that in those early moments have (wavelength) scales similar to those of the physical phenomena that modify the standard picture of slow-roll inflation.[8]

Clearly, this type of modifications of the standard model can happen within GR.[7] Most interesting, they can also appear owing to quantum effects, in a quantum description of cosmology. An example that has been studied in some detail in recent years is the case of loop quantum cosmology (LQC).[9,10] In this formalism, the cosmological background spacetime is quantized adopting the techniques of loop quantum gravity,[11] a quantum version of GR that is based on the use of holonomies and fluxes of densitized triads, and that avoids any dependence of the results on fixed spacetime structures. On top of this quantum version of the cosmological background, matter and geometry fluctuations provide the cosmological perturbations that eventually serve as seeds for the anisotropies of the CMB and the formation of large-scale structures. Different approaches have been suggested to deal with these perturbations.[12–16] Among them, here we will consider only two of them, that share the property of preserving the ultraviolet structure of the dynamical equations for the perturbations in GR. The first one is called hybrid LQC, and is based on a simultaneous quantization of the background and the gauge-invariant degrees of freedom of the perturbations, using loop quantization techniques for the former and Fock techniques for the latter.[17–23] We will focus most of our analysis on this quantization proposal. The other approach that we will mention, but will not discuss in detail in our study, is called the dressed-metric proposal.[24–29] In this case, the gauge-invariant perturbations evolve in a kind of mean-field background that is dressed with quantum corrections, in order to take into account the most relevant effects of its quantization in LQC.

Remarkably, in the case of kinetic dominance, both in GR and in LQC, the changes with respect to the standard evolution of slow-roll inflation in Einstein's theory can be encapsulated in modifications of the time-dependent mass that appears in the dynamical equations of the gauge-invariant perturbations.[30] This modified mass captures the change in the behavior of the background as compared to the standard inflationary case. Essentially, these changes incorporate (at most) two characteristic scales: one is the scale of the onset of inflation away from slow roll; the other is the typical scale of the quantum phenomena, if such corrections are present.[22]

The main purpose of this work is to introduce a formalism capable to deal with the changes introduced by a kinetically dominated era in the predictions of the primordial spectrum of the cosmological perturbations. Employing that in this era the energy density of the inflaton is dominated by the kinetic term, the basic idea is to treat the effects of the inflaton potential just as a modification to the free case of a scalar field with vanishing potential, and include them only at leading order. In the next section, we present the theoretical framework within which we will develop this formalism. Section 3 describes the cosmological system that we will consider for our study. In Sec. 4 we provide the dynamical equations of the gauge invariant perturbations, including their modified mass. We then consider the issue of the choice of vacuum state for the perturbations in Sec. 5. The following sections are devoted to calculate the leading-order correction of the potential to the modified mass and the related change in the selection of vacuum state. Section 6 discusses what types of effects can be expected owing to the presence of a potential. Then, we compute these effects in: (a) the geometric terms that provide the modified mass, (b) the evolution of the background state, (c) the modified mass as a whole, combining the two previous types of effects, and (d) the choice of a vacuum. This is carried out, respectively, in Secs. 7, 8, 9, and 10. Finally, in Sec. 11 we discuss our results, and explain their possible use in future works.

2. The framework

We will consider cosmological perturbations in the framework of LQC and in the classical counterpart that corresponds to GR. We will restrict our discussion to the case of scalar perturbations, because tensor perturbations can be treated in a similar and in fact simpler way, since the inflaton potential directly affects the scalar matter content and hence the corresponding scalar perturbations.[19] On the other hand, vector perturbations are pure gauge in the absence of vector matter fields. The scalar perturbative gauge-invariant degrees of freedom of the geometry and the matter content, when the latter is given by a scalar field, can be described e.g. by the so-called Mukhanov-Sasaki (MS) invariant, which can be straightforwardly related to the comoving curvature perturbations for spatially flat cosmologies.[31–33] The Fourier modes of the MS gauge-invariant field satisfy a second-order differential evolution equation that can be written in the form of that of a harmonic oscillator, except for the addition of a time-dependent mass term to the squared frequency (or wavenorm) contribution. It is not difficult to derive the expression of this mass in GR, using cosmological perturbation theory. Moreover, in the considered approaches to LQC, it is possible to prove that the MS modes satisfy a dynamical equation which parallels that of GR except for the modification of the time-dependent mass. In the specific case of hybrid LQC, this modified mass turns out to be given by the ratio of two expectation values of background geometry operators, quantized with loop methods.[19,23] Those expectations values are calculated employing the inner product characteristic of LQC for homogeneous and isotropic spacetimes, that is

defined using the discrete measure.[9,10] This is the paradigmatic example that we will analyze in full detail in our discussion.

Nonetheless, the study can be extended without too many complications to the case of dressed-metric LQC, case in which the modified MS mass is also provided by expectation values of geometric operators, but the corresponding expression is different from the hybrid one.[30] Similarly, one can consider the case of hybrid geometrodynamics, in which the background geometry is quantized using geometrodynamics[34,35] and the perturbations using a Fock description, as in hybrid LQC. The modified mass is given again in this alternative quantization by a ratio of two expectation values, but in this case the representation of the geometric operators and the quantum integration measure over the background are not those of LQC, but of geometrodynamics.

An exact treatment of the modified mass in any of these quantization approaches would require numerical simulations to compute the evolution of the quantum state of the background, the action on it of the geometric operators, and the expectation value using the corresponding quantum measure. These numerical simulations would be quite intrincate, because the quantum dynamics in the presence of a potential for the inflaton is extremely nontrivial (actually, it is not even guaranteed that there exists a well-defined self-adjoint operator that generates the background evolution when the potential is not zero and generic). Furthermore, the fact that the quantum background state evolves in time implies that (most of) these numerical simulations have to be repeated at each instant of time in the considered epoch. For instance, the evolution can be described in terms of the inflaton, regarded as an internal time, since this is a good clock when the inflaton energy is kinetically dominated. The need to carry out the calculation of the expectation values for each value of interest of the inflaton complicates enormously the numerical challenges. In addition, the time description in terms of the inflaton has to be re-expressed in terms of a conformal time, which is the one that appears in the MS equation for the perturbations. This change of time involves the computation of additional expectation values,[19,23] as we will see in some detail later in our discussion. Besides, of course, all of these complicated numerical calculations need to be repeated if one changes the potential, e.g. if one wants to consider the effect of different families of potentials in the evolution of the primordial perturbations.

To complicate even more the situation, it is known that the choice of the Bunch-Davies state as a natural vacuum for the perturbations[36] is no longer sustainable away from slow roll.[22,37] The vacuum state should be optimally adapted to the background evolution. When this evolution does not reproduce a de Sitter regime, the validity of the Bunch-Davies vacuum is questionable, especially for modes that are able to feel the change of dynamics. To try to deal with this issue, at least in LQC, several proposals have recently been introduced for the choice of a vacuum of the perturbations. For instance, Ashtekar and Gupt have suggested to identify the vacuum as a state with a maximal classical behavior at the end of inflation

among those that, in the genuine quantum regime, have geometric uncertainties compatible with a quantum extension of Penrose's Weyl curvature hypothesis.[38,39] Another interesting proposal, introduced by Martín-de Blas and Olmedo,[20] is to choose a state with a non-oscillating power spectrum at the end of inflation. This proposal was motivated by the finding of states with rapid oscillations superimposed in the spectrum. Typically, an average of these oscillations over phenomenologically realistic frequency bins leads to an enhancement of the power. Recent works have shown that the desirable non-oscillating behavior can be characterized by a suitable asymptotic behavior in the sector of modes with infinitely large wavenumbers.[40,41] From this sector, one would determine the vacuum for all modes by properly extending the asymptotic solution. Moreover, it has been proved that this asymptotic behavior is displayed by positive frequency solutions associated with an asymptotic diagonalization of the Hamiltonian of the perturbations. Namely, by means of that diagonalization one straightforwadly finds a background-dependent frequency that defines the desired solutions, at least in the asymptotic ultraviolet sector. We will focus our discussion on this form of the proposal for the choice of a vacuum for the perturbations, since it can be handled analytically, opposite to the situation found for the alternative form in terms of the absence of oscillations in the spectrum, or for the proposal of Ashtekar and Gupt, which in a way or another require the use of numerical methods to pick out a vacuum solution.

As we have anticipated, the basic idea of our investigation is to approximate the MS mass around its value for a free scalar field and derive the leading-order correction to it owing to the presence of a small but nonzero potential term. This approach to the problem leads to a drastic simplification of the numerical calculations required for a complete study of the evolution of the perturbations, which in any case can be related to the free evolution, that is usually manageable in most of the quantization approaches (sometimes even analytically). Furthermore, as far as kinetic dominance persists in the studied period of time, the analysis can be carried out in a parallel way, if not at once, for any possible inflaton potential.

3. The system

The cosmological system that we will consider in this work is a perturbed flat Friedmann-Lemaître-Robertson-Walker (FLRW) spacetime endowed with a scalar field as matter content. We start with a homogeneous and isotropic FLRW geometry with flat spatial sections and a homogeneous scalar field ϕ provided with a potential $W(\phi)$, which will play the role of an inflaton. In the absence of perturbations, or when their backreaction is negligible, this background is subject to a Hamiltonian constraint of the form[23,42]

$$\hat{\pi}_\phi^2 - \hat{H}_0^{(2)} = 0, \tag{1}$$

where $\hat{\pi}_\phi$ is the momentum operator of the inflaton and $\hat{H}_0^{(2)}$ contains all dependence on the FLRW geometry, namely[a]

$$\hat{H}_0^{(2)} = \left[\hat{H}_0^{(F)}\right]^2 - 2W(\phi)\hat{V}^2, \qquad H_0^{(F)} = 2\sqrt{3\pi G}|\pi_V|V. \tag{2}$$

We have set $\hbar = c = 1$, and G is Newton's constant. The operator $\hat{H}_0^{(F)}$ generates the free evolution, in the absence of potential, and can be interpreted as proportional to the generator of dilations. On the other hand, V is the physical volume of the spatial sections (in principle, we consider them compact, and take the noncompact limit at the end of the calculations about the dynamics of the perturbations[43]). Its momentum is denoted by π_V.

On this background, we introduce perturbations in the geometry and the scalar field, truncating the action of the whole system at quadratic perturbative order, which is the first nontrivial one. As we have said above, we restrict our discussion to scalar perturbations (in the continuous limit[43]) for simplicity. We adopt a canonical set of variables for the background and the perturbations in which the perturbative degrees of freedom correspond to the MS gauge invariant and its momentum, togeteher with a canonical set for the pure gauge sector.[19] The background is still described by suitable variables for the inflaton and the physical volume and their momenta. These variables differ from the original ones by quadratic perturbative corrections[19] but, in order to maintain our notation as simple as possible, we will not introduce new symbols for them and use the ones already introduced.

The resulting system has only one constraint that is not trivial to impose quantum mechanically: the spatial average, or zero-mode, of the Hamiltonian constraint[19] (truncated at quadratic order). We quantize this system and the constraint, and search for physical states by adopting an ansatz of separation of variables. The corresponding wavefunctions depend only on the MS gauge invariant, the background geometry (e.g. the volume), and the inflaton. With our ansatz, the dependence on the MS modes and the FLRW geometry separates in partial wavefunctions, that may all depend on the inflaton, used as a reference variable for the quantum evolution. Moreover, as part of the ansatz, the background state is taken to adopt the expression

$$\chi(V,\phi) = P\left[\exp\left(i\int_{\phi_0}^{\phi} d\tilde{\phi}\,\hat{H}_0(V,\tilde{\phi})\right)\right]\chi_0(V), \tag{3}$$

where $\chi_0(V)$ is the initial state of the FLRW geometry. In addition, the operator $\hat{H}_0$ is the square root of (the positive part of) $\hat{H}_0^{(2)}$. We will call it the background Hamiltonian. We can understand this operator as a(n approximate) generator of the background evolution. Finally, the symbol P denotes path ordering, since the

[a] Actually, we allow some freedom in the factor ordering for the representation of this operator. This will be useful when calculating its square root, to obtain a specially simple operator [see Eq. (14)].

integral in the exponential is defined over the inflaton, and the operator $\hat{H}_0$ depends on it.

Using this ansatz for the physical states, imposing the zero-mode of the Hamiltonian constraint, and assuming that the transitions between different background quantum states mediated by this constraint can be neglected, it is possible to derive a quantum constraint just on the perturbations, that depends on expectation values of geometric operators over the FLRW geometry of the background.[19,23] This constraint on the perturbations implies dynamical equations of the MS type, but with a background-dependent mass that is modified with respect to GR by including quantum effects via expectation values.

4. Modified MS equations

The coefficients of the Fourier expansion (in terms of sines and cosines, for instance) of the MS gauge-invariant field can be treated as time dependent variables $v_{\vec{k},\varepsilon}$, where ε is a dichotomic label that indicates the parity of the mode and $\vec{k}$ is the wavevector, restricted to have a positive first nonvanishing component (in an Euclidean fiducial spatial system of coordinates). We will call k the norm of this wavevector.

In hybrid quantum cosmology, according to the discussion of the previous section, the MS variables satisfy the following dynamical equations:

$$\ddot{v}_{\vec{k},\varepsilon} + \left[k^2 + \frac{\langle \hat{\vartheta}_e^q + (\hat{\vartheta}_o \hat{H}_0)_{sym}\rangle_\chi}{\langle \hat{\vartheta}_e\rangle_\chi}\right] v_{\vec{k},\varepsilon} = 0, \tag{4}$$

which rule their propagation on the FLRW (quantum) background. The dot denotes the derivative in conformal time η. We will call modified mass the term added to k^2 in the factor between square brackets, and denote it by $s(\eta)$. The geometric operators that appear in this modified mass and have not been defined yet are

$$\hat{\vartheta}_e = \frac{3}{2G}\hat{V}^{2/3}, \tag{5}$$

$$\hat{\vartheta}_o = \frac{3}{\pi}\sqrt{\frac{3}{\pi G}}\hat{V}^{2/3}(\hat{H}_0^{(F)})^{-1}\hat{\Lambda}_0^{(F)}(\hat{H}_0^{(F)})^{-1}\hat{V}^{2/3}W'(\phi), \tag{6}$$

$$\begin{aligned}\hat{\vartheta}_e^q = {} & \frac{1}{2\pi}\left[\hat{\frac{1}{V}}\right]^{1/3}\hat{H}_0^{(2)}\left(19 - 18(\hat{H}_0^{(F)})^{-2}\hat{H}_0^{(2)}\right)\left[\hat{\frac{1}{V}}\right]^{1/3} \\ & + \hat{V}^{4/3}\left(\frac{3}{8\pi^2 G}W''(\phi) - \frac{2}{\pi}W(\phi)\right).\end{aligned} \tag{7}$$

The norm of the operator $\hat{\Lambda}_0^{(F)}$ denotes an alternative representation of $\hat{H}_0^{(F)}$ in LQC, obtained with holonomies of double length. Besides, $\left[\hat{\frac{1}{V}}\right]$ is the so-called inverse volume operator of LQC,[9,23] which is not the inverse of the volume operator $\hat{V}$ at scales of the Planck volume or below. On the other hand, the prime denotes the derivative with respect to the inflaton.

The expectation values that appear in the modified mass have to be computed on the quantum state for the background FLRW geometry, of the form (3) according to our ansatz. In hybrid LQC, one uses for this calculation the discrete inner product characteristic of homogeneous and isotropic LQC. If one considers instead hybrid geometrodynamics (i.e. the combination of geometrodynamics and a Fock quantization of the perturbations), both the representation of all the involved geometric operators and the inner product for the expectation values must be those corresponding to a geometrodynamic quantum cosmology. In the case of the dressed-metric approach to LQC, on the other hand, the modified mass is slightly different, although defined again in terms of expectation values of certain geometric operators.[26] We will not give its expression here, but emphasize that can be handled in a similar way as we will explain for hybrid LQC. Finally, in GR, expectation values become evaluation on classical background trajectories, and operators become phase space functions, with certain subtleties that we will comment later in our analysis.

It is worth emphasizing that the modified MS equations described above dictate the evolution of the gauge-invariant scalar perturbations in conformal time. On the other hand, the evolution of the quantum state (3), as well as the explicit dependence on the potential W of the geometric operators, are in principle described in terms of the inflaton ϕ, that in the kinetic dominated regimes is a good reference variable for the quantum background dynamics. In the derivation of the modified MS equation,[19,23] one finds that the relation between the conformal time η and the inflaton as a dynamical parameter is given by the equation

$$\langle \hat{H}_0 \rangle_\chi d\eta = \langle \hat{\vartheta}_e \rangle_\chi d\phi. \tag{8}$$

This relation is state dependent, but it is well defined because $\hat{H}_0$ is a positive operator (a square root, in fact) and the expectation values translate any operator dependence into one on c-numbers (treating the inflaton as such, and realizing that its momentum does not appear in the considered equation).

5. Vacuum state

The fact that the dynamical equations of the (scalar) primordial gauge-invariant perturbations change with respect to those that would dictate the evolution on a de Sitter background, owing to the modifications suffered by the MS mass, calls for a change as well in the choice of vacuum for those perturbations, from the Bunch-Davies state adopted in the standard situations to a new state that is optimally adapted to the background dynamics. As we have commented in the Introduction, several proposals have been put forward for this choice of vacuum state in LQC. Here we will adhere to a prescription that is based on an asymptotic diagonalization of the Hamiltonian of the perturbations in the sector of infinitely large wavenorms, as a way to select a natural positive frequency in that sector, which can then be extended to all MS modes.[40] We have already commented that this prescription

has been shown to select a vacuum with non-oscillating primordial spectrum in the ultraviolet sector.

An important advantage of the asymptotic diagonalization prescription is that it can be handled in an (essentially) analytical way in the asymptotic ultraviolet sector. Let us see this in more detail. Once we are given a (modified) MS mass $s(\eta)$, we can determine a set of positive frequency solutions $\{\mu_k\}$ in the form

$$\mu_k = \frac{1}{\sqrt{-2\Im[h_k]}} e^{i\int_{\eta_0}^{\eta} d\tilde{\eta}\,\Im[h_k]}, \tag{9}$$

where h_k is a complex solution of the Riccati equation

$$\dot{h}_k = k^2 + s + h_k^2. \tag{10}$$

The positivity of the frequency would be guaranteed if and only if $\Im[h_k]$, i.e. the imaginary part of h_k, is negative. In the following, we will call h_k the complex frequency function. Note, by the way, that the above set of mode solutions depends only on the wavenorm k, and not on the specific wavevector $\vec{k}$ associated with it. The asymptotic diagonalization prescription selects complex frequencies with the following asymptotic behavior[41]:

$$\frac{1}{h_k} = \frac{i}{k}\left[1 + 2\sum_{n=0}^{\infty} \frac{\gamma_n}{(2ik)^{n+2}}\right], \tag{11}$$

where the coefficients γ_n are fixed by the recursion relation

$$\gamma_{n+1} = -\dot{\gamma}_n + 4s\left[\gamma_{n-1} + \sum_{l=0}^{n-3} \gamma_l \gamma_{n(l+3)}\right] - \sum_{l=0}^{n-1} \gamma_l \gamma_{n-(l+1)}, \tag{12}$$

starting with the data $\gamma_0 = s$. So, the complex frequency must behave asymptotically as $-ik$, with all subleading terms forming an asymptotic series in inverse powers of k, and with the coefficient γ_0 of the first term equal to the modified MS mass. This asymptotic behavior should characterize the complex frequency and hence the set of mode solutions that determine the vacuum state.

For completeness, recall that, if the solutions were valid until the end of inflation, the corresponding primordial power spectrum would be proportional to

$$P_v(k,\eta) = -\frac{k^3}{4\pi^2 \Im[h_k](\eta)}. \tag{13}$$

If our expressions for the mode solutions $\{\mu_k\}$ are applicable only in an interval that does not contain all the inflationary period, then we have to evolve their data until the end of inflation and compute the primordial spectrum there.

6. Corrections produced by the potential

In order to calculate the leading-order effect of the potential in the regime of kinetic dominance, let us first identify the different types of corrections that the potential

introduces in comparison to the case of a free evolution. First, the potential modifies the expression of the geometric operators that appear in the MS mass. Besides, it affects the evolution of the quantum background state on which the expectation values are computed, both because the generator of the evolution parametrized by the inflaton is different and because the relation between the inflaton and the conformal time that is used in the MS equation changes. Combining all these corrections one obtains the total change in the modified MS mass. This would complete the corrections to the dynamical equations of the perturbations in the kinetic regime, but we also have to consider the initial conditions for these dynamics, that are determined by the vacuum state. We have already explained that the natural choice of a vacuum changes as well with respect to the Bunch Davies state, away of slow roll, and that the new choice depends on the modified MS mass, and hence displays a dependence on the inflaton potential.

In the following sections, we will consider each of these types of corrections separately.

7. Corrections to the geometric operators in the MS mass

Let us consider the expression of the modified MS mass in Eq. (4). The corrections that the presence of a potential introduce in the geometric operators that appear in this expression are easy to calculate, taking into account that they are at most quadratic in this potential (and its derivatives), except for the dependence that may exist via the operator $\hat{H}_0$. In more detail, the operator $\hat{\vartheta}_e$ that gives the denominator is independent of the potential. Meanwhile, at leading order in this potential the operator $\hat{\vartheta}_e^q$ in the numerator contains a free and a linear contribution. Finally, the remaining operator $\hat{\vartheta}_o$, which is multiplied by $\hat{H}_0$ in the numerator, is linear. As a result, at the leading order in the potential that we are considering, we can approximate $\hat{H}_0$ by its free counterpart $\hat{H}_0^{(F)}$ in the numerator. With this replacement and the linear truncation of $\hat{\vartheta}_e^q$ in the potential, the expression of the modified mass is valid (as far as the geometric operators are concerned) at the studied order.

For later discussion, it is helpful to derive the expression of the background Hamiltonian, expanded in the potential. Clearly, the first term in this expansion is the free Hamiltonian $\hat{H}_0^{(F)}$. With a suitable choice of factor ordering, one can show that[30]

$$\hat{H}_0 = \hat{H}_0^{(F)} - W(\phi)(\hat{H}_0^{(F)})^{-1/2}\hat{V}^2(\hat{H}_0^{(F)})^{-1/2} + O(W^2), \tag{14}$$

where the symbol $O(W^2)$ denotes terms that are of quadratic or higher order in the potential and its derivatives.

8. Corrections to the background evolution

In order to calculate the effect of the potential in the quantum evolution of the background state, it is especially convenient to adopt an interaction picture,[44] in

which the dynamics of the free case is isolated and the contribution of the inflaton potential is viewed as an interaction. Approximating, to leading order in the potential, the interaction part of the background Hamiltonian according to Eq. (14) and expanding to the same order the evolution operator associated with this interaction, it is straightforward to see that

$$\chi(V,\phi) = \left[1 - i\int_{\phi_0}^{\phi} d\tilde{\phi}\,\hat{K}(\phi,\tilde{\phi})W(\tilde{\phi}) + O(W^2)\right]\chi^{(F)}(V,\phi), \tag{15}$$

$$\hat{K}(\phi,\tilde{\phi}) = \exp\left[i\hat{H}_0^{(F)}(\phi-\tilde{\phi})\right](\hat{H}_0^{(F)})^{-1/2}\hat{V}^2(\hat{H}_0^{(F)})^{-1/2}\exp\left[-i\hat{H}_0^{(F)}(\phi-\tilde{\phi})\right], \tag{16}$$

where $\chi^{(F)}(V,\phi)$ is the background state evolved with respect to the inflaton with the free Hamiltonian $\hat{H}_0^{(F)}$, namely

$$\chi^{(F)}(V,\phi) = \exp\left[i\hat{H}_0^{(F)}(\phi-\phi_0)\right]\chi_0(V). \tag{17}$$

To express this evolution in terms of the conformal time, we also need to calculate its relation with the inflaton up to the leading-order correction of the potential. Recall that this relation is given by $\langle\hat{H}_0\rangle_\chi d\eta = \langle\hat{\vartheta}_e\rangle_\chi d\phi$. Substituting the approximate expressions of $\hat{H}_0$ and χ that we have obtained, this equation for the conformal time leads first to the free relation

$$\eta^{(F)}(\phi) = \frac{3}{2G}\int_{\phi_0}^{\phi} d\tilde{\phi}\,\frac{\langle\hat{V}^{2/3}\rangle_{\chi^{(F)}}}{\langle\hat{H}_0^{(F)}\rangle_{\chi^{(F)}}}, \tag{18}$$

with inverse that we call $\phi^{(F)}(\eta)$, and next to a leading-order correction to this free term that we denote by $\eta^{(W)}(\phi)$. The expression of this correction is long but manageable. We do not reproduce it here because its explicit form is not relevant for our discussion.

In practice, we are interested in writing the inflaton as a function of the conformal time, rather than the opposite, because we want to obtain the evolution of the background state in terms of this time within our approximations. With this purpose, we can expand the functional time dependence of the inflaton as the free contribution plus corrections of the potential, in the form $\phi(\eta) = \phi^{(F)}(\eta)+\phi^{(W)}(\eta)+O(W^2)$. From our discussion above, it is then possible to show[30] that the leading-order correction to the inflaton dependence is just the negative of $\eta^{(W)}(\phi)$ mapped under the free relation $\phi^{(F)}$:

$$\phi^{(W)}(\eta) = -\phi^{(F)}\left(\eta^{(W)}\big(\phi^{(F)}(\eta)\big)\right). \tag{19}$$

9. Total correction to the MS mass

We can now combine the corrections to the geometric operators and the background state that are necessary to compute the modified MS mass. First, we note that at our leading order we can substitute the free relation between the inflaton and the conformal time in all geometric operators, since the the expression of the latter

was already linear in the potential as far as the numerator of the MS mass is concerned, whereas the operator in the denominator was free of any explicit inflaton dependence.

On the other hand, let us define the freely evolved background state in conformal time, instead of its counterpart in terms of the inflaton:

$$\tilde{\chi}^{(F)}(V,\eta) = \exp\left[i\hat{H}_0^{(F)}\left(\phi^{(F)}(\eta)-\phi_0\right)\right]\chi_0(V). \tag{20}$$

It is then straightforward to see that

$$\chi(V,\phi(\eta)) = \left[1+i\hat{J}^{(W)}(\eta)+O(W^2)\right]\,\tilde{\chi}^{(F)}(V,\eta), \tag{21}$$

$$\hat{J}^{(W)}(\eta) = \hat{H}_0^{(F)}\phi^{(W)}(\eta) - \int_{\phi_0}^{\phi^{(F)}(\eta)} d\tilde{\phi}\,\hat{K}\left(\phi^{(F)}(\eta),\tilde{\phi}\right)W(\tilde{\phi}). \tag{22}$$

With all these ingredients, we get an expansion for the modified MS mass of the form $s(\eta) = s^{(F)}(\eta) + s^{(W)}(\eta) + O(W^2)$. More especifically, the result is

$$s^{(F)} = \frac{G}{3\pi\langle\hat{V}^{2/3}\rangle_{\tilde{\chi}^{(F)}}}\langle\left[\hat{\frac{1}{V}}\right]^{1/3}(\hat{H}_0^{(F)})^2\left[\hat{\frac{1}{V}}\right]^{1/3}\rangle_{\tilde{\chi}^{(F)}} \tag{23}$$

for the free contribution to the mass, and

$$\begin{aligned} s^{(W)} = \frac{1}{\langle\hat{V}^{2/3}\rangle_{\tilde{\chi}^{(F)}}}\Bigg(&\frac{2\sqrt{3G}}{\pi\sqrt{\pi}}W'\langle(\hat{V}^{2/3}(\hat{H}_0^{(F)})^{-1}\hat{\Lambda}_0^{(F)}(\hat{H}_0^{(F)})^{-1}\hat{V}^{2/3}\hat{H}_0^{(F)})_{sym}\rangle_{\tilde{\chi}^{(F)}} \\ &+\Big(\frac{1}{4\pi^2}W''-\frac{4G}{3\pi}W\Big)\langle\hat{V}^{4/3}\rangle_{\tilde{\chi}^{(F)}}+\frac{34G}{3\pi}W\left\langle\left[\hat{\frac{1}{V}}\right]^{1/3}\hat{V}^2\left[\hat{\frac{1}{V}}\right]^{1/3}\right\rangle_{\tilde{\chi}^{(F)}} \\ &+\frac{iG}{3\pi}\left\langle\left[\left[\hat{\frac{1}{V}}\right]^{1/3}(\hat{H}_0^{(F)})^2\left[\hat{\frac{1}{V}}\right]^{1/3},\hat{J}^{(W)}\right]\right\rangle_{\tilde{\chi}^{(F)}} - is^{(F)}\langle[\hat{V}^{2/3},\hat{J}^{(W)}]\rangle_{\tilde{\chi}^{(F)}}\Bigg). \end{aligned} \tag{24}$$

In these equations, we have not displayed explicitly the functional dependence on the conformal time to simplify the expressions.

We can particularize these formulas to hybrid LQC by substituting the definitions of the involved geometric operators, that can be found in Refs.[23,30]. Similarly, the particularization to quantum geometrodynamics is quite straightforward, using the operator representation and integration measure over the volume (or the scale factor) that corresponds to this quantization. Several simplifications occur in this case, because the inverse volume operator is in fact the inverse of the operator that represents the volume, and no distinction has to be made between $|\hat{\Lambda}_0^{(F)}|$ and $\hat{H}_0^{(F)}$.

Finally, let us comment that our formulas provide as well the right result for kinetically dominated regimes in GR if the passage to the classical description is carried out correctly. For this, commutators of operators have to be translated into Poisson brackets of phase space functions using Dirac's rule, any other operator has

to be translated also into its phase space function counterpart, and the expectation values have to be regarded just as the evaluation on the background classical solution. With this correspondence, one recovers the classical relativistic equations.[30]

10. Corrections to the vacuum

As we have already seen, changes in the MS mass affect the complex frequency h_k that determines the positive frequency solution μ_k corresponding to the vacuum state in the asymptotic diagonalization prescription. We recall that this complex frequency satisfies the Ricatti equation $\dot{h}_k = k^2 + s + h_k^2$ in conformal time, with a fixed, specific asymptotic behavior for unboundedly large wavenorms. Similarly to what we have done with other functions in order to calculate their free part and the leading-order correction of the potential, we expand the complex frequency in the form $h_k = h_k^{(F)} + h_k^{(W)} + O(W^2)$. Then, linearizing the Ricatti equation, we obtain a first-order ordinary differential equation for $h_k^{(W)}$ that admits the general solution

$$h_k^{(W)}(\eta) = \left(C_k^{(W)} + \int_{\eta_0}^{\eta} d\tilde{\eta}\; s^{(W)}(\tilde{\eta}) e^{-I_{h_k}^{(F)}(\tilde{\eta})} \right) e^{I_{h_k}^{(F)}(\eta)}, \tag{25}$$

where

$$I_{h_k}^{(F)}(\eta) = 2 \int_{\eta_0}^{\eta} d\tilde{\eta}\, h_k^{(F)}(\tilde{\eta}) \tag{26}$$

and $C_k^{(W)}$ is any (possibly potential-dependent) constant for each given wavenorm k.

Integrating by parts the above expression and calling $d\tau_k = 2h_k^{(F)}(\eta)d\eta$, we obtain the following alternative form of this general solution:

$$h_k^{(W)}(\eta) = -\sum_{n=0}^{\infty} \frac{d^n}{d\tau_k^n} \left(\frac{s^{(W)}(\eta)}{2h_k^{(F)}(\eta)} \right) + D_k^{(W)} e^{I_{h_k}^{(F)}(\eta)}, \tag{27}$$

where $D_k^{(W)}$ is a constant for each k.

We still have to take into account the asymptotic behavior of the function h_k. With this aim, we expand its asymptotic coefficients γ_n around those of the free case in the form $\gamma_n = \gamma_n^{(F)} + \gamma_n^{(W)} + O(W^2)$. From the asymptotics of the total complex frequency h_k and of its counterpart for the free case with vanishing potential, $h_k^{(F)}$, we then obtain that the leading-order correction must have the asymptotic behavior

$$h_k^{(W)} = \sum_{n=0}^{\infty} \frac{\gamma_n^{(W)}}{(2ik)^{n+1}} \left[1 + 2 \sum_{n=0}^{\infty} \frac{\gamma_n^{(F)}}{(2ik)^{n+2}} \right]^{-2}, \tag{28}$$

with $\gamma_0^{(W)} = s^{(W)}$, given by the correction to the MS mass that we have computed in previous sections. The other coefficients $\gamma_n^{(W)}$ for $n \geq 1$ verify a recursion relation that can be derived from the linearization of the known relation for the coefficients γ_n, truncating it at leading order in the potential. For our discussion, the important

point about the asymptotic behavior (28) is that it does not contain any oscillating exponential (in fact, the expression can be reformulated as an asymptotic series in inverse powers of k). This result implies that the constant $D_k^{(W)}$ in Eq. (27) must vanish for the solution selected by our asymptotic condition. Hence, we conclude that (asymptotically at least)

$$h_k^{(W)}(\eta) = -\sum_{n=0}^{\infty} \frac{d^n}{d\tau_k^n} \left(\frac{s^{(W)}(\eta)}{2h_k^{(F)}(\eta)} \right). \tag{29}$$

In this way, we have succeeded in obtaining the expression of the leading-order correction to the complex frequency function, and therefore in getting the ingredients necessary to characterize the vacuum state selected by the asymptotic diagonalization prescription at our order of truncation in the potential and its derivatives.

11. Conclusions

In this work, we have considered kinetically dominated regimes in the very early evolution of the Universe. These regimes are attracting an increasing attention, both within GR and within quantum cosmology, as a mechanism to produce modifications in the CMB power spectra and other related cosmological quantities that can alleviate the possible anomalies that have been claimed in the observations, especially when this period of kinetic dominance in the energy density of the scalar field is accompanied with a later epoch of short lived inflation. In general, intrincate numerical computations are needed to study these kinetically dominated regimes previous to the slow-roll phase.

The situation is particularly complicated in quantum cosmology, where the background is described quantum mechanically. In many practical situations, this is one of the reasons why most of the analyses carried out so far in LQC have concentrated on the consideration of quantum background states that are peaked on *effective* trajectories,[9] described in the purely homogeneous and isotropic case by a corrected Hamiltonian constraint (with respect to that of GR) that incorporates effects of the quantum geometry. One of the effects that these trajectories incorporate is the existence of the renowned quantum bounce that avoids the cosmological singularity.[9, 34, 42] For this kind of states, expectation values are replaced with evaluation on the peak trajectories. However, it is not totally clear if this procedure is valid for any kind of geometric operator, like those that appear in the modified MS mass, which are highly nonlinear in the basic variables in which the peak trajectories have been confirmed. Besides, one cannot analyze in this way background states with a more genuine quantum behavior. Both issues are relevant because the modifications in the MS mass produced by the loop quantization are only significant in the regions with important quantum geometry corrections, that would correspond to the bounce in the case of the commented effective description. So, the interest in performing a fully quantum analysis in those regions is clear. In the situations that are phenomenologically appealing, the evolution is indeed kinetically dominated in those

regions. A formalism like the one that we have presented, which allows a quantum investigation employing approximations that are based on the kinetic dominance, may therefore be of great help. Notice also that, even if one accepts a simplification of the problem by using some kind of effective description for the background, the discussion would need to be carried out separately for each inflaton potential, with a complicated dynamics that would almost certainly require numerical calculations at some step of the analysis, and that would have to be repeated for any different potential that one considers.

Instead of facing any of the aforementioned, involved and time-consuming, numerical calculations, we have developed a formalism that allows us to study the problem starting from the dynamics of a free scalar field including the effects of a potential as corrections, with an applicability restricted to regimes with kinetic dominance and hence away of the period of slow-roll inflation. More especifically, we have analytically studied the leading-order corrections caused by the inflaton potential, focusing our attention on the case of a hybrid quantization in cosmology, which combines a quantization of the FLRW background with a Fock quantization of the perturbations. These corrections of the potential modify the geometric quantities (operators in general) that provide the modified MS mass in the dynamical equations for the perturbations. They also affect the evolution of the background state, both because they modify the generator of its evolution with respect to the inflaton (that can be used in kinetic dominance as an internal reference variable for the dynamics) and because the relation between the inflaton and the conformal time is changed. More subtle is the effect on the vacuum of the perturbations. Away from slow roll, the choice of a Bunch-Davies state does not seem justified anymore. We have adopted a prescription for the choice of a vacuum that rests on an asymptotic diagonalization of the Hamiltonian of the perturbations, and which has been seen to lead to an asymptotically non-oscillating primordial power spectrum. The vacuum selected with this prescription is characterized by a set of positive frequency solutions, determined by a complex function, which we have called the complex frequency. This function satisfies a Ricatti equation and has to fulfill certain asymptotic conditions. Since this Ricatti equation and also the asymptotics depend on the modifed MS mass, the presence of a potential produces corrections in them, and therefore on the complex frequency, altering the choice of vaccum state.

We have succeeded in calculating all of these leading-order corrections, providing in this way all the ingredients needed to study at that order the evolution of the primordial perturbations and the state that fixes their initial conditions. It is worth remarking that our results can be generalized to other prescriptions in quantum cosmology other than a hybrid quantization. For instance, we have commented that the dressed-metric approach to LQC can be studied in a similar way, with the only difference that the expression of the modified MS mass is not the one that we have considered in detail here.[26] Besides, we have also seen that the results are applicable to the case of GR, with certain rules for the translation of our formulas into the

classical case. On the other hand, our results have been derived at leading order in the corrections produced by the potential, but in principle there is no obstruction to extend the analysis to higher orders. The expressions will become much more intrincate, but there is no conceptual obstacle to obtain those corrections, increasing order by order the accuracy of the formalism.

Our treatment opens the possibility of comparing the effects of different potentials without the need of performing explicit calculations for each of them spearately. This is so because the potential appears in our formulas for the corrections in an abstract way, without any requirement about it apart from the validity of the kinetic dominance. It would be very interesting to use this approach and study the different effects that distinct potentials can produce in the primordial power spectra of the perturbations, left as imprints of a kinetically dominated epoch previous to slow roll. Finally, our results make possible the investigation of another very interesting issue, which is extremely relevant to ellucidate whether quantum effects can be detected or not in cosmological observations. This issue is the question of whether the effects of a classical fast-roll period (i.e. an inflationary period that does not satisfy the slow-roll conditions) can be differentiated from the effects of a quantization of the geometry. This question is crucial to answer whether the last of these types of effects has any hope to be observed. Since our formalism is applicable to kinetically dominated regimes both in GR and in the relevant quantum regions of LQC (and other quantum cosmology proposals), it can be used to analyze the effects of these distinct dynamics of the perturbations, studying the differences in the imprints that each of them may eventually leave on the spectra of the primordial perturbations.

We reexamine the computation of the equations of motion of the Ashtekar–Olmedo–Singh black hole model in order to establish whether it is possible to construct a Hamiltonian formalism such that parameters that regulate the introduction of quantum geometry effects are suitably treated as true constants of motion. After suggesting that these parameters should capture contributions from two sectors of phase space that had been considered independent in the literature, we proceed to obtain the corresponding dynamical equations and investigate the repercussions of this more general choice. We restrict our discussion exclusively to these dynamical issues. We also analyze whether the proposed procedure can be reconciled with the results of Ashtekar, Olmedo, and Singh, at least in some limit.

Keywords: Loop Quantum Cosmology, Black Holes, AOS Model.

1. Introduction

Almost three years ago, Ashtekar, Olmedo, and Singh proposed a new model to describe black hole spacetimes within the framework of loop quantum cosmology[1–3] (from now on, referred to as the AOS model for short). This model is set apart from prior related investigations[4–39] for a number of reasons, including the fact that it is claimed that its physical predictions neither depend on fiducial structures nor display large quantum corrections in low curvature regions (which count among the problems that previous studies suffered from). By means of the inclusion of quantum geometry effects, which is regulated by two polymerization parameters,[a] the classical central singularity is found to be cured. In this model, it is replaced by a transition surface between a trapped region and an anti-trapped one and the metric, that we will call effective in the sense that it can be treated classically but incorporates quantum effects, is extended to encompass what can be regarded as a white horizon. This effective geometry is shown to be smooth and, in fact, the curvature invariants turn out to admit universal upper bounds that are independent of the mass of the black hole under consideration.[1–3] The authors of the model completed their

[a]Here, the term "polymerization" refers to the name "polymer quantization", which is often used for the quantization of symmetry reduced models with loop techniques.

investigation by formulating an analogous description of the exterior region that can be matched smoothly with that of the black hole interior, resulting in an effective extension of the whole Kruskal spacetime.

One of the defining features of the AOS model is their choice of polymerization parameters. In order to overcome the issues present in earlier works, they proposed a procedure in which the parameters are identified with certain Dirac observables (i.e., quantities that are constant along any given dynamical trajectory but not on the whole phase space), defined by minimal area conditions on the transition surface. Nonetheless, the parameters are treated as constants throughout the Hamiltonian derivation of the equations of motion and only once they have been obtained and solved does the aforementioned identification occur, whereby the parameters are fixed to the value of certain functions of the ADM mass, which is a Dirac observable itself.[b] This was already pointed out by Bodendorfer, Mele, and Münch. In Ref. 40, they showed that an extra phase space dependent factor would appear in the dynamical equations should the parameters be treated as genuine constants of motion from the very beginning. For this, they employed that, given a certain choice of lapse function, the Hamiltonian constraint of the system is essentially given by the difference of two Dirac observables, the on-shell values of which coincide and become proportional to the mass of the black hole. This simple structure was exploited to divide the phase space into two independent sectors (associated with the radial and angular degrees of freedom, respectively), where the dynamics is generated by the previously mentioned Dirac observables, which can be thought of as partial Hamiltonians. Additionally, these partial Hamiltonians were assumed to serve as polymerization parameters,[40] in the sense that each parameter was chosen to be a function of only its associated partial Hamiltonian. As a result, by evaluating the study on shell, one makes contact with the original proposal of Refs. 1–3 to the extent that the on-shell parameters are functions of the mass of the black hole.

Nevertheless, given the fact that the two partial Hamiltonians have coincident values on the constraint surface, there should be no way of telling apart their on-shell contributions. Consequently, one could argue that a more general choice of polymerization parameters would be such that each of them could depend on both partial Hamiltonians, a fact that would imply that the decoupling of phase space sectors that plays a central role in previous analyses would be broken both at the Hamiltonian and dynamical levels. In the following, we will focus on analyzing whether an alternative procedure to perform the Hamiltonian calculation can be constructed starting from this observation. We will ignore for the time being issues concerning the asymptotic behavior of the effective metric and its physical interpretation and quantum covariance, which lie beyond the scope of this work (see Refs. 41, 42, 43, and 44 for details on the criticisms that the model has received). The main objective

[b]The authors of Refs. 1 and 2 presented an argument supporting this procedure that involves an extension of phase space. See Appendix A of Ref. 2 for further details.

of our investigation is to explore the possibility that an alternative dynamical analysis where the polymerization parameters depend on both partial Hamiltonians can be developed and to ascertain whether such an analysis can reconcile the derivation of the solution in Refs. 1–3 with a genuine treatment of the parameters as dynamical constants.

The rest of this article[c] is organized as follows. In Sec. 2, after a brief introduction of the main elements of the AOS model, we discuss the selection of polymerization parameters, including our new proposal. In addition, we address the derivation of the dynamical equations that follow from our choice in Sec. 2.2. In Sec. 3, we delve into certain time redefinitions that lead our equations of motion to adopt a simpler form, paying the price of employing two different time variables instead of one. We also examine whether the existing freedom in the model may allow us to set both times equal. In Sec. 4, we extend this investigation to the asymptotic limit of large masses and study the relation between both time variables for finite values of the mass. Finally, in Sec. 5, we summarize the main ideas of this work and discuss our results. Throughout this paper, we set the speed of light and the reduced Planck constant equal to one.

2. The model

In this section, we briefly introduce the main ingredients of the effective model under consideration,[1–3] followed by a comment on the choice of polymerization parameters in Sec. 2.1 and the derivation of the equations that govern the dynamics of the system in Sec. 2.2. For further details, we refer the reader to the original works.

In this paper, we focus our attention on the interior region of a Schwarzschild black hole, which can be foliated by spatial Cauchy hypersurfaces (namely those characterized by $r = \text{const}$, where r is the Schwarzschild radial coordinate). Furthermore, these spatial hypersurfaces are homogeneous, a property that permits a finite dimensional Hamiltonian description of the system. Indeed, the associated phase space is four dimensional and can be coordinatized by two connection variables b and c which encode the degrees of freedom of the Ashtekar connection, and two triad variables p_b and p_c which encode the degrees of freedom of the densitized triad. These form two canonical pairs with Poisson brackets[1,2]

$$\{b, p_b\} = G\gamma, \qquad \{c, p_c\} = 2G\gamma, \tag{1}$$

where G is the Newtonian gravitational constant and γ is the Immirzi parameter. Given that the first one contains the dynamical information about the radial direction and the second one the dynamical information about the angular directions, we will refer to these pairs and the sectors of phase space that they define as "radial" and "angular", respectively.

[c]The present manuscript is based on a previous publication of ours,[45] although we here provide a restructured and updated view on the subject.

By virtue of the symmetries inherited from general relativity, these variables are bound by a constraint, namely the Hamiltonian of the system, H. With the choice

$$N = \frac{\gamma\delta_b\sqrt{|p_c|}}{\sin\delta_b b}, \tag{2}$$

the product of the lapse function and the Hamiltonian is given by[1,2]

$$NH = \frac{L_o}{G}(O_b - O_c), \tag{3}$$

$$O_b = -\frac{1}{2\gamma}\left(\frac{\sin\delta_b b}{\delta_b} + \frac{\gamma^2\delta_b}{\sin\delta_b b}\right)\frac{p_b}{L_o}, \tag{4}$$

$$O_c = \frac{1}{\gamma}\frac{\sin\delta_c c}{\delta_c}\frac{p_c}{L_o}, \tag{5}$$

where L_o is a fiducial length introduced to avoid divergences when integrating homogeneous quantities over space. In addition, δ_b and δ_c are the polymerization parameters that capture and introduce the effects of quantum geometry in the system. Should we take the limit where these parameters vanish, the classical Hamiltonian would be recovered. Notice that, if no cross-dependence is introduced through the δ-parameters, O_b and O_c only depend on the radial and angular sector, respectively. Therefore, up to multiplicative constants, these two objects would generate the dynamics in their respective sectors of phase space. As such, we refer to them as "partial Hamiltonians", although we emphasize that this interpretation is only valid when the polymerization parameters depend at most on the canonical variables of their respective sectors. In the following subsection, we discuss how to select these parameters.

2.1. *Polymerization parameters as constants of motion*

Let us briefly go over the main idea underlying the discussed identification and handling of the polymerization parameters suggested by the authors of the original model, mentioning an alternative related proposal that was put forward in a later work as well. Afterwards, we argue that, on the light of the dynamical properties of the system, a more general choice could be made, which we adopt for the subsequent analysis.

As already mentioned in the Introduction, one of the main features of the AOS model that set it apart from previous investigations is the way in which one deals with the polymerization parameters. Instead of taking the δ-parameters as constants on the whole phase space or as arbitrary functions of phase space, the authors of Refs. 1 and 2 proposed to tread an intermediate path: the model is based on selecting these parameters in such a way that they are eventually identified as Dirac observables, i.e. constant along any given dynamical trajectory. More concretely, they proposed a procedure where δ_b and δ_c are treated as constants throughout the Hamiltonian derivation of the dynamical equations and fixed to the value of certain Dirac observables only at the very end. These Dirac observables are given

by functions of the mass of the black hole determined by minimal area conditions at the transition surface in the limit of large masses. For an argument supporting the validity of this procedure, we encourage the reader to consult Ref. 2 (and in particular its appendices).

In a later work,[40] this approach was criticized arguing that the attained dynamical equations are not the ones derived from their proposed Hamiltonian if the parameters were to be treated as constants of motion. Instead, an alternative proposal was put forward to use the partial Hamiltonians themselves as polymerization parameters in their respective sectors of phase space. In other words, the authors of Ref. 40 suggested to take each parameter as a function of its associated partial Hamiltonian. This idea is based on the fact that both partial Hamiltonians are Dirac observables in the AOS model. Furthermore, their values coincide on shell (that is, on the phase space surface on which the Hamiltonian constraint vanishes) and are proportional to the mass of the black hole

$$O_b|_{\mathrm{on-shell}} = O_c|_{\mathrm{on-shell}} = m. \tag{6}$$

With this choice, the nontrivial nature of the parameters as functions of phase space is taken into account in the Hamiltonian calculation from the very beginning, leading to contributions coming from the nonvanishing Poisson brackets of δ_b and δ_c which were absent in the original AOS dynamical equations.

Given the attention that the AOS model has drawn in the recent years and the interesting physical results derived from it, it seems to us that it is worth investigating whether these two approaches can be reconciled in some way (and if so, to which extent) in order to gain confidence on the meaningfulness of the physical picture that ensues from it. This is precisely the aim of our work and the intention behind the preliminary computation presented in the next sections. In order to address this question, we follow the ideas of Ref. 40, or rather an extension of them.

Our proposal is based on a simple observation. As we commented in the previous paragraphs, by virtue of the structure of the Hamiltonian constraint, both partial Hamiltonians have the exact same on-shell value. Therefore, we should in principle not be able to tell apart their contributions to the on-shell polymerization parameters. As such, we argue that the most general choice of this form should be

$$\delta_i = f_i(O_b, O_c), \tag{7}$$

where $i = b, c$ and f_i are functions of both O_b and O_c.[d] Moreover, we require that the on-shell value of our parameters coincide with those considered in Refs. 1–3,

[d]From now on, we will use this notation to refer to the radial and angular sectors indistinctly. Thus, letters from the middle of the Latin alphabet $(i, j, ...)$ take values on the set $\{b, c\}$; so that i, p_i, O_i, and δ_i denote the connection variable, the triad variable, the partial Hamiltonian, and the polymerization parameter associated with the radial or angular sector, depending on the value of the label i.

namely

$$\delta_b = \left(\frac{\sqrt{\Delta}}{\sqrt{2\pi}\gamma^2 m}\right)^{1/3} + o\left(m^{-1/3}\right), \quad \delta_c = \frac{1}{2L_o}\left(\frac{\gamma\Delta^2}{4\pi^2 m}\right)^{1/3} + o\left(m^{-1/3}\right), \tag{8}$$

where $o(\cdot)$ denotes the presence of terms that are subdominant with respect to the quantity in parenthesis. The inclusion of these subdominant terms has to do with the fact that the δ-parameters of the AOS model are derived in the limit of large black hole masses, where two relevant solutions to the minimal area conditions that define them in the first place coincide (see Appendix B of Ref. 2 for further details).

Notice that the proposed functional form of these parameters introduces a cross-dependence between the radial and angular sectors of phase space, which breaks the decoupling of these sectors that had been present in the literature until now. In the next subsection, we explore the immediate consequences of this decoupling as regards the derivation of the equations that govern the dynamics of the system.

2.2. *Dynamical equations*

Let us address the derivation of the equations of motion that follow from the effective Hamiltonian of the AOS model if the polymerization parameters δ_i are selected as discussed in Sec. 2.1. Since the time derivative of any phase space function can be obtained by means of its Poisson bracket with the Hamiltonian, it is immediate to see that

$$\partial_t i = s_i \frac{L_o}{G}\left(\{i, O_i\} - \{i, O_j\}\right), \tag{9}$$

where we recall that $i, j = b, c$. Besides, here $j \neq i$, t is the time variable associated with the lapse function N [see Eq. (2)], and s_i is a sign defined by

$$s_b = +1, \qquad s_c = -1. \tag{10}$$

Let us now compute $\{i, O_i\}$ and $\{i, O_j\}$. The first of these brackets is given by

$$\{i, O_j\} = \{i, p_i\}\frac{\partial O_i}{\partial p_i} + \frac{\partial O_i}{\partial \delta_i}\left(\frac{\partial f_i}{\partial O_i}\{i, O_i\} + \frac{\partial f_i}{\partial O_j}\{i, O_j\}\right). \tag{11}$$

In a similar way,

$$\{i, O_j\} = \frac{\partial O_j}{\partial \delta_j}\left(\frac{\partial f_j}{\partial O_i}\{i, O_i\} + \frac{\partial f_j}{\partial O_j}\{i, O_j\}\right). \tag{12}$$

From the form of these two expressions, we realize that Eqs. (11) and (12) constitute a system of equations linear in $\{i, O_i\}$ and $\{i, O_j\}$. Recasting this system in an appropriate manner, we have

$$\begin{pmatrix} 1-\Delta_{ii} & -\Delta_{ij} \\ -\Delta_{ji} & 1-\Delta_{jj} \end{pmatrix}\begin{pmatrix} \{i, O_i\} \\ \{i, O_j\} \end{pmatrix} = \begin{pmatrix} \{i, p_i\}\dfrac{\partial O_i}{\partial p_i} \\ 0 \end{pmatrix}, \tag{13}$$

where we have defined

$$\Delta_{ij} = \frac{\partial O_i}{\partial \delta_i} \frac{\partial f_i}{\partial O_j}. \tag{14}$$

This system can be solved provided that the determinant of the first matrix does not vanish,

$$(1 - \Delta_{ii})(1 - \Delta_{jj}) - \Delta_{ij}\Delta_{ji} \neq 0. \tag{15}$$

From now on, we assume that this invertibility condition holds. Then, we find that the Poisson brackets that enter the equations of motion are given by

$$\begin{pmatrix} \{i, O_i\} \\ \{i, O_j\} \end{pmatrix} = \frac{\{i, p_i\} \dfrac{\partial O_i}{\partial p_i}}{(1 - \Delta_{ii})(1 - \Delta_{jj}) - \Delta_{ij}\Delta_{ji}} \begin{pmatrix} 1 - \Delta_{jj} \\ \Delta_{ji} \end{pmatrix}, \tag{16}$$

which results in

$$\partial_t i = \frac{1 - \Delta_{jj} - \Delta_{ji}}{(1 - \Delta_{ii})(1 - \Delta_{jj}) - \Delta_{ij}\Delta_{ji}} \left[s_i \frac{L_o}{G} \{i, p_i\} \frac{\partial O_i}{\partial p_i} \right], \tag{17}$$

with $j \neq i$. Following the same procedure with the triad variables, their corresponding dynamical equations turn out to be

$$\partial_t p_i = \frac{1 - \Delta_{jj} - \Delta_{ji}}{(1 - \Delta_{ii})(1 - \Delta_{jj}) - \Delta_{ij}\Delta_{ji}} \left[-s_i \frac{L_o}{G} \{i, p_i\} \frac{\partial O_i}{\partial i} \right], \tag{18}$$

where, again, $j \neq i$.

It is interesting to note that, in both cases, the expressions in square brackets are the equations of motion that are attained if the parameters are treated as constant numbers (and, thus, the ones considered in Refs. 1–3). These appear rescaled via a phase space dependent factor

$$C_{ij} = \frac{1 - \Delta_{jj} - \Delta_{ji}}{(1 - \Delta_{ii})(1 - \Delta_{jj}) - \Delta_{ij}\Delta_{ji}}, \tag{19}$$

which is *a priori* different in each sector. Therefore, we conclude that these C-factors that multiply the AOS dynamical equations contain all the information about the nontrivial functional form of the polymerization parameters. Indeed, if we ignore the brackets of δ_i, Δ_{ij} would vanish identically and C_{ij} would reduce to the identity, recovering the original AOS description. Likewise, if we consider that each parameter depends only on its corresponding partial Hamiltonian (reestablishing the radial-angular decoupling), Δ_{ij} vanish if $i \neq j$ and C_{ij} reduces to $(1 - \Delta_{ii})^{-1}$, which reproduces the result obtained in Ref. 40.

In Sec. 3 we discuss how to deal with these phase space dependent factors that result from the coupling of the radial and angular sectors in order to try and find solutions to the dynamics.

3. Local time redefinitions

As we saw in the previous section, the effect of considering polymerization parameters that are functions of both partial Hamiltonians is the appearance of two phase space dependent factors in the equations of motion. Interestingly, the obtained equations turn out to be a rescaling of the ones resulting from constant δ-parameters, and these rescalings, which are different in the radial and angular sectors, are given by the aforementioned factors C_{ij}. The fact that the nontrivial nature of the polymerization parameters affects the equations of motion precisely in this way implies that it can be absorbed through suitable time redefinitions. Indeed, taking these factors to the left-hand side of their respective dynamical equations, we realise that the definitions

$$dt_i = C_{ij}dt, \qquad j \neq i, \tag{20}$$

lead to equations that are identical to those considered by the authors of Refs. 1 and 2. From now on, we often refer to t_b and t_c as the "radial time" and the "angular time", respectively, for reasons that should be obvious. In terms of these newly defined time variables, the equations of motion adopt the same form as in the AOS model, which implies that the equations associated with the radial and angular sectors can be dealt with independently. Those corresponding to the c-sector can be solved in a straightforward manner, leading to[1,2]

$$\tan\frac{\delta_c c(t_c)}{2} = \frac{\gamma L_o \delta_c}{8m} e^{-2t_c}, \tag{21}$$

$$p_c(t_c) = 4m^2\left(e^{2t_c} + \frac{\gamma^2 L_o^2 \delta_c^2}{64m^2} e^{-2t_c}\right), \tag{22}$$

where the integration constants have been fixed so that the effective metric coincides with the standard form of the interior Schwarzschild metric.

Similarly, the equation associated with b can be solved in a straightforward way. We obtain[1,2]

$$\cos\delta_b b(t_b) = b_o \tanh\left(\frac{b_o t_b}{2} + \tanh^{-1}\frac{1}{b_o}\right) = \frac{1 + b_o \tanh\dfrac{b_o t_b}{2}}{1 + b_o^{-1}\tanh\dfrac{b_o t_b}{2}}, \tag{23}$$

where $b_o = \sqrt{1+\gamma^2\delta_b^2}$ and the constant of integration has been fixed so that the horizon lies at $t_b = 0$ (which is equivalent to requiring that b vanishes there). Since the canonical variables are bound by the Hamiltonian constraint, there is no need to solve the fourth differential equation, which is more involved than the others. Indeed, it suffices to solve for p_b in $H = 0$. Since it is convenient not to mix the radial and angular times, we can employ the fact that O_b is a constant of motion. Actually, using Eqs. (21) and (22), we can determine that

$$O_c = \frac{1}{\gamma}\frac{\sin\delta_c c}{\delta_c}\frac{p_c}{L_o} = \frac{2}{\gamma L_o \delta_c}\frac{p_c \tan(\delta_c c/2)}{1+\tan^2(\delta_c c/2)} = m. \tag{24}$$

Given that both partial Hamiltonians coincide on shell (as it follows immediately from $H = 0$), we then get $O_b = m$ as well. Therefore, solving for p_b in $O_b = m$, we obtain

$$p_b(t_b) = -2\gamma L_o m \frac{\sin \delta_b b(t_b)}{\delta_b} \frac{1}{\gamma^2 + \dfrac{\sin^2 \delta_b b(t_b)}{\delta_b^2}}, \tag{25}$$

where we can see that $p_b(0) = 0$, which is consistent with the requirement that the horizon correspond to $t_b = 0$.

So far, we have shown that suitable time redefinitions lead to dynamical equations that are identical to those obtained when δ_i are treated as constants, except for the fact that they are written in terms of two time variables. Hence, the solutions to the dynamics have the same form. Again, this is the case when expressed in two *a priori* different time variables, one per sector of the phase space. Since our objective is to determine whether it is possible to recover the results of the AOS model (at least in some sense), it seems natural to wonder whether we can use the off-shell freedom of our formalism to set both times equal. In the remainder of this section, we answer this question.

To begin with, we can find the relation between the radial and angular times by solving for dt in the definitions of both t_b and t_c and integrating the result of equating both expressions:

$$\int_{t_b}^{0} dt'_b[1 - \Delta_{bb}(t'_b) - \Delta_{bc}(t'_b)] = \int_{t_c}^{0} dt'_c[1 - \Delta_{cc}(t'_c) - \Delta_{cb}(t'_c)], \tag{26}$$

where we have canceled the denominators of C_{bc} and C_{cb}, which are identical [see Eq. (19) to realize that the denominator of these factors is symmetric under the exchange of i and j]. In this equation, $\Delta_{ij}(t_i)$ is obtained by plugging the solutions discussed above into the expression of Δ_{ij}. Moreover, the limits of integration have been chosen in accordance with the fact that the time variables are negative in the interior region of the black hole, as can be understood by examining the classical limit of the solutions to the effective dynamics.[1,2] Notice as well that we have used the existing freedom to make the origins of both time variables coincide.

Once we have fixed this freedom, asking whether t_b can be set equal to t_c is equivalent to asking whether C_{bc} can be chosen equal to C_{cb}. Therefore, the condition to be studied is

$$1 - \frac{\partial O_c}{\partial \delta_c}\frac{\partial f_c}{\partial \mu} = \alpha \left(1 - \frac{\partial O_b}{\partial \delta_b}\frac{\partial f_b}{\partial \mu}\right), \tag{27}$$

where we have called $\mu = (O_b + O_c)/2$, the on-shell value of which is simply given by m, and we have implicitly employed that the dependence of f_b and f_c on O_b and O_c can be equivalently described by their dependence on the difference and the sum of these quantities (divided by 2). In the previous expression, rather than demanding that t_b and t_c coincide, we have actually allowed for the more general case that these two times be proportional to each other, with proportionality factor α, hence

reaching a strict equality in the limit $\alpha \to 1$. Evaluating this expression on shell and assuming that f_i are at least $\mathcal{C}^1$, so that the derivative and the on-shell limit commute, we obtain

$$1 - \frac{\partial f_c}{\partial m}\frac{\partial O_c}{\partial \delta_c} = \alpha\left[1 - \frac{\partial f_b}{\partial m}\frac{\partial O_b}{\partial \delta_b}\right], \tag{28}$$

where $\partial f_i/\partial m$ stands for the on-shell particularization of the partial derivative of f_i with respect to μ, and we have omitted the indication of the rest of on-shell evaluations for the sake of simplicity. In the remainder of this article, whether an expression is evaluated on shell or not will be clear from the context. At this point, the only remaining step is to compute the derivatives of the partial Hamiltonians with respect to the polymerization parameters and evaluate them on shell. A simple calculation shows that

$$\frac{\partial O_b}{\partial \delta_b} = -\frac{1}{2\gamma}\left(1 - \frac{\gamma^2\delta_b^2}{\sin^2\delta_b b}\right)\frac{\delta_b b\cos\delta_b b - \sin\delta_b b}{\delta_b^2}\frac{p_b}{L_o}, \tag{29}$$

$$\frac{\partial O_c}{\partial \delta_c} = \frac{1}{\gamma}\frac{\delta_c c\cos\delta_c c - \sin\delta_c c}{\delta_c^2}\frac{p_c}{L_o}. \tag{30}$$

The fact that these derivatives are functions on phase space appears to be in contrast with the requirement that the on-shell values of t_b and t_c be proportional (or equal), which one would ideally want to hold on the whole phase space. Therefore, we need to find a way to cancel the undesired phase space dependence. Given the fact that $\sin\delta_i i$ can be rewritten in terms of m and p_i on shell [see Eqs. (4) and (5)], every function of the connection variables i can be reexpressed in terms of the mass of the black hole and the triad variables. Hence, the above derivatives can be regarded as nontrivial functions of p_i from the point of view of their dependence on phase space. As a result, we have

$$1 - \frac{\partial f_c}{\partial m}\frac{\partial O_c}{\partial \delta_c}(p_c) = \alpha\left[1 - \frac{\partial f_b}{\partial m}\frac{\partial O_b}{\partial \delta_b}(p_b)\right], \tag{31}$$

where the form of $\partial O_i/\partial\delta_i(p_i)$ is irrelevant for the present argument, except for the fact that they are not trivial functions. Since the phase space contributions of the left-hand side cannot cancel those of the right-hand side, we conclude that the only possibility to achieve the required cancelation is by choosing $\partial f_i/\partial m$ to vanish identically. That is, we can set both time variables equal if and only if the on-shell values of the parameters are independent of the mass. However, this does not make any sense physically speaking. Indeed, we would expect the parameters to vanish in the limit of infinitely large black hole masses, so that the description of general relativity can then be recovered, but not to be constantly zero for any value of the mass.

As a result, we conclude that the answer to the question of whether we can set the radial and angular times equal on shell is in the negative as long as we want physically acceptable polymerization parameters in the sense that they have an appropriate large mass limit. Hence, we realize that the appearance of *two distinct*

time variables is a defining feature of our formalism and cannot be avoided through an astute choice of parameters.

In the next section, we examine whether the proportionality condition (28) can hold in a suitable way in the limit of large black hole masses.

4. The large mass limit

Although we have shown that the radial and angular times cannot be set equal in general, this result does not imply that they may not coincide in some regime. From the point of view of the reconciliation with the results of Refs. 1 and 2, there is a particularly interesting situation, namely that of infinitely large masses. The reason behind this interest is twofold. On the one hand, it would seem especially desirable to achieve some sort of agreement in the large mass limit since the AOS model is adapted to describe very massive black holes to begin with. Indeed, as we commented in Sec. 2.1, their proposed parameters are only valid in that limit, given that they are extracted from the leading order of an asymptotic expansion of the area conditions that define them. On the other hand, astrophysical black holes, some of which may be susceptible of being probed by observations in the near future, are tremendously massive with respect to the Planck mass, which entails the importance of having a deep understanding of the similarities and differences between models in this regime. With these ideas in mind, let us perform an asymptotic expansion of the derivatives of the partial Hamiltonians with respect to the polymerization parameters, which are the functions of phase space that appear both in condition (28) and in the relation between the radial and angular time variables (26).

According to the discussed on-shell values of the polymerization parameters, it is immediate to realize that

$$\frac{\partial f_i}{\partial m} = -\frac{1}{3}\frac{\delta_i}{m} + o\left(\frac{\delta_i}{m}\right). \tag{32}$$

This means that the dominant term goes as $m^{-4/3}$ in the asymptotic limit. Therefore, it is obvious that the proportionality condition (28) will hold for large masses provided that, in that limit,[e]

$$\frac{\partial O_i}{\partial \delta_i} \sim m^{n_i} \quad \text{with} \quad n_i \leq \frac{4}{3}. \tag{33}$$

For simplicity, let us begin by computing the dominant term associated with the angular sector. Given the effective solutions discussed in Sec. 3, we see that the dominant term of the triad variable is given by

$$p_c = 4^{2t_c} m^2 + o(m^2). \tag{34}$$

[e]If any of the two exponents n_i turned out to be equal to 4/3, then an additional condition on the coefficients of the dominant terms must be met for Eq. (28) to hold asymptotically.

An expansion of the trigonometric functions of the connection variable can be obtained in a similar manner. Since our effective solution involves the tangent of $\delta_c c/2$, it is convenient to write

$$\cos\delta_c c = \frac{1-\tan^2(\delta_c c/2)}{1+\tan^2(\delta_c c/2)} = 1 - \frac{\gamma^2 L_o^2}{32 e^{4t_c}} \frac{\delta_c^2}{m^2} + o\left(\frac{\delta_c^2}{m^2}\right). \tag{35}$$

From this expression, we can derive the asymptotic expansions of the remaining functions of the connection variable c. Nevertheless, it is important to bear in mind that, according to the conventions of Refs. 1–3, $b > 0$, $c > 0$, $p_b \leq 0$, and $p_c \geq 0$. Together with the fact that the polymerization parameters are infinitely small in this regime, this implies that every trigonometric function contained in $\partial O_c/\partial\delta_c$ is nonnegative. As a result, a simple calculation reveals that

$$\frac{\partial O_c}{\partial \delta_c} = -\frac{\gamma^2 L_o^2}{48 e^{4t_c}} \frac{\delta_c}{m} + o\left(\frac{\delta_c}{m}\right). \tag{36}$$

This result indicates that the left-hand side of Eq. (28) tends to one as the mass grows infinitely.

An analogous result can be obtained in the radial sector following the same reasoning. As a consequence of the form of the effective solution (23), we get

$$\cos\delta_b b = 1 + C_1 \delta_b^2 + o(\delta_b^2), \tag{37}$$

where

$$C_1 = \gamma^2 \frac{\tanh(t_b/2)}{1+\tanh(t_b/2)}. \tag{38}$$

After a simple computation, we obtain that the relevant function of the connection variable b behaves as follows in the large mass regime:

$$\left(1 - \frac{\gamma^2\delta_b^2}{\sin^2\delta_b b}\right) \frac{\delta_b b\cos\delta_b b - \sin\delta_b b}{\delta_b^2} = -\frac{2}{3}\left(2C_1+\gamma^2\right)\frac{C_1}{\sqrt{-2C_1}}\delta_b + o\left(\delta_b\right). \tag{39}$$

Lastly, the dominant term of the triad variable p_b can be found using Eq. (25) in conjunction with the expansion of $\sin\delta_b b$, which is easily found from that of $\cos\delta_b b$, written above. The outcome is

$$p_b = -2\gamma L_o \frac{\sqrt{-2C_1}}{\gamma^2 - 2C_1} m + o\left(m\right). \tag{40}$$

Thus, the derivative of the radial partial Hamiltonian with respect to δ_b exhibits the asymptotic behavior

$$\frac{\partial O_b}{\partial \delta_b} = -\frac{2}{3} C_1 \frac{\gamma^2 + 2C_1}{\gamma^2 - 2C_1}\delta_b m + o\left(\delta_b m\right). \tag{41}$$

This behavior indicates that $\Delta_{bb} + \Delta_{bc}$ vanishes asymptotically.

Taking into account these results, the proportionality condition reduces at leading asymptotic order to

$$\alpha = 1. \tag{42}$$

Hence, we conclude that, among all the possibilities that the two time variables become proportional in the limit of large black hole masses, the only one that is realized is that where the proportionality factor is the identity.

Using the asymptotic expansions that we have just derived, we can obtain the relation between the radial and angular times for finite masses up to the first subdominant order. Indeed, the implicit relation (26) evaluated on shell reduces to

$$t_b - t_c = \frac{\partial f_b}{\partial m}\int_0^{t_b} dt'_b \frac{\partial O_b}{\partial \delta_b}(t'_b) - \frac{\partial f_c}{\partial m}\int_0^{t_c} dt'_c \frac{\partial O_c}{\partial \delta_c}(t'_c). \tag{43}$$

Substituting the derivatives of the δ-parameters and inserting the asymptotic expansions of the derivatives of the partial Hamiltonians, we find that

$$t_b - t_c = \frac{2}{9}\delta_b^2 \int_0^{t_b} dt'_b C_1(t'_b)\frac{\gamma^2 + 2C_1(t'_b)}{\gamma^2 - 2C_1(t'_b)} + o(\delta_b^2), \tag{44}$$

where we have omitted the angular contribution because it is subdominant with respect to the radial term. Only the latter sector contributes to the difference between the two time variables at the lowest nontrivial order. A trivial integration reveals that

$$t_c = t_b - \frac{1}{9}\gamma^2(-3t_b + 3\sinh t_b + \cosh t_b - 1)\delta_b^2 + o(\delta_b^2). \tag{45}$$

This equation provides the relation between the radial and angular time variables up to first subdominant asymptotic order. The leading term reproduces the result commented before: the two time variables coincide in the limit of infinitely large masses, as made evident by the fact that their difference vanishes when $m \to \infty$. Additionally, the form of the next-to-leading order term allows us to draw yet another parallel with the results of Ref. 40: the difference $t_c - t_b$ vanishes close to the horizon, which is defined by $t_b \to 0$, at least at the considered truncation order.

To summarize, our analysis indicates that the AOS equations of motion are recovered in the limit of large masses, leading to a *partial* reconciliation with the Hamiltonian formalism presented in this work. Indeed, even though our dynamical equations reduce in the large mass limit to those that result from treating the parameters as constants and they can be written in a single time variable (the coincident limit of t_b and t_c), this time is fundamentally different from the one that appears in the AOS model as it was originally formulated. Therefore, the time component of the effective spacetime metric is altered with respect to their case. This constitutes a modification of the effective geometry that must be studied carefully, in order to fully understand the breadth of its effects. This might open the door to an alleviation of some of the criticisms that the model has received,[41–44] which lie beyond the scope of this article. We leave these issues for future studies.

5. Conclusions

In the present work, we have studied whether it is possible to formulate an effective Hamiltonian description of the interior region of a Schwarzschild black hole such

that the polymerization parameters that mediate the inclusion of quantum geometry effects are appropriately treated as Dirac observables throughout the entire Hamiltonian calculation. The idea of identifying these parameters with constants of motion is one of the defining features of the effective solution proposed by Ashtekar, Olmedo, and Singh approximately three years ago.[1,2] In these works, this identification takes place at the very end, once the whole derivation of the Hamiltonian equations has been carried out dealing with these parameters as constant numbers. Only after this derivation, the parameters are fixed equal to the value of certain functions of the mass of the black hole. This procedure was criticized by the authors of a later work,[40] who insisted that the nontrivial nature of the parameters should be taken into account from the beginning, leading to extra terms in the equations that would fail to be accounted for otherwise. They remarked that, given the structure of the Hamiltonian constraint with a certain choice of the lapse function, there are two sectors of phase space (associated with the radial and angular directions, respectively) that are dynamically decoupled provided that the polymerization parameters do not introduce any cross-dependence on these sectors. Bearing this caveat in mind, their dynamics, which is generated by their associated partial Hamiltonians, can be studied independently. Then, they proposed to take each parameter to be a function of its respective partial Hamiltonian, both of which are constants of motion with a common on-shell value, essentially given by the mass of the black hole. This definition led to more complicated equations of motion where two brand new phase space dependent factors appeared. As shown in Ref. 40, these factors can be reabsorbed through time definitions, leading to simpler equations involving two time variables, one per sector of phase space.

We have extended the analysis carried out in Ref. 40 to encompass a more general choice of parameters with the objective of determining whether the two approaches described above can be reconciled in some sense. This reconciliation would give an extra degree of confidence on the very interesting qualitative results of Refs. 1–3. Our proposal is based on the fact that both partial Hamiltonians coincide on shell, which implies that their contributions should not be able to be told apart. Therefore, we have argued in Sec. 2.1 that the most general choice of parameters should capture the contributions from both the radial and angular partial Hamiltonians, breaking the decoupling that was present in previous works in the literature. As in the case of Ref. 40, our choice leads to equations of motion that are modified with respect to those considered in Refs. 1 and 2 by means of a pair of phase space dependent factors, one associated with the radial sector and the other with the angular sector (see Sec. 2.2). These factors are substantially more complicated than those found by the authors of Ref. 40, and can remain well defined in situations where the latter present pathologies. One can see that such previous results would be recovered in the limit where the decoupling is reestablished. On the other hand, as discussed in Sec. 3, appropriate local time redefinitions make the reabsorption of these factors

possible, leading to the dynamical equations considered in Refs. 1 and 2, now written in terms of two different times. These equations can be solved analytically and the result is identical to the one obtained in Refs. 1 and 2 except for the fact that two time variables, namely the radial and angular times, now play a role instead of one. We have investigated whether the off-shell freedom of our Hamiltonian formalism can be exploited in order to set both time variables equal. Upon inspection of the mathematical condition that would guarantee this equality, we have demonstrated that this coincidence cannot be achieved with a physically reasonable choice of polymerization parameters. Therefore, we have proceeded to analyze whether this equality is possible at least in some regime. In the model under consideration, the large mass limit proves to be especially interesting. Indeed, the choice of parameters made by the authors of Refs. 1 and 2 is adapted for the description of very massive black holes in the first place. With this motivation in mind, we have analyzed in Sec. 4 the equality condition for masses much larger than the Planck mass. After performing an asymptotic expansion of the relevant functions of phase space, we have shown that this condition does hold in this regime: both time variables turn out to be equal for infinitely massive black holes. More precisely, using the exact implicit relation between both variables, we have seen that the leading contribution to the difference of both times goes as the square of the radial polymerization parameter, thus vanishing as $m^{-2/3}$ in the limit where the mass of the black hole grows infinitely. For finite masses that are sufficiently large, we find that the differences with respect to the description of Refs. 1 and 2 can be estimated by the size of this term, yielding a quantitative measure of the discrepancies between both formalisms.

Our conclusions imply that the results of Refs. 1–3 can be partially reconciled with a treatment where the polymerization parameters are regarded as proper dynamical constants for black holes with large masses, which are the focus of the analysis of those references. The wording "partially" is key here. Notably, it should not be forgotten that the spacetime geometry is modified by means of time redefinitions. Even if this apparently slight modification does not alter some of the conclusions of Refs. 1–3, it may affect e.g. the behavior of the exterior effective metric at spatial infinity, which has been claimed to be nonstandard (see Refs. 41 and 3 for further details). This issue will constitute the subject of future studies.

We review recent results that apply a reduced phase space quantization of loop quantum cosmology (LQC) for a spatially flat Friedmann-Lemaître-Robertson-Walker (FLRW) universe filled with reference fields and an inflaton field in a Starobinsky inflationary potential. All three models that we consider are two-fluid models and they differ by their choice of global clock which are chosen to be either Gaussian dust, Brown-Kuchař dust or a massless Klein-Gordon scalar field. Although two-fluid models are more complicated than models involving the inflaton only, it turns out that some of the technical hurdles in conventional quantum cosmological models can be bypassed in these models. Using the effective dynamics resulting from the reduced phase space quantization we discuss some phenomenological implications of these models including the resolution of the big bang singularity via a quantum bounce and in addition address the question whether different choices of clocks can leave an imprint on the inflationary dynamics.

Keywords: Loop quantum cosmology, reduced phase space quantization, effective techniques.

1. Introduction

Within the last decade in the framework of loop quantum gravity new models have been introduced that apply the technique of reduced phase space quantization to construct the physical Hilbert space and thus the physical sector of the theory.[1–9] This requires to construct Dirac observables at the classical level and derive their corresponding algebra. For this purpose all models have in common that they couple some kind of additional matter to gravity. In the context of the relational formalism, introduced in Refs. 10, 11 and further developed and applied in Refs. 12–17, these additional degrees of freedom are used as reference matter to construct Dirac observables and their corresponding dynamics. The latter is encoded in a so called physical Hamiltonian that becomes a non-vanishing Hamiltonian operator in the physical Hilbert space involved either in a Schrödinger-like or Heisenberg-like equations. For the reason that these reference fields are dynamically coupled to general relativity an interesting question in this context is how a given choice of reference fields influences the physical properties of the model. In full loop quantum gravity

these dynamical equations have a complicated structure and an analysis for individual models as well as a comparison between different models is a non-trivial task. Therefore, the work in Ref. 18 focus on a simplified setting in the framework of loop quantum cosmology where techniques are already available to analyze such questions. The relational formalism has been applied in the context of loop quantum cosmology for instance in Refs. 18–33. The main difference to former models in loop quantum cosmology with reference matter, often also called clocks in cosmology, is that the work in Ref. 18 considers two-fluid models because the clock is coupled in addition to an inflaton. One of the main questions that one is interested in is how the inflationary scenario is affected by the presence of the additional clock degree of freedom and how the imprint of the clock compares for different models. Such questions will be investigated using effective techniques that in LQC have in former work mainly be applied to one-fluid models.

1.1. *Dust and scalar field clock models in loop quantum cosmology*

All three models in the analysis in Ref. 18 are based on models in general relativity coupled to an inflaton field and an additional coupling of 8 and 7 respectively additional dust and scalar fields respectively yielding to a system with second class constraints. After the reduction with respect to the second class constraints one ends up with first class systems with four additional reference fields, that can be used as reference matter for the Hamiltonian and spatial diffeomorphism constraint. The details about the Brown-Kuchař dust model can be found in Ref. 34 and its quantization using LQG techniques has been performed in Ref. 1. For the classical Gaussian dust model we refer the reader to Ref. 35 and its LQG implementation has been discussed in Ref. 36. The four scalar field model in Refs. 5, 6 can be understood as a modification of the model in Ref. 37, that, as shown in Ref. 5 cannot be quantized in the framework of LQG. For flat FLRW spacetimes where the spatial diffeomorphism constraint vanishes identically, the corresponding symmetry reduced models involve one temporal reference field, the clock, only. A reduced phase space quantization for all three symmetry reduced models has been derived in Ref. 18. There it is shown that in all three models the quantum dynamics is encoded in a Schrödinger-like equation in the physical Hilbert space. The explicit form of the physical Hamiltonian differs for the dust and scalar field models where the latter involves a square root. Although the model involve an inflaton with a generic potential due to the fact that clock is coupled additionally and one does not use the inflaton as the clock, as it has for instance be done in the APS-model in Ref. 21, all models possess physical Hamiltonians that are time-independent. This is of advantage for the construction of the physical inner product of the individual models. In this review we will focus on the effective dynamics of these models that were used in Ref. 18 to investigate the above mentioned questions. The quantum dynamics is formulated in the volume representation in Ref. 18 and thus the set of elementary variables in the dynamical equations are $\mathcal{O}_b, \mathcal{O}_V, \mathcal{O}_\varphi, \mathcal{O}_{\pi_\varphi}$, where $\mathcal{O}_f$

denotes the Dirac observable of quantity f. As shown in Ref. 18 the effective physical Hamiltonians of the dust and scalar field model take the form

$$\mathbf{H}_{\text{eff}}^{\text{FLRW, dust}} = -\frac{3\mathcal{O}_V}{8\pi G\lambda^2\gamma^2}\sin^2(\lambda\mathcal{O}_b) + \frac{\mathcal{O}_{\pi_\varphi}^2}{2\mathcal{O}_V} + \mathcal{O}_V U(\mathcal{O}_\varphi) \tag{1}$$

$$\mathbf{H}_{\text{eff}}^{\text{FLRW, scalar}} = \sqrt{-2\mathcal{O}_V\left(-\frac{3\mathcal{O}_V}{8\pi G\lambda^2\gamma^2}\sin^2(\lambda\mathcal{O}_b) + \frac{\mathcal{O}_{\pi_\varphi}^2}{2\mathcal{O}_V} + \mathcal{O}_V U(\mathcal{O}_\varphi)\right)}, \tag{2}$$

where $\lambda = \sqrt{\Delta} = \sqrt{4\sqrt{3}\pi\gamma\ell_p^2}$ denotes the polymerization parameter. Taking into account that the elementary Dirac observables satisfy the following standard Poisson brackets $\{\mathcal{O}_b, \mathcal{O}_V\} = 4\pi G\gamma$ and $\{\mathcal{O}_\varphi, \mathcal{O}_{\pi_\varphi}\} = 1$ with γ denoting the Immirzi parameter and where all remaining Poisson brackets vanish, the system of equations of motion for the Dirac observables in the individual models has been been derived in Ref. 18 and they provide the basis for the results discussed in the next section. Note that although in the case of flat FLRW spacetimes the physical Hamiltonian of the Brown-Kuchař model and the Gaussian dust model agree, these model are still not identical because within the Brown-Kuchař model the dust energy density can be chosen to be either positive or negative and the effect of these two different choices has also been analyzed in Ref. 18.

2. The effect of choosing different clocks on inflation

Similar to the one-fluid models that are obtained via Dirac quantization as for instance the APS-model in Ref. 21, the effective dynamics in the scalar field and dust models can be rewritten in terms of a modified Friedmann equations of the form

$$\mathcal{O}_H^2 = \frac{\dot{\mathcal{O}}_V^2}{9\mathcal{O}_V^2} = \frac{8\pi G}{3}\mathcal{O}_\rho\left(1 - \frac{\mathcal{O}_\rho}{\rho_{\max}}\right) \tag{3}$$

with $\rho_{\max} = \frac{3}{8\pi G\gamma^2\lambda^2}$. The maximal density $\rho_{\max}$ is the same as in Refs. 21–23 but here $\mathcal{O}_\rho$ does not only depend on the inflaton but also on the clock energy density. Furthermore, the temporal coordinate with respect to which the Hubble parameter is determined is given by either the dust and scalar field clock respectively.

In order to analyze how a given choice of clock might affect inflation in Ref. 18 a Starobinsky potential

$$U = \frac{3m^2}{16\pi G}\left(1 - e^{-\sqrt{\frac{16\pi}{3}}\mathcal{O}_\varphi}\right)^2 \quad \text{with} \quad m = 2.44\times 10^{-6} \tag{4}$$

was considered. The choice of initial conditions, set at the bounce, was guided by former results in LQC models[38] and chosen to be $\mathcal{O}_{b_i} = \pi/2\lambda$ and $\mathcal{O}_{V_i} = 10^3$ in Planck units. Fixing further values for $\mathcal{O}_{\varphi_i}, \mathcal{O}_{\pi_\varphi}$ determines $\mathbf{H}_{\text{eff}}^{\text{FLRW, dust}}$ from which one can obtain $\mathcal{O}_{\rho^{\text{clock}}}$. Therefore in Ref. 18 the initial values are parametrized by $(\mathcal{O}_\varphi, \mathcal{O}_{\rho^{\text{clock}}})$. In the case of the dust models a choice of initial conditions given by $\mathcal{O}_{\varphi_i} = -1.45$, $\mathcal{O}_{\rho^{\text{clock}}} = 10^{-8}$ yields to a quantum model with a pre-inflationary

phase, often being present in LQC models after the bounce, and an inflationary phase where the number of inflationary e-foldings for the latter is 63.1. For a similar choice of initial conditions the one-fluid models without an additional clock degree of freedom yield 63.9 inflationary e-foldings, see Ref. 38. This shows that for these choice of initial conditions the dust clock plays only a subdominant role for inflation. This is exactly what one expects from a good clock because such a clock should not have a dominant imprint on the dynamics of the model. A similar analysis for the scalar field model leads to 63.8 inflationary e-foldings being closer to the value obtained in the one-fluid models and showing that the effect of the scalar field clock is weaker compared to the dust clock. However, this is also expected from the fact that the energy density of the scalar field comes with a higher inverse power of the scale factor than the dust contribution and thus decaying faster in the evolution. In a further investigation to better understand the influence of the clock energy density on inflation in Ref. 18 for the same set of initial conditions for the inflaton a varying dust energy density ranging from 10^{-8} up to 10^{-4} was considered. The results show that the number of inflationary e-foldings decrease with increasing dust energy density. The explanation given in Ref. 18 is that this results from the fact that $\mathcal{O}_{\varphi_{\mathrm{on}}}$, the value of scalar field's Dirac observable at the onset of inflation, decreases due to a larger Hubble friction when the dust energy density is increased. For an initial dust energy of $\mathcal{O}_{\rho^{\mathrm{clock}}} = 1.38 \times 10^{-4}$ in Planck units one reaches an upper bound for this set of initial conditions where inflation no longer occurs. The same analysis for the scalar field clock shows that also in this model the number of inflationary e-foldings decreases with higher clock energy density but the effect is less strong here. One sees a significant effect only if $\mathcal{O}_{\rho^{\mathrm{clock}}} \geq 0.001$ in Planck units. As far as the number of pre-inflationary e-foldings is concerned the results from Ref. 18 demonstrate that the increase of the clock energy density has the opposite effect, namely that the number of pre-inflationary e-foldings increase.

3. Conclusions

As a first step towards an investigation how choices of different reference fields affect the physical properties of models the work in Ref. 18 considers different symmetry reduced reference matter models choosing either dust or a massless scalar field as the clock in addition to gravity and the inflaton leading to two-fluid LQC models. For the choice of a Starobinsky potential the fingerprint of the clock on the inflationary dynamics was analyzed in the framework of effective techniques. The analysis shows that initial conditions can be chosen such that the clock has no significant effect on the dynamics. Both models with dust and the scalar field clock respectively show a qualitatively similar behavior and can serve as good clocks. Some difference in the two models are found such as that the model with the scalar field clock has a larger number of inflationary e-foldings compared to the dust model. Furthermore, the scalar field model serves in larger parameter space as a good clock since it is less sensitive to the initial conditions of the clock energy density. Going beyond

the first steps investigated in Ref. 18 and reviewed here requires a more detailed understanding on the physical solutions in these models at the level of the quantum theory. For this purpose the already existing numerical techniques[23,39] need to be generalized to the two-fluid case. Next to the question of singularity resolution at the level of the physical Hilbert space, such kind of generalization will be important because it will also allow to test the validity of effective techniques for two-fluid models.

We compare the behavior of the effective masses in the Mukhanov-Sasaki equations of the linear scalar perturbations in the dressed metric and hybrid approaches in the standard loop quantum cosmology (LQC) and the modified LQC models (mLQCs). The effective mass of the Mukhanov-Sasaki equations depend on both the specific model and the approach we study. Analyzing the behavior of the effective masses plays an important role in the choice of the initial states for the scalar perturbations. Based on the properties of the effective masses in the contracting phase, we provide the initial states of the linear perturbations in LQC and mLQCs for the dressed metric and the hybrid approaches.

Keywords: Mukhanov-Sasaki equations; loop quantum cosmology.

1. Introduction

In loop quantum cosmology(LQC), the big bang singularity in the standard cosmology is resolved and replaced with a quantum bounce, and correspondingly the inflationary paradigm, which resolves several big bang puzzles and provides initial seeds for the formation of the large scale structure in the universe, can be extended to the Planck regime by using the effective dynamics.[1,2] Several approaches have been developed in LQC to compute the primordial power spectral produced by the quantum fluctuations which propagate on quantum geometries. However, such effects become negligible soon after the quantum bounce. In particular, at the beginning of inflation, where the energy density has decreased about 12 orders in comparing that at the bounce, $\rho_i/\rho_c \simeq 10^{-12}$, the quantum spacetime can be well approximated by a classical one, whereby the standard relativistic cosmology follows. Two of the most studied approaches are the dressed metric approach[3–5] and the hybrid approach.[6–9] Although these two approaches are formulated in different ways, the resulting equations of motion for the scalar modes in both approaches can be cast into the form

$$\nu_k^{''} + \left(k^2 + m_{\rm eff}\right)\nu_k = 0, \tag{1}$$

here $m_{\rm eff}$ denotes the effective mass which accounts for the differences between two approaches. Similar to the situation in the classical cosmology, the initial condition problem persists in LQC in the form that up to now there is no consensus on whether

the initial states should be imposed in the Planck regime or in the contracting phase where the background dynamics becomes classical again. In this paper, we take the viewpoint to impose the initial states in the deep contracting phase. As a result, we focus on the behavior of the effective mass in the deep contracting phase. Besides, in addition to the standard LQC, we also investigate the behavior of the effective mass in two modified LQC models (mLQCs) in order to study the potential effects of the quantization ambiguities on the observables.

The said mLQCs originate from a separate treatment of the Lorentz term in the classical Hamiltonian constraint in the spatially flat FLRW universe.[10] Two of the mLQCs which attract attention recently are the so-called mLQC-I and mLQC-II. Both the background dynamics and the primordial power spectra of these two mLQCs have been extensively studied in the literature.[11–17] From these studies, we learn that the background dynamics in mLQC-II is qualitatively similar to that in LQC while the contracting phase of mLQC-I has distinctive feature which is characterized by an emergent cosmological constant and a rescaled Newton's constant. When applying the dressed metric and the hybrid approaches to the mLQCs, Planck scale magnitude of the power spectrum is observed in the infrared(IR) regime of mLQC-I with the dressed metric approach while in the hybrid approach, the magnitudes of the power spectra in mLQCs and LQC become comparable. As a result, the modified LQC models also provide good examples to compare the two approaches. In the following, we compare the effective masses in LQC, mLQC-I and mLQC-II, respectively, in the dressed metric and the hybrid approaches, and from the properties of the effective masses in the contracting phase, we seek the appropriate initial states to be imposed during this phase. For more details, we refer readers to Ref. 17.

2. The initial states in LQC/mLQCs in the dressed metric approach

In the dressed metric approach, the quantum fluctuations are described as propagating on a quantum background spacetime whose geometry can be well approximated by a manifold with a dressed metric for the sharply peaked states. Using the effective dynamics, it can be shown that the effective mass in (1) takes the same form as in the classical perturbation theory while the difference originates from two sources.[15] Firstly, the background quantities in $m_{\rm eff}$ should come from the effective dynamics governed by the effective Hamiltonian constraint in LQC. Secondly, the regularization of the conjugate momentum of the scale factor in $m_{\rm eff}$ should be also consistent with the effective Hamiltonian constraint for the background dynamics. With the above two points in mind, we impose the kinetic-energy-dominated initial conditions for the background evolution at the bounce and study the behavior of the effective mass for the chaotic and the Starobinsky potentials. In practice, one can define the comoving Hubble radius as,[17]

$$\lambda_H^2 = -\frac{1}{m_{\rm eff}}. \tag{2}$$

When the wavelength of the relevant modes is larger than λ_H^2, the mode function is oscillating. On the other hand, when the wavelength of the relevant modes are less than λ_H^2, the mode function is exponentially decaying or growing.

From our numerical results, we find the behavior of the comoving Hubble radius in mLQC-II is very similar to that in LQC. Its evolution is almost symmetric with respect to the bounce point. During the deflationary stage in the contracting phase, the comoving Hubble radius keeps increasing until it reaches positive infinity at some time $t = t_i < 0$ where a'' vanishes. After $t = t_i$, it is the intermediate regime where the comoving Hubble radius becomes negative and correspondingly all the modes are oscillating in this regime. Near the bounce, the comoving Hubble radius becomes positive and reaches its minimal right at the bounce, which corresponds to the characteristic wavelength in LQC/mLQC-II. As a result, we find the Bunch-Davies vacuum can be chosen in the intermediate regime of the contracting phase where $\lambda_H^2 < 0$ in LQC and mLQC-II. On the other hand, we find a different behavior of λ_H^2 in the contracting phase of mLQC-I. In particular, λ_H^2 is always positive in the contracting phase and it can be well approximated by $\eta^2/2$ with η denoting the conformal time in the quasi de Sitter regime of the contracting phase. As a result, we can choose the de Sitter state as the initial state in the contracting phase. The above analysis on the behavior of the comoving Hubble radius is robust with respect to the choice of the inflaton potentials and the regularization of the conjugate momentum of the scale factor in the effective mass as long as the bounce is dominated by the kinetic energy of the inflaton field.

3. The initial states in LQC/mLQCs in the hybrid approach

The application of the hybrid approach to the mLQCs is studied in detail in[16] where the equation of motion for the scalar perturbations are given explicitly. Using the effective mass given in the mode equation, we study its properties in the contracting phase when the initial conditions of the background dynamics are chosen the same as in the dressed metric approach. From our numerical results, we find the evolution of the comoving Hubble radius is generally not symmetric with respect to the bounce in any model and it also depends on the specific inflationary potential. Surprisingly, with the chaotic potential, the comoving Hubble radius behaves similarly in all three models. It increases monotonically from some negative value in the deep contracting phase and tends to positive infinity at time $t = \tilde{t}_i < 0$ where $a'' = 0$. Afterwards, it remains negative until the onset of inflation in the expanding phase. This implies the effective mass is always negative near the bounce. As a result, with the chaotic potential, one can choose the BD vacuum in the deep contracting regime or near the bounce in all three models. However, since the comoving Hubble radius becomes infinity at $t = \tilde{t}_i$, choosing BD vacuum at different times, either in the deep contracting regime or near the bounce is expected to give different power spectra in the IR regime due to particle creation effect.

On the other hand, with the Starobinsky potential, we find the comoving Hubble radius has similar behavior in LQC and mLQC-II. It remains negative throughout the contracting phase until the onset of inflation in the expanding phase. As a result, the choice of the BD vacuum can be made either in the deep contracting phase or near the bounce and the resulting power spectra are expected not to be significantly different from one to another. In contrast, in mLQC-I, although the comoving Hubble radius is still negative near the bounce, there exists a finite time interval in the contracting phase where it become positive. In the deep contracting phase, it becomes negative again. So similar to the case of the chaotic potential, imposing the BD vacuum at different times, either in the deep contracting phase or near the bounce is expected to yields different power spectra in the IR regime.

If we compare different approaches for the same model, the most striking difference lies in mLQC-I where the choice of the de Sitter state in the contracting phase in the dressed metric approach yields a Planck scale magnitude of the power spectra in the IR regime, while the choice of the BD vacuum in the deep contracting phase in the hybrid approach highly suppresses the magnitude of the resulting power spectrum in the IR regime. This serves as a concrete example where the different approaches can result in different qualitative behaviors in the power spectra.

4. Summary

We study the behavior of the effective masses in the equation of motion for the scalar mode in LQC and mLQCs in the dressed metric and the hybrid approaches. With the same kinetic-energy-dominated initial conditions for the background dynamics, we find the properties of the comoving Hubble radius in the contracting phase. In the dressed metric approach, the comoving Hubble radius has similar behavior for the chaotic and the Starobinsky potentials. One can choose the BD vacuum in the deep contracting phase of LQC and mLQC-II and the de Sitter state in the contracting phase of mLQC-I. On the other hand, the properties of the comoving Hubble radius in the hybrid approach depends on the specific inflationary potentials. One common feature of the comoving Hubble radius for all the models is that it is negative near the bounce and we find it appropriate to choose the BD vacuum in the hybrid approach for all three models in the deep contracting phase.

We are grateful to Robert Brandenberger and David Wands for valuable comments and helpful discussions. We thank Javier Olmedo and Tao Zhu for various discussions. This work is supported by NSF grant PHY-1454832.

We develop a systematic method to obtain spherically symmetric midisuperspace models with modifications inherited from loop quantum gravity. We obtain a family of effective constraints satisfying Dirac's deformation algebra and show that holonomy corrections can be consistently implemented in the presence of matter with local degrees of freedom.

Keywords: Polymerization; effective theories: loops quantum gravity.

1. Introduction

Holonomy-modified cosmological effective models capture the behavior of the dynamics predicted by loop quantum cosmology.[1,2] Such effective descriptions usually modify the Hamiltonian by hand to include the expected effects from loop quantum gravity. Holonomy corrections are directly related to the spacetime discreteness and replace the initial singularity by a quantum bounce.

We will work with spherically symmetric models of general relativity. The phase-space variables are the components of the symmetry-reduced triad and extrinsic curvature components,[3] with Poisson brackets given by

$$\{E^r(r_a), K_r(r_b)\} = \{E^\varphi(r_a), K_\varphi(r_b)\} = -\delta(r_a - r_b). \tag{1}$$

In addition, we will include the dynamics through a spherically symmetric scalar field:

$$\{\phi(r_a), P_\phi(r_b)\} = \delta(r_a - r_b). \tag{2}$$

In these effective midisuperspaces, the quantized notion of spacetime collides with the continuous diffeomorphism symmetry of general relativity. Hence, we will search for effective theories that explicitly satisfy covariance through Dirac's algebra,

$$\big\{D[N^r_1], D[N^r_2]\big\} = D\big[N^r_1 N^{r\prime}_2 - N^{r\prime}_1 N^r_2\big], \tag{3a}$$

$$\big\{D[N^r], H[N]\big\} = H\big[N^r N'\big], \tag{3b}$$

$$\big\{H[N_1], H\big[N_2\big]\big\} = D\big[\beta E^r (E^\varphi)^{-2}\,(N_1 N_2' - N_1' N_2)\big], \tag{3c}$$

where $H[N] := \int dr\, N\mathcal{H}$ and $D[N^r] := \int dr\, N^r\mathcal{D}$ are, respectively, the infinitesimal generators of normal and tangential hypersurface deformations and β stands for possible quantum modifications.

In terms of the above variables, the classical constraints read,

$$\mathcal{D} = -E^{r\prime}K_r + E^{\varphi}K'_{\varphi} + \phi' P_{\phi}\,, \tag{4}$$

$$\mathcal{H} = -\frac{E^{\varphi}}{2\sqrt{E^r}}\left(1+K_{\varphi}^2\right) - 2\sqrt{E^r}K_rK_{\varphi} + \frac{(E^{r\prime})^2}{8\sqrt{E^r}E^{\varphi}} - \frac{\sqrt{E^r}}{2E^{\varphi 2}}E^{r\prime}E^{\varphi\prime} + \frac{\sqrt{E^r}}{2E^{\varphi}}E^{r\prime\prime} + \frac{P_{\phi}^2}{2\sqrt{E^r}E^{\varphi}} + \frac{(E^r)^{3/2}}{2E^{\varphi}}(\phi')^2 + \sqrt{E^r}E^{\varphi}V(\phi)\,. \tag{5}$$

2. Deformed algebra

Previous studies acknowledge that holonomy corrections cannot be implemented in the presence of minimally coupled matter fields.[4] In fact, we extended that affirmation to the case when no coupling between the radial derivatives of the triads and curvature components are considered.[5]

For that reason, here we suggest a more ambitious approach in which we compute the algebraic relations (3) for the classical diffeomorphism constraint (4) along with a generic Hamiltonian constraint,

$$\begin{aligned}\mathcal{H} = {} & a_0 + (E^{r\prime})^2 a_{rr} + (E^{\varphi\prime})^2 a_{\varphi\varphi} + (\phi')^2 a_{\phi\phi} \\ & + E^{r\prime}E^{\varphi\prime}a_{r\varphi} + E^{r\prime}\phi' a_{r\phi} + E^{\varphi\prime}\phi' a_{\varphi\phi} + E^{r\prime\prime}a_2,\end{aligned} \tag{6}$$

that contains all quadratic combinations of the radial derivatives of E^r, E^{φ}, ϕ. The coefficients are given in terms of certain free functions $a_{ij} = a_{ij}(E^r, E^{\varphi}, \phi, K_r, K_{\varphi}, P_{\phi})$, with $i,j = r,\varphi,\phi$, that depend on all the variables and momenta of the model. Concerning second-order radial derivatives, only $E^{r\prime\prime}$ has been considered, as it also appears in the classical Hamiltonian (5). Finally, $a_0 = a_0(E^r, E^{\varphi}, \phi, K_r, K_{\varphi}, P_{\phi})$ encodes all the different terms that do not contain any radial derivative.

2.1. *The $\{D, H\}$ bracket*

First, we compute the Poisson brackets between the modified Hamiltonian constraint (6) and the classical diffeomorphism constraint (4). A number of anomalies appear, which can be easily solved. This procedure leads to the following most general form of the Hamiltonian constraint

$$\begin{aligned}\mathcal{H} = -\sqrt{E^r}\frac{g}{2}\Big(& E^{\varphi}b_0 + E^{\varphi-1}(E^{r\prime})^2 b_{rr} - E^{\varphi-1}(\phi')^2 b_{\phi\phi} + E^{\varphi-1}E^{r\prime}\phi' b_{r\phi} \\ & + E^{\varphi-2}E^{r\prime}E^{\varphi\prime} - E^{\varphi-1}E^{r\prime\prime}\Big),\end{aligned} \tag{7}$$

which provides a weakly vanishing bracket with the classical diffeomorphism constraint. In this expression, $b_0 = b_0\left(E^r, \phi, K_r/E^{\varphi}, K_{\varphi}, P_{\phi}/E^{\varphi}\right)$ and $b_{ij} = b_{ij}\left(E^r, \phi, K_r/E^{\varphi}, K_{\varphi}, P_{\phi}/E^{\varphi}\right)$, with $i,j = r,\phi$, are arbitrary functions of all possible scalar combinations of the model. In addition, a generic global factor g has been

defined. The anomaly-free bracket between this constraint and the diffeomorphism constraint reads,

$$\big\{D[N^r], H[N]\big\} = H\big[N^r N'\big] + H\big[\mathcal{G}\big], \tag{8}$$

with the smearing $\mathcal{G}$ being a function of N, N^r, g and their derivatives. Nonetheless, for the Hamiltonian to be a density of weight $+1$, it is necessary that the global factor g is a scalar function. This means that all its arguments must be scalar quantities and thus the global factor takes the form $g = g\left(E^r, \phi, K_r/E^\varphi, K_\varphi, P_\phi/E^\varphi\right)$. Under this last condition, the function $\mathcal{G}$ vanishes. Hence, for any scalar global factor g, the bracket between the modified Hamiltonian constraint (7) and the diffeomorphism constraint (4) is given by its classical form (3b).

2.2. *The $\{H, H\}$ bracket*

The requirement of anomaly freedom in the bracket between the modified Hamiltonian constraint with itself, $\{H, H\}$, immediately fixes the form of the Hamiltonian with respect to all the densities (K_r, E^φ, P_ϕ), except as arguments of the global factor g. Hence, let us define the new modified constraint:

$$\begin{aligned}\mathcal{H} = -\sqrt{E^r}\frac{g}{2}\Bigg(& E^\varphi\left(f_0 + \frac{K_r}{E^\varphi}f_1 + \frac{P_\phi}{E^\varphi}h_0 + \frac{P_\phi^2}{{E^\varphi}^2}f_3\right) \\ & + \frac{(E^{r\prime})^2}{E^\varphi}\left(f_2 + \frac{K_r}{E^\varphi}h + \frac{P_\phi}{E^\varphi}h_1 + \frac{P_\phi^2}{{E^\varphi}^2}h_2\right) \\ & + \frac{(\phi')^2}{E^\varphi}f_4 + \frac{E^{r\prime}\phi'}{E^\varphi}\left(h_3 + \frac{P_\phi}{E^\varphi}h_4\right) + \frac{E^{r\prime}E^{\varphi\prime}}{{E^\varphi}^2} - \frac{E^{r\prime\prime}}{E^\varphi}\Bigg),\end{aligned} \tag{9}$$

where $h = h(E^r, \phi, K_\varphi)$, $f_i = f_i(E^r, \phi, K_\varphi)$ and $h_i = h_i(E^r, \phi, K_\varphi)$, for $i = 0, 1, 2, 3, 4$, are free functions of the scalar variables (E^r, ϕ, K_φ). Note that the form of the classical Hamiltonian (5) is recovered for $f_0 \to (1 + K_\varphi^2)/E^r$, $f_1 \to 4K_\varphi$, $f_2 \to -1/(4E^r)$, $f_3 \to -1/E^r$, $f_4 \to -E^r$, $g \to 1$ and for a vanishing value of all the functions h_i and h. With this definition at hand, it is now possible to reduce the requirement of vanishing anomalies to the following system of differential equations:

$$\frac{\partial f_0}{\partial K_\varphi} = 2f_0 h - 2f_1 f_2 - h_0 h_3 + \frac{\partial f_1}{\partial E^r}, \tag{10a}$$

$$\frac{\partial f_1}{\partial K_\varphi} = f_1 h_4 + 4f_3 f_4, \tag{10b}$$

$$\frac{\partial f_2}{\partial K_\varphi} = -h_1 h_3 + \frac{\partial h}{\partial E^r}, \tag{10c}$$

$$\frac{\partial f_4}{\partial K_\varphi} = 2f_4(h - h_4), \tag{10d}$$

$$\frac{\partial f_3}{\partial K_\varphi} = -2f_1 h_2 + 2f_3(h - h_4), \tag{10e}$$

$$\frac{\partial f_1}{\partial \phi} = f_1 h_3 + 2h_0 f_4 \tag{10f}$$

$$\frac{\partial h_0}{\partial K_\varphi} = h_0(2h - h_4) - 2f_1 h_1 - 2f_3 h_3, \tag{10g}$$

$$\frac{\partial h_1}{\partial K_\varphi} = -h_1 h_4 - 2h_2 h_3, \tag{10h}$$

$$\frac{\partial h_2}{\partial K_\varphi} = -2h_2 h_4, \tag{10i}$$

$$\frac{\partial h_3}{\partial K_\varphi} = h_3(h - h_4) - 2h_1 f_4 + \frac{\partial h}{\partial \phi}, \tag{10j}$$

$$\frac{\partial h_4}{\partial K_\varphi} = h_4(h - h_4) - 4h_2 f_4 + \frac{\partial h}{\partial K_\varphi}. \tag{10k}$$

This is a system of eleven first-order partial differential equations for the eleven functions f_i, h_i, and h. The non-linearity of the system due to quadratic combinations of the functions makes the analytical resolution to be very complicated. But it is clear that the possible dependence of the Hamiltonian on the curvature component K_φ is severely restricted, since all the equations except one contain derivatives of the different functions with respect to K_φ.

In summary, whenever the above differential relations are satisfied, the constraint (9) will form a first-class algebra with the classical diffeomorphism constraint, and it will weakly commute with itself: $\{H[N_1], H[N_2]\} \approx 0$. Nonetheless, for H to be the generator of infinitesimal normal hypersurface deformations, one must impose an additional condition on the global factor, that is, $g = \exp(-2\int h\, dK_\varphi)$. In this way, the Poisson bracket of (9) with itself will be of the form (3c) with a deformation function,

$$\beta = \frac{g^2}{4}\left(\frac{\partial f_1}{\partial K_\varphi} + \left(\frac{E^{r\prime}}{E^\varphi}\right)^2 \frac{\partial h}{\partial K_\varphi}\right). \tag{11}$$

3. The vacuum reduction

Before trying a particular solution for the complete anomaly system (10), we proceed to solve the vacuum model. In the absence of matter, f_3, f_4, h_0, h_1, h_2, h_3 and h_4 vanish and we only need to worry about the reduced versions of (10a) and (10c) (Eq. (10b) is an additional restriction that appears only when matter is incorporated).

The general solution for the remaining functions f_0, f_1, f_2 and h can be written in terms of the global factor $g(E^r, K_\varphi)$ and two integration functions $f = f(E^r, K_\varphi)$ and $v = v(E^r)$. More precisely, the form of the modified vacuum Hamiltonian constraint reads,

$$\begin{aligned}\mathcal{H} = -\sqrt{E^r}\Bigg[E^\varphi\left(\frac{1+f^2}{v}\frac{\partial v}{\partial E^r} + \frac{\partial f^2}{\partial E^r}\right) + K_r\frac{\partial f^2}{\partial K_\varphi} - g\frac{E^{r\prime\prime}}{2E^\varphi} \\ + g\frac{E^{r\prime}E^{\varphi\prime}}{2E^{\varphi 2}} - \left(\frac{E^{r\prime}}{2E^\varphi}\right)^2\left(\frac{E^\varphi}{v}\frac{\partial(gv)}{\partial E^r} + K_r\frac{\partial g}{\partial K_\varphi}\right)\Bigg].\end{aligned} \tag{12}$$

In addition, we have been able to obtain a weak Dirac observable of the system,

$$m = \frac{v}{2}\left(1 + f^2 - g\left(\frac{E^{r\prime}}{2E^\varphi}\right)^2\right), \tag{13}$$

which commutes on-shell with the total Hamiltonian $\dot{m} = \{m, H[N] + D[N^r]\} \approx 0$, and represents the mass. In particular, the classical limit of the system is obtained for $g \to 1$, $f \to K_\varphi$ and $v \to \sqrt{E^r}$. In this limit, the above observable is just the usual expression of the Hawking (Schwarzschild) mass.

It is interesting to note that the expression of the effective mass (13) can be used to rewrite the deformation function as follows:

$$\beta = \frac{g^2}{2}\left(\frac{\partial}{\partial K_\varphi}\left[\frac{1}{g}\frac{\partial f^2}{\partial K_\varphi}\right] - \frac{1}{g}\frac{\partial^2 \ln g}{\partial K_\varphi^2}\left(1 + f^2 - \frac{2m}{v}\right)\right), \tag{14}$$

which is free from radial derivatives.

4. An effective Hamiltonian with holonomy corrections

In effective models for cosmological scenarios, holonomy corrections are usually implemented through a polymerization of the connection components. In our current scenario, only K_φ might be subjected to modifications, since the dependence of the Hamiltonian on the other two momenta, K_r and P_ϕ, is completely fixed in (9).

Furthermore, we will search for the Hamiltonian that remains the most similar to the classical constraint. Hence, we fix the matter coefficients $f_3 = -1/E^r$ and $f_4 = -E^r$ (although further couplings with K_φ might be present through the global factor g). In addition, we consider that the scalar field ϕ only appears in a classical potential term $V(\phi)$.

Now, we can obtain a solution to the system (10) in terms of three integration functions $f = f(E^r, K_\varphi)$, $v = v(E^r)$ and $w = w(E^r)$:

$$f_1 = \frac{2}{g}\frac{\partial f^2}{\partial K_\varphi}, \tag{15a}$$

$$f_2 = -\frac{1}{2}\frac{\partial \ln(gv)}{\partial E^r}, \tag{15b}$$

$$h = h_4 = -\frac{1}{2}\frac{\partial \ln g}{\partial K_\varphi}, \tag{15c}$$

$$g = \left(\frac{\partial f}{\partial K_\varphi}\right)^2 \left(1 + \frac{w}{f^2}\right)^{-1}, \tag{15d}$$

$$f_0 = \frac{2}{g}\left(\frac{\partial f^2}{\partial E^r} + \left(1 + f^2\right)\frac{\partial \ln v}{\partial E^r} - V(\phi)\right), \tag{15e}$$

$$h_0 = h_1 = h_2 = h_3 = 0\,. \tag{15f}$$

Notice that when $V(\phi) = 0$, the solutions for f_0, f_1, f_2 and h take exactly the same form as that in the previous section. However, while in the vacuum model the global factor was completely free, when we couple matter g is determined by f and w through relation (15d). In essence, we lost one degree of freedom involving K_φ.

Classically, we have that $f(E^r, K_\varphi) = K_\varphi$. Therefore, in the classical limit $v \to \sqrt{E^r}$ and $w \to 0$. Indeed, we fix these two functions to their classical values in order

to find the polymerized constraint that is closest to (5). In this way, we obtain

$$\begin{aligned}\mathcal{H} = &-\frac{E^\varphi}{2\sqrt{E^r}}\left(1+f^2+4E^r f\frac{\partial f}{\partial E^r}\right)-2\sqrt{E^r}K_r f\frac{\partial f}{\partial K_\varphi}\\ &+\left(\frac{(E^{r\prime})^2}{8\sqrt{E^r}E^\varphi}-\frac{\sqrt{E^r}}{2{E^\varphi}^2}E^{r\prime}E^{\varphi\prime}+\frac{\sqrt{E^r}E^{r\prime\prime}}{2E^\varphi}\right)\left(\frac{\partial f}{\partial K_\varphi}\right)^2\\ &+\left(\frac{P_\phi^2}{2\sqrt{E^r}E^\varphi}+\frac{{E^r}^{3/2}(\phi')^2}{2E^\varphi}\right)\left(\frac{\partial f}{\partial K_\varphi}\right)^2+\sqrt{E^r}E^\varphi V(\phi)\\ &+\frac{\sqrt{E^r}}{2{E^\varphi}^2}E^{r\prime}\left(E^{r\prime}K_r+\phi' P_\phi\right)\frac{\partial f}{\partial K_\varphi}\frac{\partial^2 f}{\partial {K_\varphi}^2}+\frac{\sqrt{E^r}}{2E^\varphi}(E^{r\prime})^2\frac{\partial f}{\partial K_\varphi}\frac{\partial^2 f}{\partial E^r\partial K_\varphi},\end{aligned}\tag{16}$$

which forms a first-class algebra along with the classical diffeomorphism constraint for any function $f = f(E^r, K_\varphi)$. This result allows us to consider holonomy corrections in the presence of a scalar field. In fact, these modifications can be made scale-dependent thanks to the free dependence on E^r. Nonetheless, in order to obtain a K_φ-periodic Hamiltonian constraint, we will restrict ourselves to a scale-invariant function. Setting $f = \sin(\lambda K_\varphi)/\lambda$,

$$\begin{aligned}\mathcal{H}^{(pol)} = &-\frac{E^\varphi}{2\sqrt{E^r}}\left(1+\frac{\sin^2(\lambda K_\varphi)}{\lambda^2}\right)-\sqrt{E^r}K_r\frac{\sin(2\lambda K_\varphi)}{\lambda}\left(1+\left(\frac{\lambda E^{r\prime}}{2E^\varphi}\right)^2\right)\\ &+\left(\frac{(E^{r\prime})^2}{8\sqrt{E^r}E^\varphi}-\frac{\sqrt{E^r}}{2{E^\varphi}^2}E^{r\prime}E^{\varphi\prime}+\frac{\sqrt{E^r}}{2E^\varphi}E^{r\prime\prime}\right.\\ &\qquad\left.+\frac{P_\phi^2}{2\sqrt{E^r}E^\varphi}+\frac{{E^r}^{3/2}(\phi')^2}{2E^\varphi}\right)\cos^2(\lambda K_\varphi)\\ &+\sqrt{E^r}E^\varphi V(\phi)-\frac{\sqrt{E^r}}{4{E^\varphi}^2}E^{r\prime}\phi' P_\phi\lambda\sin(2\lambda K_\varphi).\end{aligned}\tag{17}$$

This constraint satisfies relation (3c) with the deformation function,

$$\beta = \cos^2(\lambda K_\varphi)\left(1+\left(\frac{\lambda E^{r\prime}}{2E^\varphi}\right)^2\right).\tag{18}$$

Following the results in the previous section, we can find the effective mass for this polymerized model:

$$m_{pol} = \frac{\sqrt{E^r}}{2}\left(1+\frac{\sin^2(\lambda K_\varphi)}{\lambda^2}-\left(\frac{E^{r\prime}}{2E^\varphi}\right)^2\cos^2(\lambda K_\varphi)\right).\tag{19}$$

While in vacuum it is a weak observable, the addition of matter makes its evolution non-trivial. Nevertheless, in either case, we can write the deformation as a function of this polymerized mass:

$$\beta = 1+\lambda^2\left(1-\frac{2m_{pol}}{\sqrt{E^r}}\right).\tag{20}$$

In this way, β is covariantly defined. The positiveness requirement for β that can be read from (18) means that the model has a lower bound for the radial component of the triad,

$$\sqrt{E^r} \geq \frac{2\lambda^2 m_{pol}}{1+\lambda^2}. \tag{21}$$

Its saturation corresponds to $\beta = 0$, i.e. the point where the curvature departs most from its classical behavior. In vacuum, m_{pol} should be positive (it is a generalized Schwarzschild mass), and the classical singularity at $E^r = 0$ is inside the forbidden region. In the dynamical case, in order to check whether the system might reach the singularity, one should study the behavior of m_{pol} as E^r approaches zero.

5. Discussion

We have systematically built modified spherically symmetric models coupled to a scalar matter field through a comprehensive study of Dirac's deformation algebra for a generic constraint with quadratic dependence on radial derivatives. The main result of our study is the modified Hamiltonian constraint (9), along with the consistency equations (10) that ensure that the theory remains covariant.

We have found the general vacuum solution in terms of two free functions, which provides the anomaly-free Hamiltonian (12). Moreover, the weak Dirac observable (13) can be interpreted as the mass of the modified system since its classical limit yields the Schwarzschild mass.

Then, we have obtained a particular solution for the full system of anomaly equations and found that a covariant polymerization of the system is possible even under the presence of a scalar field. This solution has led us to the constraint (16), which is parametrized by one free function of E^r and K_φ.

Finally, the polymeric constraint (17) shows a regular behavior for all values of K_φ and forms a first-class algebra with a deformation given by (20). The vanishing of this function corresponds to a minimum positive value of E^r and avoids the classical singularity.

We study the radiation profile of the unitarily evolving wave packet constructed for the quantum model of spherically symmetric dust shell collapsing in marginally bound Lemaître-Tolman-Bondi (LTB) model. In this analysis, we consider the quantum model of dust shell collapse in LTB spacetime,[1] where the dust shell collapse to black hole singularity is replaced by a bounce. We identify the observable natural to collapse/expansion character of dust shell, and study the mode decomposition in the quantum model. The incoming/outgoing modes are associated with the eigenfunctions of the Hermitian extension of the operator corresponding to this observable. For the wave packet representing the collapsing and expanding phase of the dust shell, we estimate the contributions of the incoming/outgoing modes. We find that the collapsing and expanding branches do not comprise entirely of incoming and outgoing radiation. The dust shell dynamics is insensitive to the large wavenumber modes as their contribution is negligible. Near the bounce point, the contribution of outgoing (incoming) modes in the collapsing (expanding) branch is substantial and it decreases as the dust shell moves away from the singularity. In the early (later) stage of the collapsing (expanding) phase, the incoming (outgoing) modes dominate. As the dynamics of the dust shell is sensitive to the near-infrared modes of the radiation, the information of the bounce is carried over to infrared modes much before it reaches the observer. In the infrared regime, a flip is observed from largely incoming to largely outgoing radiation as the evolution progresses from collapsing to expanding phase. The information of the short-scale physics is carried over to the longest wavelength in this quantum gravity model.

Keywords: Shell collapse; quantum bounce.

1. Introduction

Ever since the original analysis by Hawking and Unruh,[2,3] the study of particle content of the vacuum and the radiation profile in various geometries have been the frontier research topic in the quantum effects in curved spacetime. These effects are investigated in the context of quantum field theories in the curved spacetime.[4] The key result in this paradigm is that the particle content in the quantum states is not a generally covariant notion, which is the gist of the Hawking-Unruh effect.

The analysis of matter collapse in a consistent quantum gravity model has been addressed in the context of dust shell collapse,[5,6] LTB dust collapse model in canonical quantum gravity[7,8] and loop quantum gravity.[9–11] The radiation profile of dust collapse in the LTB model is studied in[12,13] under the midisuperpace quantization of this model. The Hawking radiation is recovered from the regularized solution of

the Wheeler-DeWitt equation for this model and the non-thermal correction to the spectrum and entropy associated are also computed. In this approach, the Hawking radiation is thought of as the projection of wave functional along the outgoing modes defined in that approach.

There are some issues associated with the aforementioned quantum models. The incoming/outgoing modes defined in this approach are not orthogonal, thus, rendering the notion of incoming/outgoing modes mathematically ill-defined. This issue stems from the fact that the momentum operator in this model is not Hermitian. Apart from that the states in the Kernel of Hamiltonian constraint need not be orthonormal as they are degenerate states with zero eigenvalue.

In this work, we study the radiation profile for the unitarily evolving wave packet constructed for the quantum model for dust shell collapse in a marginally bound LTB geometry.[1] For the collapsing/expanding character of the dust shell, momentum conjugate to areal radius is a good indicator. In the quantum model, we study the mode decomposition viz-a-viz the eigenstates of momentum operator.

2. Minisuperspace Construction of Dust Collapse in Marginal LTB Model

LTB model is an inhomogeneous extension of the FRW model, which is spherically symmetric and sourced by a non-rotational dust of energy density ϵ.[14] The line element for the LTB model is,

$$ds^2 = -c^2 d\tau^2 + \frac{R'^2}{1+2f(\rho)} d\rho^2 + R^2 d\Omega^2, \tag{1}$$

here τ is the dust proper time and $R(\tau, \rho)$ is the areal radius of dust shell with coordinate label ρ at time τ, and $f(\rho)$ is called the energy function. Here, we will restrict ourselves with the marginally bound case of the LTB model for which $f(\rho) = 0$. Einstein's equation for this model is,

$$\frac{F'}{R^2 R'} = \frac{8\pi G\epsilon}{c^2} \quad \text{and} \quad \frac{R\dot{R}^2}{c^2} = F, \tag{2}$$

where $F(\rho)$ is first integral of Einstein's equation and is equal to twice of the Misner-Sharp(MS) mass[15] for LTB spacetime. This model has a curvature singularity when the cloud collapses to a point i.e., at $R = 0$.

Since the equation of motion which dictates the dynamics of the areal radius (2) depends only on R and F, and not on their spatial derivatives, it implies that the different dust shells are dynamically decoupled for a given mass function. We can write an on-shell action which dictates the dynamics of the outermost dust shell. The dynamics of the full dust cloud is then deduced from the action.[1]

$$\mathcal{S} = -\frac{1}{2} \int d\tau R\dot{R}^2 \tag{3}$$

Here R is the areal radius of the outermost dust shell. The Hamiltonian for this model is,

$$H = -\frac{P^2}{2R} \tag{4}$$

Using Brown-Kuchař dust[16,17] as the matter source, the Hamiltonian constraint for the model takes the form

$$\mathcal{H} \equiv p_\tau + H \approx 0. \tag{5}$$

Since the momentum conjugate to scalar field τ appears linearly, the Wheeler-DeWitt equation takes a Schrödinger equation like form,

$$i\hbar \frac{\partial \Psi(R,\tau)}{\partial \tau} = \frac{1}{2} R^{-1+a+b} \frac{d}{dR} R^{-a} \frac{d}{dR} R^{-b} \Psi(R,\tau). \tag{6}$$

The Hamiltonian is the product of areal radius and conjugate momentum, which implies that it does not have a unique quantum counterpart and that the model suffers from operator ordering ambiguity which is parameterized by a and b in equation (6). The eigenvalue of the Hamiltonian is interpreted as the ADM energy. The Hilbert space $L^2(\mathbb{R}^+, R^{1-a-2b}dR)$ is chosen, that makes this Hamiltonian Hermitian. The self adjoint extensions of the Hamiltonian (6) are discussed in.[1] A unitarily evolving wave packet is constructed from positive energy eigenstates,

$$\phi^1_E(R) = \frac{2}{\sqrt{3}} E^{\frac{1}{4}} J_{\frac{2|q|}{3}} \left(\frac{2}{3} \sqrt{2E} R^{\frac{3}{2}} \right). \tag{7}$$

by choosing a Poisson-like distribution

$$A(\sqrt{E}) = \frac{\sqrt{2}\lambda^{\frac{1}{2}(\kappa+1)}}{\sqrt{\Gamma(\kappa+1)}} \sqrt{E}^{\kappa+\frac{1}{2}} e^{-\frac{\lambda}{2}E}, \tag{8}$$

$$\psi(R,\tau) = \int_0^\infty d\sqrt{E} \phi_E(R) e^{iE\tau} A(\sqrt{E}), \tag{9}$$

where the parameters of the distribution satisfy $\kappa \geq 0$ and $\lambda > 0$. The expectation value of the Hamiltonian operator with this choice of distribution is inversely proportional to λ. To simplify the expression, a prescription $\kappa = |1+a|/3$ is adopted[1] and the expression for the wave packet reduces to

$$\psi(R,\tau) = \sqrt{3} \frac{R^{\frac{1}{2}(1+a+|1+a|+2b)}}{\sqrt{\Gamma(\frac{1}{3}|1+a|+1)}} \left(\frac{\frac{\sqrt{2\lambda}}{3}}{\frac{\lambda}{2} - i\tau} \right)^{\frac{1}{3}|1+a|+1} e^{-\frac{2R^3}{9\left(\frac{\lambda}{2} - i\tau\right)}}. \tag{10}$$

This choice comes at the cost that the distribution is now a function of operator ordering parameters. Since the dependence of observables on this parameter is contentious, one cannot be sure if it is a genuine signature of operator ordering or just a dependence on the shape of the distribution. In this analysis, we will focus on the radiation profile of the dust shell and address operator ordering ambiguity elsewhere.[18]

3. Mode Decomposition of Wave Packet

In the earlier midisuperspace models, various prescriptions are used to write incoming and outgoing modes. In,[12] the modes are associated with the asymptotic limit of the solutions of the WDW equation on $\mathcal{I}^+$ written in terms of the Killing time. While in,[13] the modes are associated with the positive/negative frequency solutions of the WDW equation after making transformation from the comoving time to the Killing time. In all these prescriptions, the modes are not orthonormal, making them ill-defined for the Bogoliubov analysis. The problem might lie with the fact that the states belong to the Kernel space of the operator and are degenerate and therefore, orthonormality is not guaranteed. Therefore, we need to identify another observable suitable for the mode decomposition.

Classically, the momentum conjugate to areal radius is given by $P = -R\dot{R}$ and we can associate positive momentum with the collapsing phase and negative momentum with the expanding phase of the dust shell. Thus, the momentum operator is a good choice for an observable that depicts the mode decomposition in the quantum model. The model[1] discussed in the previous section is robust enough for us to accommodate Hermitian Hamiltonian and momentum operator. Although the momentum operator on real half line is not self-adjoint, we will work with the Hermitian extension of the momentum operator. The detailed discussion on the self-adjointness and the Hermiticity of the momentum operator can be found in[18] and we have shown that the states are orthogonal in this case, making them suitable as incoming/outgoing modes.

Using the measure R^2 following the quantum scattering theory in spherical polar coordinates, we have a constraint $1+a+2b = 0$ on operator ordering parameters. For this model, the expectation value of the general observable in a general wave packet is independent of the parameter b.[18] Therefore it appears as a free parameter in the model and the above constraint does not affect the physical content of the model. In this case, the Hermitian extension of the momentum operator is $\hat{P} = -iR^{-1}\partial_R R$. The eigenfunction of the momentum operator with eigenvalue k is given by e^{ikR}/R, where $k \in \mathbb{R}$. The wave packet can be expressed in the form,

$$\psi(R,\tau) = \int_0^\infty dE \int_0^\infty dk \left(\mathcal{A}(k,E) \frac{e^{ikR+i\tau E}}{R} + \mathcal{A}(-k,E) \frac{e^{-ikR+i\tau E}}{R} \right). \tag{11}$$

The contribution of incoming/outgoing radiation in the dust cloud is estimated by computing the projection of wave packet along incoming($u_{k,E} \equiv e^{ikR+iE\tau}/R$) and outgoing modes($u_{-k,E} \equiv e^{-ikR+iE\tau}/R$) .

$$\tilde{\psi}_k(\tau) = \langle u_{k,E}(\tau) | \psi(R,\tau) \rangle = \int dR\, R^2\, \psi(R,\tau) \frac{e^{-ikR-iE\tau}}{R}, \tag{12}$$

$$= \frac{\sqrt{3} e^{-iE\tau}}{\sqrt{\Gamma(\frac{2}{3}|b|+1)}} \left(\frac{\frac{\sqrt{2\lambda}}{3}}{\frac{\lambda}{2} - i\tau} \right)^{\frac{2}{3}|b|+1} \int dR\, e^{-i\,kR} R^{1+|b|} e^{-\frac{2R^3}{9(\frac{\lambda}{2}-i\tau)}}, \tag{13}$$

$$= C(\tau) \int dR\, e^{-i\,kR} R^{1+|b|} e^{-\frac{2R^3}{9(\frac{\lambda}{2}-i\tau)}}. \tag{14}$$

The wavepacket in k space is normalized which implies $|\tilde{\psi}_k(\tau)|^2$ gives the contribution of modes with wavenumber k to the radiation profile at time τ. At $\tau = 0$, equation (14) can be written as

$$\tilde{\psi}_k(0) = C(0)\left(\int dR\ \cos(kR)\, R^{1+|b|} e^{-\frac{4R^3}{9\lambda}} - i\int dR\ \sin(kR)\, R^{1+|b|} e^{-\frac{4R^3}{9\lambda}}\right), \quad (15)$$

and we can see, $|\psi_k(0)|^2 = |\psi_{-k}(0)|^2$. Thus, at the point of classical singularity, the number of incoming modes is equal to the number of outgoing modes for all k. On the other hand, for finite τ, the equation (14) can be cast into the form,

$$|\tilde{\psi}_k(\tau)|^2 = |C(\tau)|^2 \int dR \int dS\ e^{-ik(R-S)} (RS)^{1+|b|} e^{-\frac{2R^3}{9\left(\frac{\lambda}{2}-i\tau\right)} - \frac{2S^3}{9\left(\frac{\lambda}{2}+i\tau\right)}}. \quad (16)$$

Here, $k \to -k$ is same as $\tau \to -\tau$. Thus, the ratio of incoming to outgoing modes $r_k(\tau) = |\tilde{\psi}_k(\tau)|^2/|\tilde{\psi}_{-k}(\tau)|^2$ flips after the bounce happens i.e. $r_k(\tau) = [r_k(-\tau)]^{-1}$, which can be seen in Fig. 1. The difference between the number of incoming and outgoing modes at an instant of time and at a fixed k can be written as,

$$\delta_k(\tau) = |\tilde{\psi}_k(\tau)|^2 - |\tilde{\psi}_{-k}(\tau)|^2, \quad (17)$$

$$= -2i|C(\tau)|^2 \int dR \int dS\ \sin(k(R-S))(RS)^{1+|b|} e^{-\frac{2R^3}{9\left(\frac{\lambda}{2}-i\tau\right)} - \frac{2S^3}{9\left(\frac{\lambda}{2}+i\tau\right)}}. \quad (18)$$

$\delta_k(\tau)$ vanishes when $k \to \infty$, as $\lim_{k\to\infty} \sin(kx) = x\delta(x) = 0$. Thus, we expect the ratio to approach unity for large k, which can be seen in Fig. 1. On the other hand, for $k \to 0$ we have

$$\delta_k(\tau) = \frac{4k|C(\tau)|^2}{9^{(|b|+8)/3}} \Gamma\left[\frac{|b|}{3}+1\right] \Gamma\left[\frac{|b|+2}{3}\right] \left(\frac{\lambda^2}{4}+\tau^2\right)^{\frac{2|b|+5}{6}} \sin\left(\frac{1}{3}\tan^{-1}\left(\frac{-2\tau}{\lambda}\right)\right). \quad (19)$$

In the collapsing branch ($\tau < 0$), this function is positive and therefore, the incoming modes are dominating in this case. In the expanding branch ($\tau > 0$), this function is negative and the outgoing modes dominate in this case.

We have plotted the fraction of modes with wavenumber k and the ratio of the incoming to outgoing modes for fixed time in the Fig. 1 with the parameters specifying a narrow wave packet of unit energy. Early in the collapsing phase ($\tau = -10$), most of the contribution comes from the incoming modes and the outgoing modes contribute a small fraction only in the infrared (small k) regime. As we approach the classical singularity, the contribution of outgoing radiation in the collapsing phase keeps on increasing and becomes equals to the contribution of incoming radiation at the bounce point. After the bounce, initially in the expanding phase, there is significant contribution of incoming radiation. As the expansion progresses, this contribution keeps on decreasing to become negligible and contributes only in the infrared regime.

In the early stage of collapse, the ratio of incoming to outgoing modes starts from unity at $k = 0$ and comes back to one again at a finite wavenumber. In between,

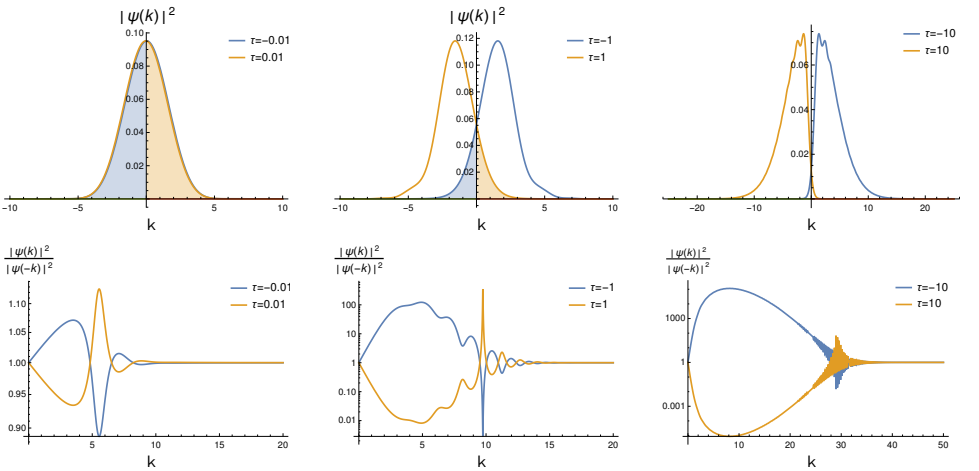

Fig. 1. Fraction of modes $|\tilde{\psi}_k(\tau)|^2$ and ratio of the incoming to outgoing modes vs k at different times. The blue shaded region gives the contribution of outgoing radiation in collapsing phase and the orange shaded region gives the contribution of incoming radiation in expanding phase.

the ratio attains a maximum and oscillates before settling at unity. Since for large wavenumbers, the contribution is minimal, these modes are insensitive to the dynamics of the dust shell. A ratio greater than one implies that the incoming modes are dominating. As we approach the bounce point, the magnitude of the maximum decreases and the ratio goes to unity at shorter wavenumber. At the bounce point, this ratio is one for all wavenumbers. Apart from this, there exists a crossover window of wavenumbers in which the fraction of outgoing modes is greater than incoming modes in the collapsing phase when the dust shell is closer to the classical singularity. This behavior is inverted for the expanding phase - the ratio attains a minimum before settling at unity.

Therefore, we see that the small wavenumber (infrared) modes are most sensitive to the dynamics of the dust cloud. If one observes in the infrared regime, there is an instantaneous flip from largely incoming to largely outgoing radiation when the dust shell goes from collapsing phase to expanding phase. Moreover, the contribution of the outgoing/incoming radiation in the collapsing/expanding regime is coming from the infrared part of the spectrum only. Thus, one should focus on the infrared regime of the dust shell for a signature of quantum bounce.

We have plotted the radiation profile for the wave packets which represents low energy dust shell broadly peaked ($\lambda = 10$) and high energy dust shells sharply peaked ($\lambda = 0.01$) on the classical trajectory in Fig. 2. We see that for the case of sharply peaked wave packet, the major contribution to radiation profile is coming from incoming (outgoing) modes in the collapsing (expanding) regime even near the classical singularity. Whereas, for low energy dust shells, the contribution of incoming (outgoing) modes in expanding (collapsing) branch is significant even far away from singularity.

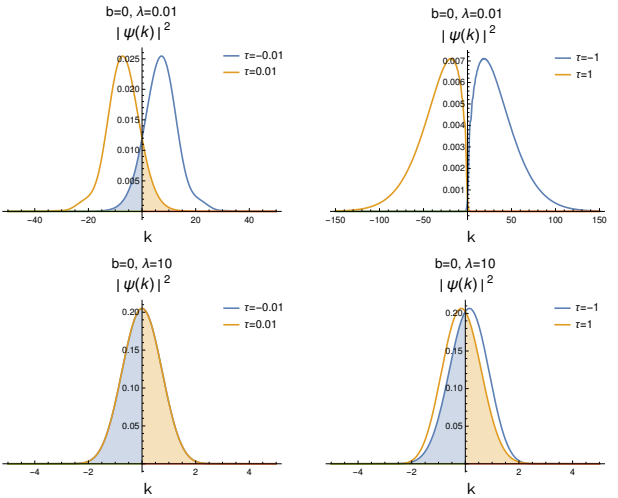

Fig. 2. Fraction of modes $|\tilde{\psi}_k(\tau)|^2$ and the ratio of incoming to outgoing modes for wave at different times. The parameters specify the high energy dust cloud ($\lambda = 0.01$) representing sharper wave packet, and low energy dust cloud($\lambda = 10$) representing broader wave packet.

At the classical singularity, the fraction of infrared modes is directly proportional to the minimal size of the dust shell i.e., the bounce radius.[18]

$$|\tilde{\psi}_{k\to 0}(0)|^2 = \frac{2^{(2|b|-5)/3}3^{2/3}\Gamma\left(\frac{|b|+2}{3}\right)^2\Gamma\left(\frac{2|b|+4}{3}\right)}{\sqrt{2}\pi\Gamma\left(\frac{2|b|+1}{3}\right)\Gamma\left(\frac{2|b|+3}{3}\right)}\bar{R}(0). \tag{20}$$

Thus, the infrared regime of the radiation profile provides a direct estimation of the bounce radius.

4. Conclusions

In this work, we have studied the mode decomposition of wave packet constructed for the Quantum LTB model. We have considered the minisuperspace construction of the dust shell collapse in the LTB model.[1] The classical model of dust shell collapse exhibits black hole singularity which is replaced by bounce from the collapsing phase to expanding phase in the quantum model. We have identified the observable depicting mode decomposition, which is momentum conjugate to areal radius. After identifying the incoming and outgoing modes with the momentum's eigenstates with positive and negative eigenvalues, we have estimated the contribution of the incoming/outgoing modes in the contracting/expanding phase.

We choose the operator ordering parameters for which the Hamiltonian as well as the momentum operator are Hermitian. This is achieved by working with R^2 measure space and choosing the representation which is symmetric with this choice

of inner product. This particular choice puts the constraint $a+2b+1 = 0$ on operator ordering parameters.

We find that at the point of classical singularity or bounce point $\tau = 0$, the number of incoming and outgoing modes is the same. In the contracting branch, apart from the incoming dust, we also have small contribution from the outgoing dust in the infrared regime. As the dust shell continues to move towards the singularity configuration, the contribution of outgoing modes in the infrared regime keeps increasing, culminating in an equal number of incoming and outgoing modes at the point of singularity. This behavior is inverted in the expanding branch. There exists a threshold wavenumber, above which the number of incoming modes is equal to the number of outgoing modes. For the contracting branch, the ratio of incoming to outgoing modes starts from one at $k = 0$, increases to attain a maximum, and then settles back to unity. After the bounce, outgoing modes start to dominate with a small fraction of incoming modes as well. As the dust shell expands, the fraction of the incoming modes keeps decreasing and while the contribution of the outgoing modes keeps increasing. At the later stage of dust shell expansion, most contribution comes from the outgoing modes. Thus, we can conclude that in quantum bounce, incoming radiation is always accompanied by outgoing radiation.

The infrared sector of the wave packet contains significant information about the dynamics of the dust cloud. The major contribution to the incoming/outgoing dust in collapsing/expanding branch comes from the modes with smaller wavenumber. There is a flip from largely incoming to largely outgoing radiation, observed in the infrared regime, as the evolution progresses from the contracting branch to the expanding branch. Therefore, the observer should look at small wavenumber or large wavelength modes to observe if the bounce has happened. Moreover, the fraction of infrared modes near classical singularity is proportional to the bounce radius. Thus, the infrared sector of the process apart from being highly sensitive to the dynamics of the dust cloud is also a direct estimator of the bounce radius, thereby, providing a unique infrared signature of the quantum gravity in the radiation profile of the dust cloud.

We show that loop quantum gravity effects leads to the finiteness of expansion and its rate of change in the effective regime in the interior of the Schwarzschild black hole. As a consequence the singularity is resolved. We find this in line with previous results about curvature scalar and strong curvature singularities in Kantowski-Sachs model which is isometric to Schwarzschild interior.

Keywords: Black hole singularity, loop quantum gravity, expansion, Raychaudhuri equation

1. Introduction

Singularities are well-known predictions of General Relativity (GR). They are recognized as regions that geodesics can reach in finite proper time but cannot be extended beyond them. Such geodesics are called incomplete. This notion can be formulated in terms of the existence of conjugate points using the Raychaudhuri equation.[1] The celebrated Hawking-Penrose singularity theorems prove that under normal assumptions, all spacetime solutions of GR will have incomplete geodesics, and will therefore be singular.[1–3] These objects, however, are in fact predictions beyond the domain of applicability of GR. So there is a consensus among the gravitational physics community that they should be regularized in a full theory of quantum gravity. Although there is no such theory available yet, nevertheless there are a few candidates with rigorous mathematical structure with which we can investigate

the question of singularity resolution. One such candidate is loop quantum gravity (LQG),[4] which is a connection-based canonical framework.

Within LQG, there have been numerous studies of both the interior and the full spacetime of black holes in four and lower dimensions.[5–18] These attempts were originally inspired by loop quantum cosmology (LQC), more precisely a certain quantization of the isotropic Friedmann-Lemaitre-Robertson-Walker (FLRW) model[19,20] which uses a certain type of quantization of the phase space variables called polymer quantization.[21–25] This quantiztion introduces a so called polymer parameter that sets the scale at which the quantum effects become important. There are various schemes of such quantization based on the form of the polymer parameter.

In this paper, we examine the issue of singularity resolution via the LQG-modified Raychaudhuri equation for the interior of the Schwarzschild black hole. By choosing adapted holonomies and fluxes, which are the conjugate variables in LQG, and using polymer quantization, we compute the corresponding expansion of geodesics and derive the effective Raychaudhuri equation. This way we show effective terms introduce a repulsive effect which prevents the formation of conjugate points. This implies that the classical singularity theorems are rendered invalid and the singularity is resolved, at least for the spacetime under consideration. The boundedness of expansion scalar and the resolution of strong curvature singularities have been studied and shown in the context of Kantowski-Sachs model in.[26,27]

This paper is organized as follows. In Sec. 2, we review the classical interior of the Schwarzschild black hole. In Sec. 3, we briefly discuss the classical Raychaudhuri equation and its importance. Then, in Sec. 4.1 we present the behavior of the Raychaudhuri equation in the classical regime. In Sec. 4.2, the effective Raychaudhuri equation for three different schemes of polymer quantization are derived and are compared with the classical behavior. Finally, in Sec. 5 we briefly discuss our results and conclude.

2. Interior of the Schwarzschild black hole

It is well known that the metric of the interior of the Schwarzschild black hole can be obtained by switching the the Schwarzschild coordinates t and r, due to the fact that spacelike and timelike curves switch their causal nature upon crossing the horizon. This yields the metric of the interior as

$$ds^2 = -\left(\frac{2GM}{t} - 1\right)^{-1} dt^2 + \left(\frac{2GM}{t} - 1\right) dr^2 + t^2 \left(d\theta^2 + \sin^2\theta d\phi^2\right). \quad (1)$$

This metric is in fact a special case of a Kantowski-Sachs cosmological spacetime[28]

$$ds^2_{KS} = -N(T)^2 dT^2 + g_{xx}(T)dx^2 + g_{\theta\theta}(T)d\theta^2 + g_{\phi\phi}(T)d\phi^2 \quad (2)$$

One can obtain the Hamiltonian of the interior system in connection variables, one first considers the full Hamiltonian of gravity written in terms of (the curvature) of the $su(2)$ Ashtekar-Barbero connection A^i_a and its conjugate momentum, the

densitized triad $\tilde{E}^i_a$. Using the Kantowski-Sachs symmetry, these variables can be written as[5]

$$A^i_a \tau_i dx^a = \frac{c}{L_0}\tau_3 dx + b\tau_2 d\theta - b\tau_1 \sin\theta d\phi + \tau_3 \cos\theta d\phi, \tag{3}$$

$$\tilde{E}^a_i \tau_i \partial_a = p_c \tau_3 \sin\theta \partial_x + \frac{p_b}{L_0}\tau_2 \sin\theta \partial_\theta - \frac{p_b}{L_0}\tau_1 \partial_\phi, \tag{4}$$

where b, c, p_b, and p_c are functions that only depend on time and $\tau_i = -i\sigma_i/2$ are a $su(2)$ basis satisfying $[\tau_i, \tau_j] = \epsilon_{ij}{}^k \tau_k$, with σ_i being the Pauli matrices. Here L_0 is a fiducial length of a fiducial volume, chosen to restrict the integration limits of the symplectic form so that the integral does not diverge. Substituting these into the full Hamiltonian of gravity written in Ashtekar connection variables, one obtains the symmetry reduced Hamiltonian constraint adapted to this model as[5–7, 10, 16]

$$H = -\frac{N}{2G\gamma^2}\left[\left(b^2 + \gamma^2\right)\frac{p_b}{\sqrt{p_c}} + 2bc\sqrt{p_c}\right]. \tag{5}$$

while the diffeomorphism constraint vanishes identically due to the homogenous nature of the model. Here, γ is the Barbero-Immirzi parameter,[4] and $p_c \geq 0$. The corresponding Poisson brackets of the model become

$$\{c, p_c\} = 2G\gamma, \qquad \{b, p_b\} = G\gamma. \tag{6}$$

The general form of the Kantowski-Sachs metric written in terms of the above variables becomes

$$ds^2 = -N(T)^2 dT^2 + \frac{p_b^2(T)}{L_0^2\, p_c(T)} dx^2 + p_c(T)(d\theta^2 + \sin^2\theta d\phi^2). \tag{7}$$

Comparing this with the standard Schwarzschild interior metric one obtains

$$p_b = 0, \qquad p_c = 4G^2M^2, \qquad \text{on the horizon } t = 2GM, \tag{8}$$

$$p_b \to 0, \qquad p_c \to 0, \qquad \text{at the singularity } t \to 0. \tag{9}$$

3. The Raychaudhuri equation

The celebrated Raychaudhuri equation[1]

$$\frac{d\theta}{d\tau} = -\frac{1}{3}\theta^2 - \sigma_{ab}\sigma^{ab} + \omega_{ab}\omega^{ab} - R_{ab}U^aU^b \tag{10}$$

describes the behavior of geodesics in spacetime purely geometrically and independent of the theory of gravity under consideration. Here, θ is the expansion term describing how geodesics focus or defocus; $\sigma_{ab}\sigma^{ab}$ is the shear which describes how, e.g., a circular configuration of geodesics changes shape into, say, an ellipse; $\omega_{ab}\omega^{ab}$ is the vorticity term; R_{ab} is the Ricci tensor; and U^a is the tangent vector to the geodesics. Note that, due the sign of the expansion, shear, and the Ricci term, they all contribute to focusing, while the vorticity terms leads to defocusing.

In our case, since we consider the model in vacuum, $R_{ab} = 0$. Also, in general in Kantowski-Scahs models, the vorticity term is only nonvanishing if one considers metric perturbations.[28] Hence, $\omega_{ab}\omega^{ab} = 0$ in our model, too. This reduces the Raychaudhuri equation for our analysis to

$$\frac{d\theta}{d\tau} = -\frac{1}{3}\theta^2 - \sigma_{ab}\sigma^{ab}. \tag{11}$$

To obtain the right hand side of the equation above, we need to consider a congruence of geodesics and derive their expansion and shear. By choosing such a congruence with 4-velocities $U^a = \left(\frac{1}{N}, 0, 0, 0\right)$ we obtain

$$\theta = \frac{\dot{p}_b}{Np_b} + \frac{\dot{p}_c}{2Np_c}, \tag{12}$$

$$\sigma^2 = \frac{2}{3}\left(-\frac{\dot{p}_b}{Np_b} + \frac{\dot{p}_c}{Np_c}\right)^2. \tag{13}$$

4. Classical vs effective Raychaudhuri equation

4.1. *Classical Raychaudhuri equation*

Having obtained the adapted form of the Raychaudhuri equation for our model, we set to find it explicitly. Looking at (11)-(13) we see that we need the solutions to the equations of motion to be able to compute them. In order to facilitate such a derivation, we choose a gauge where the lapse function is

$$N(T) = \frac{\gamma\sqrt{p_c(T)}}{b(T)}, \tag{14}$$

for which the Hamiltonian constraint becomes

$$H = -\frac{1}{2G\gamma}\left[\left(b^2 + \gamma^2\right)\frac{p_b}{b} + 2cp_c\right]. \tag{15}$$

The advantage of this lapse function is that the equations of motion of c, p_c decouple from those of b, p_b. These equations of motion should be solved together with enforcing the vanishing of the Hamiltonian constraint (15) on-shell (i.e., on the constraint surface). Replacing these solutions into (11) one obtains

$$\theta = \pm\frac{1}{2\sqrt{p_c}}\left(\frac{3b}{\gamma} - \frac{\gamma}{b}\right) = \pm\frac{-2t + 3GM}{t^{\frac{3}{2}}\sqrt{(2GM - t)}}, \tag{16}$$

$$\frac{d\theta}{d\tau} = -\frac{1}{2p_c}\left(1 + \frac{9b^2}{2\gamma^2} + \frac{\gamma^2}{2b^2}\right) = \frac{-2t^2 + 8GMt - 9G^2M^2}{(2GM - t)\,t^3}. \tag{17}$$

As expected, the right hand side of $\frac{d\theta}{d\tau}$ is negative (since $p_c > 0$) and both θ and $\frac{d\theta}{d\tau}$ diverge at the singularity in the classical regime. This can be seen from Fig. 1 which reaffirm the existence of a classical singularity at the center of the black hole.

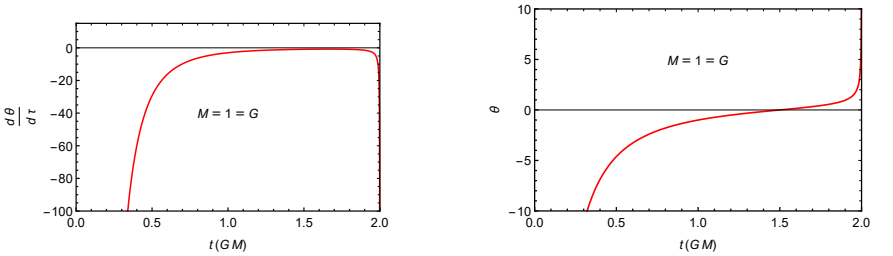

Fig. 1. Left: $\frac{d\theta}{d\tau}$ as a function of the Schwarzschild time t. Right: negative branch of θ as a function of t. Both θ and $\frac{d\theta}{d\tau}$ diverge as we approach $t \to 0$. Note that the divergence at the horizon is due to the choice of Schwarzschild coordinate system.

4.2. *Effective dynamics and Raychaudhuri equation*

The effective behavior of the interior of the Schwarzschild black hole can be deduced from its effective Hamiltonian (constraint). There are various equivalent ways to obtain such an effective Hamiltonian from the classical one.[5–7, 10, 16] It turns out that the easiest way is by replacing

$$b \to \frac{\sin(\mu_b b)}{\mu_b}, \tag{18}$$

$$c \to \frac{\sin(\mu_c c)}{\mu_c}, \tag{19}$$

in the classical Hamiltonian.

The free parameters μ_b, μ_c are the minimum scales associated with the radial and angular directions.[5, 7, 10, 29] If these μ parameters are taken to be constant, the corresponding approach is called the μ_0 scheme. If, however, these parameters depend on the conjugate momenta, the approach is called improved dynamics which itself is divided into various subcategories. In case of the Schwarzschild interior and due to lack of matter content, it is not clear which scheme yields the correct semiclassical limit. Hence, for completeness, in this paper we will study the effective theory in the constant μ scheme, which here we call the $\mathring{\mu}$ scheme, as well as in two of the most common improved schemes, which we denote by $\bar{\mu}$ and $\bar{\mu}'$ schemes.

Replacing (18) and (19) into the classical Hamiltonian (5), one obtains an effective Hamiltonian constraint,

$$H_{\text{eff}}^{(N)} = -\frac{N}{2G\gamma^2}\left[\left(\frac{\sin^2(\mu_b b)}{\mu_b^2} + \gamma^2\right)\frac{p_b}{\sqrt{p_c}} + 2\frac{\sin(\mu_b b)}{\mu_b}\frac{\sin(\mu_c c)}{\mu_c}\sqrt{p_c}\right]. \tag{20}$$

In order to be able to compare the effective results with the classical case, we need to use the same lapse as we did in the classical part. Under (18), this lapse (14) becomes

$$N = \frac{\gamma\mu_b\sqrt{p_c}}{\sin(\mu_b b)}. \tag{21}$$

Using this in (20) we obtain

$$H_{\rm eff} = -\frac{1}{2\gamma G}\left[p_b\left[\frac{\sin(\mu_b b)}{\mu_b} + \gamma^2\frac{\mu_b}{\sin(\mu_b b)}\right] + 2p_c\frac{\sin(\mu_c c)}{\mu_c}\right]. \tag{22}$$

Note that both (20) and (22) reduce to their classical counterparts (5) and (15) respectively, as is expected.

To obtain the effective Raychadhuri equation, we consider three cases:

(1) $\mathring{\mu}$ scheme where $\mu_b = \mathring{\mu}_b$ and $\mu_c = \mathring{\mu}_c$ are constants,
(2) $\bar{\mu}$ scheme where we set

$$\mu_b = \bar{\mu}_b = \sqrt{\frac{\Delta}{p_b}}, \tag{23}$$

$$\mu_c = \bar{\mu}_c = \sqrt{\frac{\Delta}{p_c}}, \tag{24}$$

(3) $\bar{\mu}'$ scheme where we choose

$$\mu_b = \bar{\mu}'_b = \sqrt{\frac{\Delta}{p_c}}, \tag{25}$$

$$\mu_c = \bar{\mu}'_c = \frac{\sqrt{p_c\Delta}}{p_b}. \tag{26}$$

After replacing these (separately for each case) into the effective Hamiltonian constraint (22) and finding their corresponding equations of motion,[30] one replaces the solutions in the Raychadhuri equation (11) to obtain the form of $\frac{d\theta}{d\tau}$. It turns out that for all the three cases above we obtain

$$\begin{aligned}\frac{d\theta}{d\tau} =& \frac{1}{\gamma^2 p_c}\frac{\sin^2(\mu_b b)}{\mu_b^2}\left[\cos(\mu_b b)\cos(\mu_c c) - \frac{\cos^2(\mu_b b)}{4} - 3\cos^2(\mu_c c)\right] \\ &+ \frac{\cos(\mu_b b)}{p_c}\left[\frac{\cos(\mu_b b)}{2} - \cos(\mu_c c) - \frac{\gamma^2}{4}\cos(\mu_b b)\frac{\mu_b^2}{\sin^2(\mu_b b)}\right],\end{aligned} \tag{27}$$

where it is understood that μ's should be substituted for from cases 1–3 suitably for each case.

4.2.1. *$\mathring{\mu}$ scheme*

Let us first consider this case perturbatively in an analytic manner. Replacing $\mu_b = \mathring{\mu}_b$ and $\mu_c = \mathring{\mu}_c$ as constants in (27) and then expanding for small values of μ's up to the second order we obtain

$$\frac{d\theta}{d\tau} \approx -\frac{1}{2p_c}\left(1 + \frac{9b^2}{2\gamma^2} + \frac{\gamma^2}{2b^2}\right) + \mathring{\mu}_b^2\frac{1}{2p_c}\left(\frac{b^4}{\gamma^2} + \frac{\gamma^2}{3}\right) + \mathring{\mu}_c^2\frac{c^2}{2p_c}\left(1 + \frac{5b^2}{\gamma^2}\right). \tag{28}$$

It is seen that the first term on the right-hand side above is the classical expression (17) which is always negative and leads to the divergence of classical expansion

rate at the singularity, i.e., infinite focusing. However, Eq. (28) now involves two additional effective terms proportional to $\mathring{\mu}_b^2$ and $\mathring{\mu}_c^2$, both of which are positive. Furthermore, from the solutions to equations of motion,[30] one can infer that these two terms take over close to where the classical singularity used to be and stop θ and $\frac{d\theta}{d\tau}$ from diverging. This can, in fact, be confirmed by looking at the full nonperturbative behavior of $\frac{d\theta}{d\tau}$ plotted in Fig. 2. There, it is seen that the quantum gravity effects counter the attractive nature of classical terms and turn the curve around such that $\frac{d\theta}{d\tau}$ goes to zero for $t \to 0$.

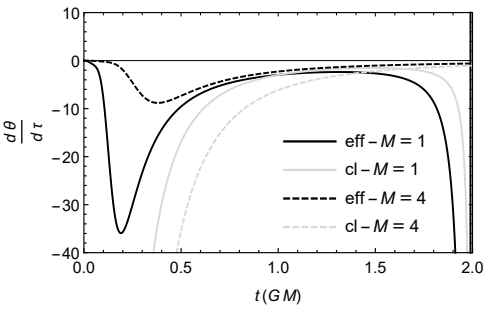

Fig. 2. Plot of $\frac{d\theta}{d\tau}$ as a function of the Schwarzschild time t, for two different masses in classical vs effective regimes. The figure is plotted using $\gamma = 0.5$, $G = 1$, $L_0 = 1$, and $\mathring{\mu}_b = 0.08 = \mathring{\mu}_c$.

4.2.2. $\bar{\mu}$ *scheme*

Similar to the $\mathring{\mu}$ scheme we start by analyzing the perturbative expansion of $\frac{d\theta}{d\tau}$ for this case by replacing (23) and (24) in (27) and expanding it for small $\bar{\mu}$'s up to the lowest correction terms which in this case is Δ (which can be considered as the second order in $\bar{\mu}$ scales). This way we get

$$\frac{d\theta}{d\tau} \approx -\frac{1}{2p_c}\left(1+\frac{9b^2}{2\gamma^2}+\frac{\gamma^2}{2b^2}\right)+\frac{\Delta}{p_c}\left[\frac{1}{6p_b}\left(\frac{3b^4}{\gamma^2}+\gamma^2\right)+\frac{c^2}{2p_c}\left(1+\frac{5b^2}{\gamma^2}\right)\right]. \quad (29)$$

Once again, the first term on the right-hand side is the classical expression of the Raychaudhuri equation (17), which contributes to infinite focusing at the singularity, but all the correction terms are positive and take over close to the position of the classical singularity. This stops $\frac{d\theta}{d\tau}$ from diverging similar to the $\mathring{\mu}$ scheme.

The full nonperturbative form of the modified Raychaudhuri equation in terms of t can also be plotted plotted by substituting the numerical solutions of the equations of motion for the $\bar{\mu}$ in (27). The result is plotted in Fig. 3. We see that, approaching from the horizon to where the classical singularity used to be, an initial bump or bounce in encountered, followed by a more pronounced bounce closer to where the singularity used to be. Once again, the quantum corrections become dominant close to the singularity and turn back the $\frac{d\theta}{d\tau}$ such that at $t \to 0$ no focusing happens at all. Furthermore, from the right plot in Fig. 3, we see that the first bounce in the

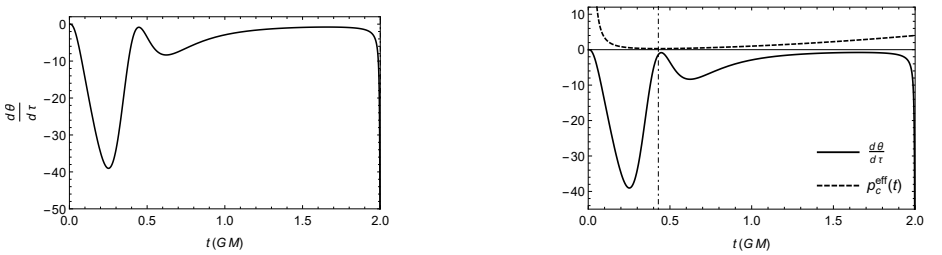

Fig. 3. Left: Raychaudhuri equation in the $\bar{\mu}$ scheme. Right: Raychaudhuri equation vs p_c. The vertical dot-dashed line at $t \approx 0.43GM$ is the position of the bounce of p_c where its minimum $p_c^{\min} = 0.29$ happens in this case. The figure is plotted using $\gamma = 0.5$, $M = 1$, $G = 1$, $L_0 = 1$, and $\Delta = 0.1$.

Raychaudhuri equation happens much earlier than the bounce in p_c for this batch of geodesics.

4.2.3. $\bar{\mu}'$ *scheme*

The perturbative analytical form of $\frac{d\theta}{d\tau}$ for this case, up to the first correction term turns out to be

$$\frac{d\theta}{d\tau} \approx -\frac{1}{2p_c}\left(1 + \frac{9b^2}{2\gamma^2} + \frac{\gamma^2}{2b^2}\right) + \frac{\Delta}{6\gamma^2}\left[\frac{1}{p_c^2}\left(3b^4 + \gamma^4\right) + \frac{3c^2}{p_b^2}\left(5b^2 + \gamma^2\right)\right]. \tag{30}$$

Although this perturbative form of the Raychaudhuri equation is a bit different from previous cases, nevertheless it exhibits the property that the quantum corrections are all positive and take over close to where the classical singularity used to be, and hence once again contribute to defocusing of the geodesics. This case is, however, rather different from the previous two cases since the behavior of some of the canonical variables as a function of the Schwarzschild time t deviates significantly from those cases. In particular, both b and p_c show a kind of damped oscillatory behavior close to the classical singularity,[30] which contributes to a more volatile behavior of the Raychaudhuri equation.

The full nonperturbative Raychaudhuri equation and its close-ups in this case are plotted in Fig. 4. It is seen that in this scheme, the Raychaudhuri equation exhibits a more oscillatory behavior and has various bumps particularly when we get closer to where the singularity used to be. Very close to the classical singularity, its form resembles those of b and p_c, behaving like a damped oscillation.[30]

Two particular features are worth noting in this scheme. First, as we also saw in previous schemes, quantum corrections kick in close to the singularity and dominate the evolution such that the infinite focusing is remedied, hence signaling the resolution of the singularity. Second, this scheme exhibits a nonvanishing value for $\frac{d\theta}{d\tau}$ at, or very close to, the singularity. In Fig. 4 with the particular choice of numerical values of γ, M, G, L_0 and Δ, the value of $\frac{d\theta}{d\tau}$ for $t \to 0$ is approximately -5.5. Hence, although a nonvanishing focusing is not achieved in this case at where

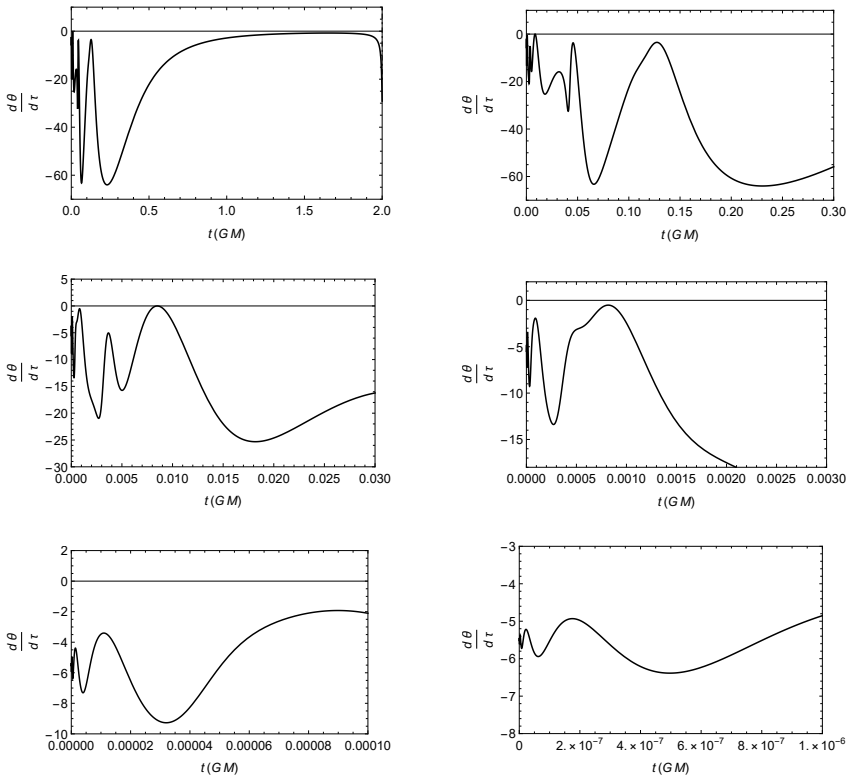

Fig. 4. Raychaudhuri equation in the $\bar{\mu}'$ scheme. The top left figure shows the behavior over the whole $0 \leq t \leq 2GM$ range. Other plots show various close-ups of that plot over smaller ranges of t. The figure is plotted using $\gamma = 0.5$, $M = 1$, $G = 1$, $L_0 = 1$, and $\Delta = 0.1$.

the singularity used to be, nevertheless, there exists a relatively small focusing and certainly $\frac{d\theta}{d\tau}$ remains finite.

5. Discussion and outlook

In this work, we probed the structure of the interior of the Schwarzschild black hole, particularly the region close to the classical singularity, using the effective Raychaudhuri equation. The effective terms in this equation result from considering the effective modifications to the Hamiltonian of the interior due to polymer quantization, which is equivalent to loop quantization of this model. We found out that while the classical rate of expansion $\frac{d\theta}{d\tau}$ diverges for $r \to 0$, the effective terms counter such a divergence close to the singularity and make $\frac{d\theta}{d\tau}$ finite at $r \to 0$. We considered three main schemes of polymer quantization and the results hold in all three. This is a strong indication that LQG points to the resolution of the singularity in the effective regime.

It is also worth noting that very similar behavior has been derived recently for several cases of Generalized Uncertainty Principle (GUP) models.[31,32] In particular, it seems that these cases bare a significant resemblance to $\mathring{\mu}$ and $\bar{\mu}$. This can be taken as a cross-model affirmation that quantum gravity in general does resolve the singularity of the Schwarzschild black hole.

We review recent developments in the physical implications of two loop quantization strategies for the interior of a homogeneous dust cloud. The first is the loop quantization with holonomies and the triads while the second is with holonomies and the gauge covariant fluxes. Although both of the quantization schemes resolve the classical central singularity regardless of the initial conditions, they also lead to a distinct phenomenology. For the first loop quantization, we find that when the dust mass is larger than a threshold value, both black hole and white hole would form and their evolution is symmetric with respect to the bounce point, leading to black hole-white hole twins. In contrast, in the second quantization, the evolution of the outermost dust shell is asymmetric with respect to the bounce point, and as a result the black hole-white hole twins can never form. Even in the situation when both black hole and white hole can form, the mass of the latter is only $2/\pi$ of the mass of the former.

Keywords: Homogeneous dust collapse; loop quantum cosmology.

1. Introduction

The singularity problem in the gravitational collapse results from the breakdown of the classical theory of general relativity (GR) and can thus be resolved by quantum gravity. Understanding the role of quantum gravity in determining the final state of the collapsing stars can help provide insights on the fundamental questions related with cosmic censorship conjecture and black hole evaporation. Because of the quantization ambiguities in quantum theories, it is important to understand if the physical predictions are robust against various quantization prescriptions. In the following, we address this question for a collapsing dust cloud whose interior spacetime is described by the Lemaître-Tolman-Bondi(LTB) metric and study two quantization prescriptions in a loop quantum gravity (LQG) scenario.

To make the problem of a collapsing dust cloud more manageable, we further assume a homogeneous evolution of the dust cloud in the marginally bound case. We then make use of the techniques from LQG to quantize the interior of the dust cloud. The loop quantization of the spacetimes with spherical symmetry dates back to quantization of the interior of the Schwarzschild black hole.[1–6] Later it was extended to include both interior and exterior of the black hole[7–13] as well as the dynamical collapsing spacetime which is filled with a massless scalar or the dust.[14–18] All these studies focussed on the resolution of the central singularity by incorporating quantum geometry effects via holonomies and/or inverse triad

modification but not on comparaing the physics in different quantizations. Further, none of the forementioned models have been directly derived from LQG. Therefore, it is reasonable to ask whether the physical predictions in those models are robust when further modifications from LQG are included in the dynamics. To answer this question, we have studied two distinct quantization prescriptions for the interior of a collapsing dust cloud and compared their physical implications.[19] The first quantization employs holonomy and triads while in the second quantization, in addition to the holonomy corrections, we have also considered the contributions from the gauge-covariant fluxes[20] which have beenr ecently explored in the cosmological setting.[21–23] Our results have shown that although the resolution of the central singularity is robust against different quantization strategies, the resulting dynamics also exhibit distinctive features for each quantization ansatz. In particular, the first quantization results in black hole-white hole twins while the second quantization strategy generally leads to black hole-white hole asymmetry.

2. The classical dust shell model

The classical dust shell model describes the dynamics of the outermost shell of a collapsing dust cloud. It is based on the LTB model which is obtained from a spherically symmetric solution of Einstein's equations in GR with non-rotational dust as a matter source. The metric of LTB spacetime is given by

$$ds^2 = -d\tau^2 + \frac{(R')^2}{1+2f}dx^2 + R^2 d\Omega^2, \tag{1}$$

where R is the areal radius, $f(x)$ is the total energy of a unit mass at x and a prime denotes derivative with respect to the radial coordinate x. Depending on the sign of f, there are three distinct cases: the marginally bound case with $f = 0$, the bound case with $f < 0$ and the unbound case with $f > 0$. In the following, we focus on the marginally bound case. The corresponding Hamiltonian constraint for the LTB dust model is explicitly given in terms of both canonical ADM variables and the Ashtekar variables for a general inhomogeneous dust cloud in.[24] The classical dust shell model can then be obtained from the LTB model by a homogeneous reduction where the energy density of the dust cloud is assumed to depend only on time.[25] Thanks to the spherical symmetry and the homogeneity of the dust cloud interior, one can integrate the classical Hamiltonian constraint of the LTB model along the radial direction as well as the angular part and arrive at the Hamiltonian constraint for the outermost dust shell which can be expressed in terms of a canonical pair consisting of the radial components of the extrinsic curvature and the densitized triad.[19] It turns out that for the homogeneous dust collapse, the interior spacetime is isometric to the spatially-flat Friedmann-Lemaître-Robertson-Walker (FLRW) spacetime. As a result, the classical Hamiltonian constraint of the outermost dust shell can be related with the one for the spatially-flat FLRW spacetime.[19]

For a complete description of thiS collapsing model, in addition to the dust interior, one still needs to specify the exterior spacetime which is glued to the dust interior at the boundary. We choose the exterior spacetime to be the generalized

Vaidya spacetime[26] so that it allows a non-vanishing effective dust pressure after quantum geometrical effects are taken into account.[14] The matching conditions are worked out under the requirements that the first and the second fundamental forms should be continuous across the boundary. In this way, it turns out that in the marginally bound case the Vaidya mass which is the mass of the dust cloud as seen by an outside observer differs from the mass function of the dust cloud by a factor of $1/2G$ with G denoting the Newton's constant.

3. Loop quantization of the dust shell model with holonomy and triad variables

The loop quantization of the dust shell model is based on the classical Hamiltonian constraint of the outermost dust shell which is expressed in terms of the Ashtekar variables.[19] Due to the quantization ambiguities, there are different quantization prescriptions which can result in distinct effective dynamics. Since the interior of a homogeneous dust cloud is isometric to a spatially-flat FLRW spacetime, one can apply techniques developed in loop quantum cosmology (LQC)[27] in a straightforward way. After quantizing the outermost dust shell by employing holonomies and the triads with the $\bar{\mu}$ scheme,[28] we find that the classical central singularity is resolved and replaced with a bounce which takes place at a fixed maximum energy density in the Planck regime. Meanwhile, the collapse of the dust cloud is succeeded by a re-expansion after the bounce point. The formation of the trapped surfaces during the contraction and the expansion of the dust cloud depends solely on the initial dust mass. There also exists a threshold dust mass M^* below which no black hole or white hole can form during the evolution of the dust cloud. On the other hand, when the initial dust mass is larger than M^*, a dynamical black hole can form during the collapse of the dust cloud and correspondingly a white hole can form during the re-expansion of the dust cloud. The evolution of the black hole and the white hole is always symmetric with respect to the bounce point and in particular the mass of the black hole is the same as the mass of the white hole. Moreover, right at the bounce, the trapped surfaces vanishes and the Vaidya mass becomes zero which implies that an asymptotic flat Minkowski spacetime emerges at the bounce point due to the quantum repulsive force. This repulsive force is also reflected by a negative effective pressure near the bounce point when the energy density is in the Planck regime.

4. Loop quantization of the dust shell model with holonomy and gauge covariant flux variables

Apart from the holonomy and triad quantization, we also study the physical consequences of using holonomy and the gauge covariant fluxes[20] which is motivated from the need to go beyond symmetry reduced triads in to obtain an effective Hamiltonian with loop quantum modifications from LQG using suitable coherent states. Its physical implications have been explored for the spatially-flat FLRW model recently.[21–23] This quantization strategy leads to distinct dynamical evolution of the outermost dust shell as compared with the one discussed in the last section.

In particular, although the classical central singularity is resolved and replaced with a quantum bounce which also takes place in the Planck regime, the formation/evolution of the black hole and the white hole is no longer symmetric with respect to the bounce point. Due to quantum gravity effects there exist two characteristic dust masses M_1 and M_2 ($M_1 < M_2$). When the initial dust mass is less than M_1, no trapped surfaces can form during the entire evolution of the dust cloud. On the other hand, when the initial dust mass lies between M_1 and M_2, only a black hole can form during the collapse of the dust cloud. Finally, when the initial dust mass is larger than M_2, both black hole and the white hole can form. In the last case, we find the evolution of the black hole and the white hole is not symmetric with respect to the bounce point and in particular the effective mass of the white hole is only $2/\pi$ of the one for the black hole and the black hole always outlives the white hole in the proper time. This asymmetry is due to the difference in the classical limits of the pre- and post-bounce regimes of the effective dynamics. As a result, black hole-white hole twins do not exist in this quantization strategy.

5. Summary

The gravitational collapse of a homogeneous dust cloud provides a platform to test different loop quantizations and investigate their resulting physical implications. We find even in this simple setting, quantization ambiguities can lead to very distinct phenomenological effects. In particular, we have studied two quantization strategies in this context, the one employing holonomies and triads and the other using holonomies and gauge covariant fluxes. Although in both cases, the central singularity is resolved and replaced with a quantum bounce, there are qualitative differences between two quantization prescriptions. In the former, when the dust mass is larger than the threshold mass, there are black hole-white hole twins. While in the latter, a black hole and white hole twin system is not possible and the the mass of the white hole is only $2/\pi$ of the mass of the black hole because of quantum gravity effects. Further, there can be situations in which only black hole forms during the collapse of the dust cloud.

We wish to thank Jahnvi Verma and Anzhong Wang for discussions. This work is supported by the DFG-NSF grants PHY-1912274 and 425333893, and PHY-1454832 and PHY-2110207.

Summary of the parallel session QG3

Jorge Pullin and Parampreet Singh

Department of Physics and Astronomy, Louisiana State University, Baton Rouge, LA 70803, USA

We summarize the main results of 19 talks presented at the QG3 session (loop quantum gravity: cosmology and black holes) of the 16th Marcel Grossmann Meeting held online from July 5^{th}-10^{th}, 2021.

Keywords: Loop quantum gravity; cosmology; black holes

The QG3 session was organized in two parts with a total of 19 talks. The first part of the session was held on July 5th (9 talks) focussing on loop quantum gravity effects in black hole spacetimes, and the second part was on July 8th (10 talks) focussing on cosmological implications. A summary of talks in a chronological order is as follows.

We-Cong Gan presented his joint work with Nilton O. Santos, Fu-Wen Shu, and Anzhong Wang on spherically symmetric polymer black holes.[1] Their work is based on a model by Bodendorfer, Mele and Münch and depend on three independent parameters. An exploration of the parameter space was made showing a wealth of physical possibilities including singularity resolution, wormholes and space-times with singularities.

Harkirat Singh Sahota discussed joint work with Kinjalk Lochan[2] about the quantization of the Lemaître–Tolman–Bondi model as a minisuperspace. It leads to a bounce eliminating the singularity and the talk explored how it manifests itself in the infrared regime to an observer looking at the collapse.

Aurélien Barrau discussed joint work with Léonard Ferdinand, Killian Martineau and Cyril Renevey.[3] There have been several proposals discussed in the literature in which after their evaporation black holes tunnel into metastable white holes. They have been considered a dark matter candidate. The talk showed that such models are severely constrained and suggested some possible detection paths.

Parampreet Singh presented his work with Kristina Giesel and Bao-Fei Li on a non-singular collapse of a dust shell model in Lemaître–Tolman–Bondi spacetime.[4] Two quantization prescriptions were studied. One using holonomies and triads, and another using holonomies and gauge-covariant fluxes. While both the prescriptions result in a bounce of the dust shell they lead to different mass gaps at which a trapped surface may form. Unlike in a quantization based on holonomies and triads,

in presence of gauge-covariant fluxes, a formation of white hole in the expanding phase when a black hole forms in the contracting phase is not guaranteed.

Asier Alonso-Bardaji presented work with David Brizuela where they consider holonomy and inverse-triad corrections in spherically symmetric models of loop quantum gravity.[5] It constructs systematically anomaly-free constraints with such corrections. It concludes that holonomy corrections are consistent in the presence of matter fields. Contrary to earlier claims, authors demonstrate a model which provides a family of deformed Hamiltonian constraints with scale-dependent holonomy corrections in the presence of a scalar matter field.

Cong Zhang talked about joint work with Yongge Ma, Shupeng Song and Xiangdong Zhang on the loop quantum gravity quantization of the interior of the Schwarzschild black hole.[6] They study a Dirac observable corresponding to the ADM mass and note that zero is not in its spectrum, suggesting that a remnant is left after the evaporation of the black hole.

Alejandro García Quasimodo talked about work with Guillermo Mena Marugán about some modifications to the Ashtekar–Olmedo–Singh black hole model, in particular the use of polymerization parameters that are Dirac observables.[7] This may modify the asymptotic behavior of the model.

Saeed Rastgoo presented work with Keagan Blanchette, Saurya Das and Samantha Hergott on loop quantum gravity corrections to the Raychaudhuri equation.[8] These corrections imply defocusing of geodesics providing insights on the eliminiation of singularities in this context.

Patrick Fraser analyzed how classical are the Gaussian states in loop quantum cosmology.[9] He showed that contrary to common intuition, such states do not saturate their uncertainty relations and there exist Gaussian states for which the fluctuations are arbitrarily large. However, the usual volume regularization procedure allows to suppress those fluctuations as much as one wishes.

V. Sreenath talked about alleviating tensions in the cosmic microwave background using Planck scale physics in a joint work with Abhay Ashtekar, Brajesh Gupt and Donghui Jeong.[10] The idea is that there are several anomalies of low significance in the agreement of the predictions of the usual Λ-CDM model for the cosmic microwave background. Taken as a whole, however, they imply a tension between theory and data. The talk showed that considering loop quantum cosmology leads to a primordial power spectrum that is scale dependent at large scales. This can potentially alleviate the anomalies.

Sahil Saini discussed a matter-Ekpyrotic bounce model in loop quantum cosmology in a joint work with Bao-Fei Li and Parampreet Singh.[11] Unlike previous attempts in this direction in loop quantum cosmology, Ekpyrotic phase was sourced by a potential motivated from Ekpyrotic scenarios. It was shown that in contrast to previous results where a fixed ultra-stiff equation of state was assumed, the magnitude of power spectrum changes during evolution resulting from an Ekpyrotic potential. It was found that the bouncing regime only leaves imprints on the modes

outside the scale-invariant regime. Further refinements in this direction are necessary since the spectral index shows inconsistency with the observational data.

Kristina Giesel presented a reduced phase space quantization for loop quantum cosmology in presence of inflationary potentials. This was a joint work with Bao-Fei Li and Parampreet Singh.[12] Unlike the case of a massless scalar field which has been addressed rigorously in loop quantum cosmology, singularity resolution at the quantum level in the presence of a potential has remained an open problem because of several conceptual and technical challenges. The idea is to introduce an additional clock degree of freedom to measure time evolution. It was shown that singularity resolution occurs in the presence of potentials at the level of quantum difference equation. Some properties of non-singular solutions were discussed using effective dynamics.

Guillermo Mena Marugán talked about his work with Beatriz Elizaga Navascués and Rafael Jiménez-Llamas on the way potential effects primordial perturbations in kinetic dominated regimes in classical and loop quantum cosmology.[13] Such a situation is of particular interest in loop quantum cosmology where so far kinetic dominated bounce has been studied. Authors found that the choice of Bunch-Davies vacuum may no longer be preferred in presence of such corrections. Further, there are changes in the effective mass in the Mukhanov-Sasaki equation.

Anzhong Wang discussed his joint work with Bao-Fei Li and Parampreet Singh on various subtleties in imposing initial conditions for cosmological perturbations in loop quantum cosmology and its modified versions (mLQC-I and mLQC-II).[14] The talk highlighted differences in choices which are forced by the assumptions in the dressed metric and hybrid approaches. Issues related to when to impose initial conditions – whether at bounce or in the contracting phase, and constraints on possible choices were discussed. It was shown that a consistent choice of the initial conditions depends not only on the choice of a potential but also on the two approaches used in loop quantum cosmology.

Javier Olmedo talked about effects on primordial perturbations in a bouncing model in loop quantum cosmology for a Bianchi-I spacetime in a joint work with Ivan Agullo and V. Sreenath.[15] They considered an evolution where anisotropies are non-vanishing at a bounce dominated by matter energy density. Though anisotropies were diminished in the pre-inflationary branch, effects were found in the scalar and tensor power spectrum. Modification to the angular correlation functions and the way EB and TB correlations may arise was discussed.

Bao-Fei Li discussed features of primordial power spectrum in modified versions of loop quantum cosmology in a joint work with Javier Olmedo, Parampreet Singh and Anzhong Wang.[16] They discussed the way dressed metric and hybrid approaches to perturbations result in different signatures in the primordial power spectrum, especially for mLQC-I model. Differences with loop quantum cosmology in the infra-red and intermediate regimes were also found which show that different loop quantum prescriptions potentially leave distinct signatures in CMB.

Dimitrios Kranas talked about his joint work with Ivan Agullo and V. Sreenath on understanding the origin of various anomalies in the CMB using a bouncing model.[17] They find that that non-Gaussian correlations between CMB modes and super-horizon wavelengths in the power spectrum can potentially explain a power suppression, a dipolar asymmetry, and existence of odd-parity correlations in the power spectrum.

Adriá Delhom i Latorre discussed hos joint work with Gonzalo Olmo and Parampreet Singh.[18] They investigate the existence of a covariant action in $f(R)$ Palatini theories which can reproduce effective equations for modified versions of loop quantum cosmology. It was found that the Lagrangians which result in effective dynamics of LQC, mLQC-I and mLQC-II are part of a three-parameter family of f(R) theories, where two parameters are fixed by initial conditions at the bounce.

Hongguang Liu talked about his work with Muxin Han on a path integral approach based on reduced phase space loop quantum gravity to derive effective dynamical equations in which the graph changes dynamically in the physical time evolution.[19] They were able to derive the so-called improved dynamics from this method found earlier in loop quantum cosmology by Ashtekar, Pawlowski and Singh which results in a singularity resolution. The method also generalizes the path integral formulation used in full LQG to take into account an additional real scalar field.

Acknowledgments

This work was supported in part by grant NSF-PHY-1454832, NSF-PHY-1903799, DFG-NSF-PHY-1912274, NSF-PHY-2110207 and funds of CCT-LSU and the Horace Hearne Institute for Theoretical Physics.

Reliable equations of state of viscous strong and electroweak matter

A. Tawfik

Egyptian Center for Theoretical Physics (ECTP), Cairo, Egypt
World Laboratory for Cosmology And Particle Physics (WLCAPP), Cairo, Egypt
E-mail: a.tawfik@cern.ch

For the first time, a reliable estimation for the equations of state (EoS), bulk viscosity, and relaxation time, at temperatures ranging from a few MeV up to TeV or energy density up to 10^{16} GeV/fm^3. This genuine study covers both strong and electroweak epochs of the early Universe. Non–perturbation (up, down, strange, charm, and bottom quark flavor) and perturbative calculations (up, down, strange, charm, bottom, and top quark flavors), are phenomenologically combined, at vanishing baryon–chemical potential. In these results, calculations from Polyakov linear–sigma model (PLSM) of the vacuum and thermal condensations of the gluons and the quarks (up, down, strange, and charm flavors) are also integrated. Furthermore, additional degrees of freedom (photons, neutrinos, charged leptons, electroweak particles, and scalar Higgs boson) are found significant along the entire range of temperatures. As never done before, the present study brings the standard model of elementary particles closer to the standard model for cosmology.

Keywords: Strong and electroweak epochs, Perturbative and non–perturbative calculations, Equations of state, Bulk viscosity, Relaxation time

1. Introduction

Understanding the strong and electroweak epochs of the early Universe, at least, through determining their equations of state (EoS) is impactful for various cosmological studies, such as the nucleosynthesis and the cosmological large–scale structure. Until present date, cosmology is dictated by the standard model of cosmology (SMC). SMC assumes that the cosmic background is isotropically and homogeneously characterized by an ideal fluid. With this regard, we recall that a first proposal that the viscous coefficients are also connected with particle physics was presented Ref.[1,2]. It was also assumed that the influence of viscous coefficients becomes significant first at the end of the lepton era,[3] i.e., during neutrino decoupling epoch or temperature $T \simeq 10^{10}$ K ($\simeq 1$ MeV) which takes place not long after the end of the QCD phase transition from colored quark–gluon plasma (QGP) to colorless hadrons. The QCD phase transition[4–7] takes place at $T \simeq 160$ MeV. Recent studies concluded that the viscous coefficients likely impact early epoches of the Universe.[8]

Taking advantage of recent developments in ultra–relativistic nuclear experiments and non–perturbative lattice QCD simulations, and perturbative calculations, various thermodynamic quantities including pressure p, energy density ρ, bulk viscosity ζ, and relaxation time τ are calculated up to the TeV-scale and a reliable evolution of the early Universe could be achieved. The present study offers

an access to deep epochs of the early Universe with T up to TeV-scale and ρ up to 10^{16} GeV/fm^3.

For Friedmann–Lemaitre–Robertson–Walker (FLRW) metric

$$ds^2 = dt^2 - a(t)^2 \left[\frac{dr^2}{1-kr^2} + r^2 \left(d\theta^2 + \sin^2 \theta d\phi^2 \right) \right], \tag{1}$$

where $a(t)$ is the dimensionless scale factor, $k = \{-1, 0, +1\}$ represents elliptical, flat (Euclidean), and hyperbolic cosmic space, or negative, flat, and positive curvature, respectively. The theory of general relativity (GR) inters the play, when temporal evolution of the line element $s(t)$ can be determined. To this end, GR has to be combined with the matter–energy content of the cosmic geometry,

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R + \Lambda_{\mu\nu} = \frac{8\pi}{3} T_{\mu\nu}, \tag{2}$$

where μ, ν run over 0, 1, 2, and 3.

Then, the Einstein field equations in natural units read

$$H(t)^2 = \frac{8\pi}{3} \rho(t) - \frac{k}{a(t)^2} + \frac{\Lambda}{3}, \tag{3}$$

$$\dot{H}(t) + H(t)^2 = -\frac{4\pi}{3} \left[\rho(t) + 3p_{\mathtt{eff}(t)} \right] + \frac{\Lambda}{3}, \tag{4}$$

where $H(t) = \dot{a}(t)/a(t)$ is the Hubble parameter. From (3) and (4), the time evolution of the Hubble parameter can be deduced

$$\dot{H}(t) = -4\pi \left[\rho(t) + p_{\mathtt{eff}}(t) \right] + \frac{k}{a(t)^2}. \tag{5}$$

An EoS relating p with ρ is needed to have a closed system of equations.

The present script is organized as follows. The most reliable non-perturbative and perturbative calculations are reviewed in section 2. Our results on EoS, bulk viscosity and relaxation time for almost the entire SM dof are presented in section 3. The conclusions are outlined in section 4.

2. Most reliable non-perturbative and perturbative calculations

For relaible EoS, various general considerations have been assumed in the recent non-perturbative lattice QCD simulations.[9] The first one is the quark masses. For a dynamical dependence of the quark masse m_q and the lattice spacing a on the guage coupling β, four flavor staggered action with 4 levels of stout smearing has been utilized, where u, d, s, and c quarks are realized as 2+1+1 and 3+1,[9] i.e., except for strange and charm quark masses, $m_{ud} = R \times m_s^{st}(\beta)$, with $m_s^{st}(\beta)$, $1/R = 27.63$ and β is the guage coupling. The c quark mass is given as a function of the gauge coupling; $m_c = C \times m_s^{st}(\beta)$, with $C = 11.85$. Although the degenerate masses of the light quarks, a small isospin asymmetry could also be included, analytically.[9]

The second general consideration is the temperature T, which can primarily be determined as a function of the temporal lattice dimension; $T = (aN_\tau)^{-1}$. Alternatively, varying the gauge coupling β leads to changing T, as well, even if the spacial

and temporal lattice dimensions might not be varied. The gauge coupling can not only allow for varying T, but also it measures the pseudoscalar pion mass m_π and the Wilson–flow based scale ω_0, where $\omega_0 = 0.153 \pm 0.001$ fm and $m_\pi = 712 \pm 5$ MeV. At $T = 0$, ω_0 gives the inverse flow time.[10]

The third general consideration is the lattice QCD computational procedure. After applying a Wilson–flow equation, the clover definition of the topological charge was made in $2 + 1 + 1$ and $3 + 1$ ensembles. To make the computational process more economic, an adaptive step size integration scheme was utilized. The time flow $(8T^2)^{-1}$ was introduced to estimate the finite T of both ensembles, where a variation in the time flow is also allowed. This procedure has greatly contributed to reducing the systematic errors. To control their simulations, it should be checked whether these configurations lead to saturated susceptibility, at large flow times.[9] To determine the topological susceptibility, topological charge was utilized with and without rounding.

The fourth general consideration is the acceptance accuracy. As already outlined for the $2+1+1$ simulations, same configurations have been used also for $3+1$ simulations. Here, the mass ratio of the charm quark and the degenerate lighter quarks (u, d, and s) was taken to be 11.85. As mentioned, for the masses of up– and down–quarks, the physical values are used, while the mass of the strange quark is a function of the guage coupling, $m_s^{\mathtt{st}}(\beta)$. At $T = 0$, simulations were done on 64×32^3 lattice with seven values of the lattice spacing descendingly ranging from 0.15 to 0.06 fm. But at finite T, the same parameters as in $2+1+1$ case were used. The topological charge is measured for every Hybrid Monte–Carlo trajectory. The configurations leading to a topology change are rejected. In other words, configurations are generated, at fixed topology. Quantitatively, this leads to an acceptance probability of about 40% for the coarsest lattice, but higher probabilities for the finest ones.

In the following section we review how various thermodynamic quantities have been determined.

2.1. *Lattice QCD Equation of State in Non-Perturbative Regime*

The inclusion of up–, down–, strange–, and charm–quark in non–perturbative lattice QCD simulations[11,12] assumes that the masses of some quarks are very heavy (partially quenched). Other lattice QCD simulations assume that the four quarks are non–degenerate with unphysical masses.[13,14] The ultimate goal is to carry out non–perturbative simulations with dynamical quarks and physical masses.[15] To this end, $2+1+1$ simulations with staggered action, and 4 levels of stout smearing have been carried out in Ref.[16].

One restriction in the lattice QCD simulations is the universal assumption of thermal equilibrium. This might not fully true, especially because the hadron and parton matter is undergoing phase transition, whether prompt of slows crossover, at critical temperatures, i.e., non–equilibrium due to changes in the underlying

dynamics, symmetry, and degrees of freedom. Another restriction is that the temperature dependence of pressure p, energy density ρ, and entropy s can be deduced from the trace anomaly, at vanishing chemical potential,

$$\frac{I(T)}{T^4} = \frac{\rho - 3p}{T^4}, \tag{6}$$

$$\frac{\rho + p}{T^4} = \frac{s}{T^3}. \tag{7}$$

A third restriction is the common practice to get rid of the temperature independent divergence of the trace anomaly so that its physical value can be evaluated, accurately. A vanishing–T ensemble is subtracted from each finite–T ensemble. As this method doesn't work well at high temperatures, where short lattice spacing and increasing autocorrelation times and computational costs are likely, a renormalization ensemble is generated for each finite–T ensemble, at exactly half of its temperature.[9] The physical trace anomaly in a wide range of temperatures including low T, can be obtained from the subtraction of each half–T from its finite–T ensemble, $[I(T) - I(T/2)]/T^4$. The resulting ρ and s can straightforwardly be estimated from Eqs. (6) and (7).

Up to four quark flavors were included in the non–perturbative lattice QCD simulations. This was achieved by several steps of tree–level corrections.

2.2. *Inclusion of c–Quark in Non–Perturbative Lattice QCD Simulations*

It was concluded[17] that the free energy calculated in next–to–next–to–leading order (NNLO) Hard Thermal Loop (HTL) perturbation theory is in good agreement with $2 + 1$ and $2 + 1 + 1$ non–perturbative lattice QCD simulations, where c–quark is taken massless in the perturbative calculations but assigned the physical mass in the non–perturbative simulations. The mass of c–quark was perturbatively[18] and non–perturbatively[9] estimated. In the perturbative calculations, the effect of heavy quarks is determined to a lower leading order, and accordingly, it was concluded that this refers to $(3 + 1)$ quark flavors pressure normalized to (3) quark flavors pressure p. On the other hand, when comparing p with and without c–quark in both non–perturbative and perturbative calculations, an excellent agreement ($< 3\%$) was obtained.[9] The tree–level correction due to c–quark reads

$$\frac{p^{(2+1+1)}(T)}{p^{(2+1)}(T)} = \frac{SB^{(3)}(T) + F_Q(m_c/T)}{SB^{(3)}(T)}, \tag{8}$$

where SB stand for Stefan–Boltzmann approximation and $F_Q(m_c/T)$ is the free energy density of a free quark with mass $m_c = 1.29$ GeV.

The following section elaborates how the b–quark flavor is included non–perturbative lattice QCD simulations. This was achieved by several steps of tree–level corrections.

2.3. *Inclusion of b–Quark in Non–Perturbative Lattice QCD Simulations*

The success with the inclusion of the c–quark encouraged a recent attempt with the bottom quark, especially that the $2+1+1$ non–perturbative simulations up to $T \lesssim 1$ GeV control the accuracy of the proposed procedure and the perturbative contributions likely dominate, at $T \gtrsim 500$ MeV).[19,20] Recent perturbative calculations were performed up to $\mathcal{O}(g^6 \log g)$.[9] Thus, the inclusion of b–quark and a continuation to higher T look straightforward. A tree–level correction for the b–quark similar to that for the c–quark, Eq. (8), was suggested.

It was concluded that tree–level correction for b–quark works well. When comparing the ratio of the massless 2+1+1 to 2+1+1+1 perturbative pressure with the pressure ratio in the SB limit, an excellently agreement ($< 0.3\%$) is obtained. With a phenomenological approach similar to Eq. (8), reliable non–perturbative lattice QCD simulations become feasible, at 500 MeV $< T <$ 10 GeV. This T–range apparently covers various epochs in the early Universe, where different phase transitions and accordingly different dynamics and degrees of freedom become dominant.

In the following section, we review features of the perturbative calculations up to TeV temperatures.

2.4. *Perturbative Calculations up to TeV Temperature–Scales*

In the previous sections, we have discussed on the various restrictions of the non–perturbative lattice QCD simulations and their possible extensions to a large number of quark flavors and to higher temperatures. The perturbative calculations, on the other hand, allow to cover much higher temperatures and to include more quark flavors. By combining recent perturbation calculations up to a largest leading order with the non–perturbative lattice QCD simulations, relaible EoS for strong and electroweak matter can be deduced.[21,22] It is conjectured that this covers temperatures up to ~ 200 TeV.

2.4.1. *QCD Domain*

In this domain, $0.2 \lesssim T \lesssim 1$ GeV, the gluons and the lightest four quark flavors and the gluons are partonic dof of the strongly interacting matter.[21] The perturbative corrections to the ideal (masslss, noninteracting) Stefan-Boltzmana (SB) EoS can be determined up to different orders of strong coupling constant $\mathcal{O}(g)$. Although, the perturbative contributions up to $\mathcal{O}(g^6 \log g)$ are well known,[19,23,24] where g is expressed as function of N_c the colors dof, N_f the massless quark flavors dof, and μ_f the quark chemical potential, only $\mathcal{O}(g^2)$ terms, at $T = 0$ but $\mu_f \neq 0$, have been precisely, analyzed.

Besides the contributions of gluons up to $\mathcal{O}(g^6 \log g)$ and that of NLO $\mathcal{O}(g^2)$, it was found that these are similar to that of LO $\mathcal{O}(g^0)$, where no $\mathcal{O}(g^6 \log g)$ calculations for finite quark masses are available so far.[18] An alternative procedure was

suggested. This starts with $N_f = 0$ and $N_c = 3$ corresponding to very heavy quark flavors. Then, it calculates the change in the pressure by lowering the quark masses down to their physical values[a]. This procedure suggests that the perturbative calculations are based on the grand–canonical pressure (or free energy).[9] As discussed earlier, the non–perturbative lattice QCD simulations starts with the trace anomaly (also known as the interaction measure) $I(T, \mu_f, \cdots)$, Eq. (6), from which the various thermodynamic quantities can be determined. Based on this renormalization procedure, the ultraviolet divergences are likely removed.

In order to extend the perturbative calculations to the electroweak domain, the so–called *hard modes* should first be removed through either integration with respect to momenta or summation over the Matsubara frequencies, $2\pi T$, gT, g^2T, $\cdots$. Second, the effective mass parameters and the gauge couplings have to be specified and normalized in $\overline{\mathtt{MS}}$–scheme. Third, the connection factors should then be estimated, at changing T and fixed $\Lambda_{\overline{\mathtt{MS}}}$. These can be achieved, when multiplying the non–perturbative lattice results for $N_f = 0$, $N_c = 3$, finite quark masses by the corresponding ones obtained in the SB limit, Eq. (8). The connection factors facilitate the inclusion of heavier quarks, at temperatures greater that strong QCD scale parameter $\Lambda_{QCD} \sim 200$ MeV.

2.4.2. *Electroweak Domain*

As discussed, the perturbative calculations are initiated from the free energy (or thermodynamic pressure), the Higgs potential parameters $v^2(\bar{\mu})$ and $\lambda(\bar{\mu})$ are given as functions of the normalization scale $\bar{\mu}$. Assuming that the bottom and top quarks weakly interact, the free energy, at finite T and $\boldsymbol{\mu}$, reads[18]

$$f(v, T, \boldsymbol{\mu}) = -\frac{1}{2}\nu^2(\bar{\mu})v^2 + \frac{1}{4}\lambda(\bar{\mu})v^4 + \sum_{i}^{n_q+n_g} \pm J_i(m_i(v), T, \mu_i), \tag{9}$$

where n_q (n_g) are the number of quarks (gluons), v is the Higgs expectation value, $m_i(v)$ is the tree–level mass of i–th particle, $\pm$ stand for bosons and fermions, respectively, and $J_i(m_i(v), T, \mu_i)$ counts for the contributions of the physical dof (scalars, vectors, and fermions). The normalization scale $\bar{\mu}$ could be fixed to 100 GeV[b]. Nevertheless, the electroweak free energy, Eq. (9), can be determined, at temperatures far beyond the electroweak scale $\bar{\mu} \sim 100$ GeV.

As the proposed EoS characterizes electroweak matter, a few remarks on the nature of the phase transitions is now in order. In some perturbative calculations, it was concluded that the electroweak EoS seems approaching that of an ideal gas,[18] while in others significant deviations have been obtained.[25] With this regard, it should be considered that the strength of electroweak phase transition is

[a] Decreasing the quark masses increases the thermodynamic pressure.

[b] This is a model–depending assumption. Originally, the electroweak theory has different scales along its wide range of temperatures and chemical potentials.

determined by different SM Lagrangian parameters, which so far aren't determined. The recently estimation of the Higgs mass allowed for a smooth crossover and electroweak baryogenesis.[26, 27]

2.5. *Combining Non-Perturbative and Perturbative EoS*

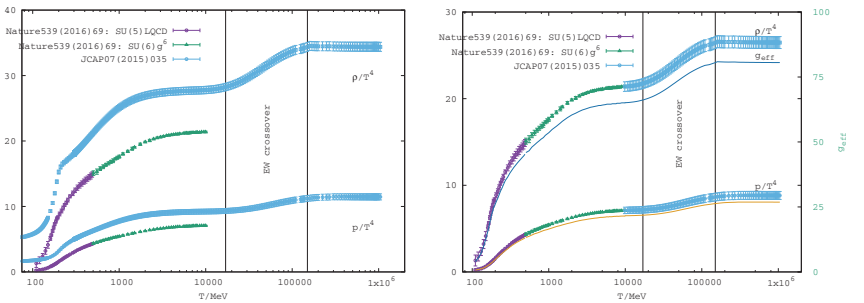

Fig. 1. Left panel: A comparison between non–perturbative lattice QCD simulations[9] and the perturbative calculations[18] for normalized pressure and energy density as functions of temperatures. Right panel: The same as in the left panel but here the perturbative calculation are rescalled (see main text). The vertical lines approximately determine the temperatures, where the electroweak crossover takes place. The curves in right panel present the effective dof $\mathtt{g_{eff}}(T)$ related to pressure and energy density.

As discussed, the proposal to combine reliable non–perturbative with perturbative calculations was already applied in various studies. In the present study, we combine the non–perturbative[9] with the perturbative calculations[18] for different thermodynamic quantities.

The temperature dependence of the normalized pressure and energy density calculated non–perturbatively and perturbatively is illustrated in the left panel of Fig. 1. Here, the temperature covers up to $\sim$ 10 GeV and $\sim$ 1 TeV in non–perturbative and perturbative simulations, respectively. It is obvious that although both types of simulations look quantitatively different, they are qualitatively similar. We find that the perturbative results are significantly larger than the non–perturbative ones.

There are many reasons supporting the assumption that the non–perturbative lattice QCD simulations are more reliable than the perturbative ones, especially at low temperatures. In this range of temperatures, even the vacuum energy change is best evaluated by non–perturbative simulations. On one hand, the non–perturbative lattice QCD simulations are most reliable, at low temperatures, the so–far perturbative calculations are not as accurate even at high temperatures. Thus, we concretely propose that the non–perturbative lattice QCD simulations are most reliable, at $T \gtrsim \Lambda_{\mathtt{QCD}} \approx 200$ MeV up to a few GeV,[28] while the perturbative calculations are the only approach possible, at temperatures up to the TeV–scale. From Fig. 1,

a temperature–indenedent systematic difference of $\sim 20\%$ between both sets of calculations[c] is obtained. Also, we assumed that the systematic difference of $\sim 20\%$ ins the same for both pressure and energy density.

For a contineous temperature–dependence of pressure and energy density, we propose to rescale the perturbative calcuations, at high temperatures.[18] The rescaling factor is phenomenologically adjusted to match the perturbative calculations, at high temperatures, with the non–perturbative lattice QCD simulations, at low temperatures. We assume that a rescaling factor of 0.77 remains constant, at the entire range of temperatures, right panel of Fig. 1. The non–perturbative lattice QCD simulations aren't rescaled, at all. In both thermodynamic quantities, both non–perturbative (T up to ~ 10 GeV) and perturbative ($10\ \texttt{GeV} \lesssim T \lesssim 1$ TeV) calculations are phenomenologically combined. The effective dof $\mathtt{g_{eff}}(T)$ corresponding to pressure, $\mathtt{g_{eff}}(T) = p(T)/p_0$, and to energy density, $\mathtt{g_{eff}}(T) = \rho(T)/\rho_0$, are also depicted in the right panel of Fig. 1, where $\rho_0 = (\pi^2/30)T^4$ is the energy density and p_0 is the pressure for an ideal gas of scalar massless bosons $p_0 = (\pi^2/90)T^4$. The perfect matching of $\mathtt{g_{eff}}(T)$, at low and high temperatures, supports the conclusion that the temperature–independent proposed rescaling, 0.77, seems precise.

3. EoS, bulk viscosity and relaxation time for almost entire SM dof

3.1. *EoS for Strong and Electroweak Matter*

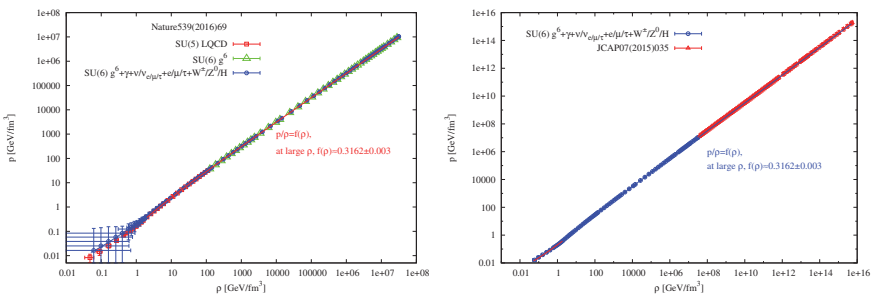

Fig. 2. Left panel: The thermodynamic pressure calculated in $\mathtt{SU(5)}$ non–perturbative and perturbative lattice QCD in dependence on the corresponding energy density (red and green symbols)[9] is confronted to the same calculations extended to other dof; γ, neutrinos, leptons, EW, and Higgs bosons (blue symbols). Right panel: The extended $\mathtt{SU(5)}$ lattice QCD calculations are combined with $\mathtt{SU(6)g^6}$ non–perturnative calculations.[21,29]

Left panel of Fig. 2 shows the EoS deduced from $\mathtt{SU(5)}$ non–perturbative and perturbative lattice QCD simulations (red and green symbols).[9] The thermodynamic contributions from γ, ν, e, μ, τ, ν_e, ν_μ, ν_τ, $W^\pm$, and the Higgs boson H are summed

[c]It was reported in Ref.[9] that this difference reads $7 - 17\%$ and is temperature dependent!

up with the SU(5) results (blue symbols). For each type of the additional particles, a partition function is constructed, from which the temperature dependence of the different thermodynamic quantities, such as the thermodynamic pressure and the energy density, can straightforwardly be derived. It is obvious that the additional dof considerably contribute to both thermodynamic quantities. The quantitative contributions are considrable, for example, within the hadronic phase, the proportionality constant in $p \propto \rho$ increases with the additive dof, i.e., increasing speed of sound squared.[30] In quark–gluon plasma and electroweak phases, more structures are added to the one corresponding EoS based on SU(5) lattice QCD simulations.

The fitting functions illustrated in the bottom panel of Fig. 2 are

$$\texttt{HP}: \qquad p = \alpha_1 + \alpha_2 \rho, \tag{10}$$

$$\texttt{QGP/EW}: \qquad p = \beta_1 + \beta_2 \rho + \beta_3 \rho^{d_2}, \tag{11}$$

$$\texttt{Asymp.}: \qquad p = \gamma \rho, \tag{12}$$

where $\alpha_1 = 0.0034 \pm 0.0023$, $\alpha_2 = 0.1991 \pm 0.0022$, $\beta_1 = 0.0484 \pm 0.0164$, $\beta_2 = 0.3162 \pm 0.0031$, $\beta_3 = -0.21 \pm 0.014$, and $\gamma = 0.3162 \pm 0.003$.

3.2. *Bulk Viscosity for Strong and Electroweak Matter*

It was concluded that the shear viscosity normalized to the entropy density for perturbative gauge QCD likely approaches the lower bound of Anti–de Sitter/Conformal Field Theory (AdS/CFT).[31] A non–perturbative estimation for viscous coefficients, at temperatures several times the QCD scale, has been reported in Ref.[32,33]. This was possible through accumulating a large amount of configurations for the Green function expressed in the Matsubara frequencies and implemented on isotropic $24^2 \times 8$ and $16^2 \times 8$ lattices. The viscous coefficients are determined as slopes of the spectral functions, at vanishing Matsubara frequency. A recent estimation for the temperature dependence of the bulk viscosity of SU(3) gluodynamics was possible with $48^3 \times 16$ lattice QCD simulations.[33] Another estimation is based the retarded Green function defined by the Kramers–Kronkig relation in terms of different thermodynamic quantities.[34,35] In Ref.[35], it was taken into consideration that the bulk viscosity measures the violation of the conformal invariance. This allowed to conclude that QCD at classical level is conformally invariant.

$$\begin{aligned}\zeta = \frac{1}{9\omega_0}\Big[& T\,s\left(\frac{\partial \rho}{\partial p} - 3\right) - 4(\rho - 3p) && \texttt{thermal parts} \\ & + \left(T\frac{\partial}{\partial T} - 2\right)\langle \bar{q} q \rangle(T) + g_g\, G^2(T) && \texttt{thermal q \& g condensates} \\ & + g_f\left(m_\pi^2 f_\pi^2 + m_K^2 f_K^2 + m_D^2 f_D^2 + \cdots\right)\Big]. && \texttt{vacuum q \& g condensates}\end{aligned} \tag{13}$$

where g_g (g_f) are the degeneracy factors for gluons (quarks). The spin polarization multiplied is $g_g = 16$. The color degrees of freedom reads $N_c^2 - 1$, with N_c is the color quantum number. $g_f = 12\, n_f$ with n_f are the degrees of freedom of the quark

flavors. m_D (f_D) are mass (decay constant of D-meson). The scale parameter ω_0 determines the applicability of the parturbation theory. ζ is obtained by using the frequency limit of the spectral density, at vanishing spatial momentum[35,36] and by implementing the various thermodynamic quantities are detailed in Eq. (13).

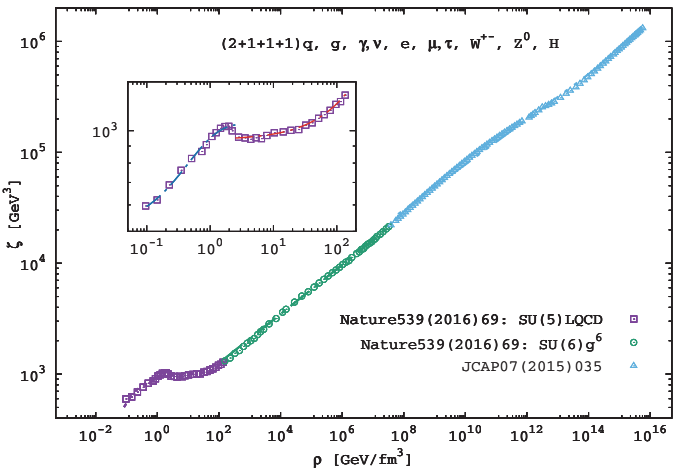

Fig. 3. The bulk viscosity ζ in dependence of the energy density ρ. Both quantities are calculated, at vanishing baryon–chemical potential and given in physical units. The inside box magnifies the region, at low temperature, where $\zeta(\rho)$ is non–monotonic.

By combining the gluons and $(2+1+1+1)$ quark contributions and that of the gauge bosons; the photons, $W^{\pm}$, and Z^0, of the charged leptons; neutrino, electron, muon, and tau, and of the Higgs bosons; scalar Higgs particle,[8] the bulk viscosity is shown in Fig. 3. We conclude that the almost entire SM contributions are very significant. The missing SM–contributions are vacuum and thermal bottom quark condensate, the entire gravitational sector, neutral leptons, and top quark. ζ almost linearly increases with increasing energy–density, so that following three regions of parameterizations (curves) can be distinguished

$$\texttt{Hadron}-\texttt{QGP}:\ \zeta = a_1 + a_2\rho + a_3\rho^{a_4}, \tag{14}$$

$$\texttt{QCD}:\ \zeta = b_1 + b_2\rho^{b_3}, \tag{15}$$

$$\texttt{EW}:\ \zeta = c_1 + c_2\rho^{c_3}. \tag{16}$$

For Hadron–QCD: $a_1 = -9.336 \pm 4.152$, $a_2 = 0.232 \pm 0.003$, $a_3 = 11.962 \pm 4.172$, and $a_4 = 0.087 \pm 0.029$. For QCD: $b_1 = 8.042 \pm 0.056$, $b_2 = 0.301 \pm 0.002$, and $b_3 = 0.945 \pm 0.0001$. For EW: $c_1 = 0.350 \pm 0.065$, $c_2 = 10.019 \pm 0.934$, and $c_3 = 0.929 \pm 8.898 \times 10^{-5}$.

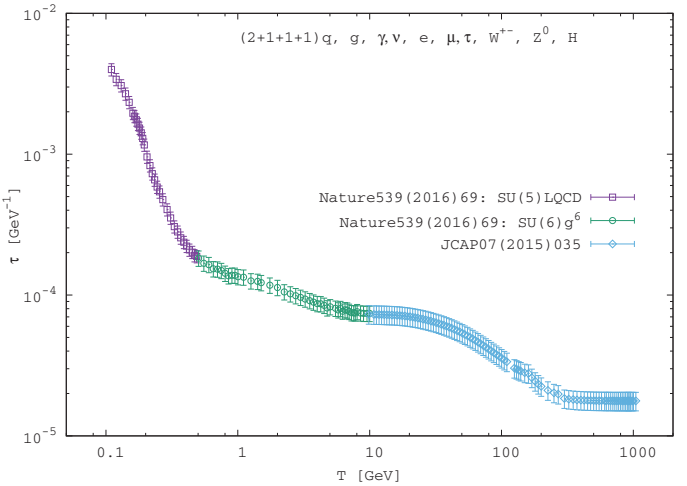

Fig. 4. At vanishing baryon–chemical potential, the relaxation time τ is presented in dependence on the temperature T. The results are based on non–perturbative and perturbative lattice QCD simulations, in which contributions from the quark and gluon condensates and the thermodynamic quantities of gauge bosons, charged leptons, and Higgs bosons (left symbols) are integrated.

3.3. *Relaxation Time for Strong and Electroweak Matter*

The relaxation time τ_f, which involves complicated collision integrals, can be determined as the mean collision time and averages of thermodynamic quantities[37–39]

$$\tau_f(T) = \frac{1}{n_f(T)\,\langle v(T)\rangle \sigma(T)}, \tag{17}$$

where σ is cross section, $\langle v(T)\rangle$ stands for mean relative velocity, and $n_f(T)$ represents the number density. Approaches for $\langle v(T)\rangle$ and σ have been discussed in Ref.[39]. The temperature dependence of the relaxation time $\tau_f(T)$ plays an essential role in bulk viscosity $\zeta(T)$.

Figure 4 presents $\tau(T)$ deduced from the non–perturbative and perturbative QCD simulations[8,9,21,29] (bottom symbols). Contributions from the quark and gluon condensates and the thermodynamic quantities of the gauge bosons, charged leptons, and Higgs bosons are added (left symbols). We notice that τ steadily decreases with increasing T. In the different phases, there are different rates of decreasing τ.

4. Conclusions

Most reliable non–perturbative lattice QCD simulations and perturbative calculations with as much as possible quark flavors with physical masses are phenomenologically combined. The thermodynamic contributions of photons, charged neutrinos, leptons, electroweak particles ($W^{\pm}$ and Z^0 bosons), and the scalar Higgs bosons are also integrated in. This makes the present study pioneering in a) simultaneous

accessing hadron, quark–gluon plasma and electroweak epochs of the early Universe and b) including almost all degrees of freedom of the standard model. With this regard, we emphasize that the only missing SM dof are vacuum and thermal bottom quark condensate, the entire gravitational sector, neutral leptons, and top quark flavor.

We have introduced various thermodynamic quantities, including pressure, energy density, bulk viscosity, and relaxation time, at vanishing net–baryon cosmic matter and temperatures up to the TeV–scale. The main result is that recent non–perturbative lattice QCD simulations and perturbative calculations jointly lead to EoS covering a wide range of temperatures. As never done before, this study makes introduces a framework to combine the standard model of the elementary particles and the standard model for cosmology.

We review our recent results on the creation from the vacuum of neutral fermions with anomalous magnetic moments by a Sauter-like magnetic field. We construct in- and out solutions of the Dirac-Pauli equation with this field and calculate with their help pertinent quantities characterizing the vacuum instability, such as differential mean numbers and flux density of created pairs and and vacuum-to-vacuum transition amplitudes. Special attention is paid to situations where the external field lies in two particular configurations, varying either "gradually" or "sharply" along the inhomogeneity direction. We also estimate critical magnetic field intensities, near which the phenomenon could be observed.

Keywords: Dirac-Pauli equation; quantum electrodynamics; pair production; neutral fermions with anomalous magnetic moment

1. Introduction

The violation of the vacuum stability stimulated by external electromagnetic fields is commonly associated with the possibility of such backgrounds producing work

on virtual pairs of particles and antiparticles. The most well-known examples are electric-like fields, as they produce work on charged particles and are able to tear apart electron/positron pairs from the vacuum if the field amplitudes approach the so-called Schwinger critical value $E_{\rm c} = m^2c^3/e\hbar \approx 1.3 \times 10^{16}\,{\rm V/cm}$.[1] The phenomenon has been a subject of intense investigation since the seminal works of Klein,[2] Sauter,[3,4] Heisenberg and Euler,[5] and Schwinger.[1] An extensive discussion about the origin of the effect, theoretical foundations, and experimental aspects can be found in some reviews and monographs; see e.g.[6–15] and references therein.

Following the above interpretation, one may ask oneself about the possibility that inhomogeneous macroscopic magnetic fields which produce a work on particles with a magnetic moment, may create pairs from the vacuum. The answer to this question is affirmative, provided the particles are neutral and have an anomalous magnetic moment. Bearing in mind, first of all, very strong magnetic fields observed in astrophysics, we can assume that this type of field is practically time-independent and steplike, that is, their gradient has a well-defined sign. At present, there exist two types of particles enjoying the properties mentioned above: the neutron and the neutrino. According to experimental data, neutrons have a magnetic moment $\mu_N \approx -1.04187563(25) \times 10^{-3}\mu_{\rm B}$,[16] where $\mu_{\rm B}$ is the Bohr magneton. As for neutrinos, there is not a general consensus because of the different types of neutrinos, mechanism under which neutrinos acquires magnetic moment, specific models, etc. Presently, experimental constraints range from $\mu_{\nu_\tau} < 3.9 \times 10^{-7}\mu_{\rm B}$ (for the tau neutrino)[17] until $\mu_{\nu_e} < 2.9 \times 10^{-11}\mu_{\rm B}$ (for the electron neutrino).[18] Moreover, stringent constraints obtained from astrophysical observations[19–24] indicate that $\mu_\nu < (2.6 - 4.5) \times 10^{-12}\mu_{\rm B}$ while lower upper bounds, predicted by effective theories above the electroweak scale, suggest that $\mu_\nu < 10^{-14}\mu_{\rm B}$.[25] It is important to point out that for some theories beyond the Standard Model (SM),[26] it was reported that the magnetic moment for the neutrinos lie within the range $\left(10^{-12} - 10^{-14}\right)\mu_{\rm B}$. For a more extensive discussion concerning experimental aspects and theoretical predictions for neutrinos' electromagnetic properties, see e.g. the reviews[27–31] and references therein.

In this work, we review our recent results on the creation of neutral fermions with anomalous magnetic moments from the vacuum by Sauter-like magnetic field.[32] We follow the general formulation developed to describe the effect nonperturbatively, which is based on the canonical quantization of fermion fields with time-independent inhomogeneous external fields.[33–35] The system under consideration is placed in the four-dimensional Minkowski spacetime, parameterized by coordinates $X = (X^\mu\,,\ \mu = 0, i) = (t, \mathbf{r})$, $X^0 = t$, $X^i = \mathbf{r} = (x, y, z)$, $i = 1, 2, 3$, with the metric tensor $\eta_{\mu\nu} = {\rm diag}\,(+1, -1, -1, -1)$. We also employ natural units, in which $\hbar = 1 = c$.

2. Solutions of Dirac-Pauli equation with Sauter-like magnetic step

The Dirac-Pauli (DP) equation[36] for a neutral spin 1/2 particle with the anomalous magnetic moment μ, the mass m interacting with external electromagnetic backgrounds $A^\mu = \left(A^0, \mathbf{A}\right)$ has the form:

$$\left(i\gamma^\mu \partial_\mu - m - \frac{1}{2}\mu\sigma^{\mu\nu}F_{\mu\nu}\right)\psi\left(X\right) = 0\,,$$
$$\sigma^{\mu\nu} = \frac{i}{2}\left[\gamma^\mu, \gamma^\nu\right]_-\,, \quad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu\,. \tag{1}$$

Here $\psi\left(X\right)$ is a bispinor, $\gamma^\mu = \left(\gamma^0, \boldsymbol{\gamma}\right)$ are Dirac matrices, and μ is the algebraic value of the anomalous magnetic moment (e.g., $\mu = -\left|\mu_N\right|$ for a neutron). In what follows we consider external electromagnetic fields of a specific type, corresponding to a time-independent magnetic field oriented along the positive direction of the z-axis, inhomogeneous along the y-direction, $\mathbf{B}\left(\mathbf{r}\right) = \left(0, 0, B_z\left(y\right)\right)$, and homogeneous at remote distances, $B_z\left(\pm\infty\right) = \text{const}$. Moreover, it is assumed that its gradient is always positive $\partial_y B\left(y\right) \geq 0$, $\forall\, y \in \left(-\infty, +\infty\right)$, meaning that $B_z\left(+\infty\right) > B_z\left(-\infty\right)$ and that the field is genuinely a step (or steplike, in short). To study neutral fermion pair production by steplike magnetic fields, we consider that the magnetic field inhomogeneity is given by the analytic function

$$B_z\left(y\right) = \varrho B' \tanh\left(y/\varrho\right)\,, \quad B' > 0\,, \quad \varrho > 0\,, \tag{2}$$

which meets the conditions discussed above and allows solving the DP equation exactly. The amplitude B' and the length scale ϱ describe, respectively, the "slope" of the field with respect to the y-axis and how "rectilinear" it is in the neighborhood of the z-axis. Thus, the larger B' and ϱ, the more "steep" and the more "rectilinear" the pattern of (2) near the z-axis. Because the field (2) resembles a step-like "potential" for charged particles and its gradient has a Sauter profile,[4] we call the field (2) Sauter-like magnetic step. For illustrative purposes, we present the field (2) and its gradient for some values of ϱ and B' in Fig. 1.

In the Schrödinger form, the DP equation (1) reads[32,33,37]

$$i\partial_t\psi\left(X\right) = \hat{H}\psi\left(X\right)\,, \quad \hat{H} = \gamma^0\left(\gamma^3\hat{p}_z + \Sigma_z\hat{\Pi}_z\right)\,. \tag{3}$$

Here $\Sigma_z = i\gamma^1\gamma^2$ and

$$\hat{\Pi}_z = \hat{\pi}_z - \mathbb{I}\mu B_z\left(y\right)\,, \quad \hat{\pi}_z = \Sigma_z\left(\boldsymbol{\gamma}\hat{\mathbf{p}}_\perp + m\right)\,, \tag{4}$$

is an integral-of-motion spin operator, $\left[\hat{\Pi}_z, \hat{H}\right]_- = 0$. The subscript "$\perp$" labels quantities perpendicular to the field, e.g. $\hat{\mathbf{p}}_\perp = \left(\hat{p}_x, \hat{p}_y\right)$ and $\mathbb{I}$ denotes the 4×4 identity matrix. Since the operators $\hat{p}_0$, $\hat{p}_x$, and $\hat{p}_z$ are compatible with the Hamiltonian (and also with $\hat{\Pi}_z$), the DP spinor admits the general form $\psi_n\left(X\right) = \exp\left(-ip_0 t + ip_x x + ip_z z\right)\psi_n\left(y\right)$, where $\psi_n\left(y\right)$ depends exclusively on y

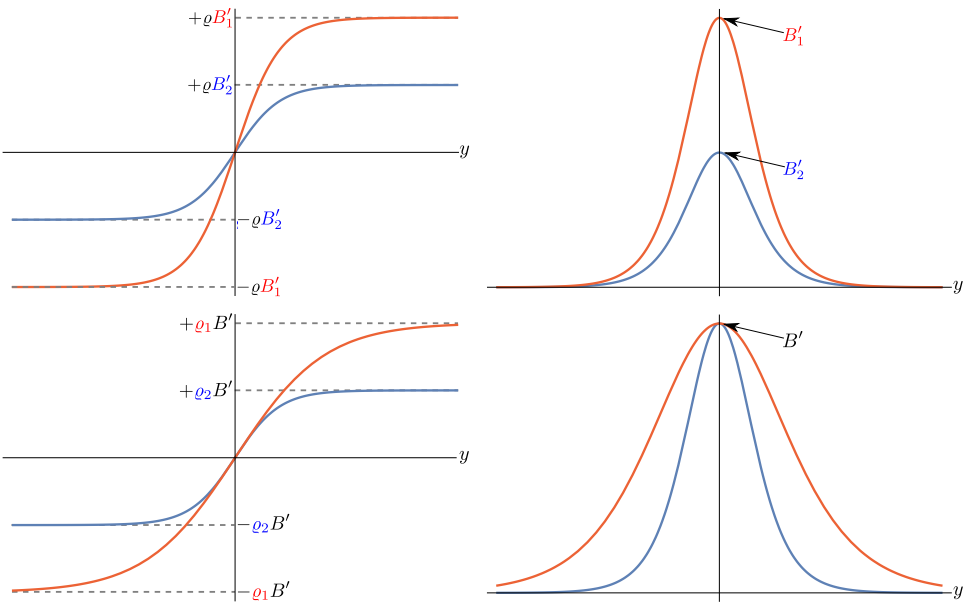

Fig. 1. Sauter-like magnetic steps (2) (pictures on the left) and its gradient (pictures on the right). In the upper panel, $B_1' = 2 \times B_2'$ while in the lower panel, $\varrho_1 = 2 \times \varrho_2$.

and is solution of the eigenvalue equation:

$$\hat{\Pi}_z \psi_n(X) = e^{-ip_0 t + ip_x x + ip_z z} \Pi_z \psi_n(y) \ , \quad \Pi_z \psi_n(y) = s\omega \psi_n(y) \ , \quad s = \pm 1 \, ,$$
$$\Pi_z = \hat{\pi}_z - \mathbb{I}\mu B_z(y) \ , \quad \hat{\pi}_z = \Sigma_z \left(\gamma^1 p_x + \gamma^2 \hat{p}_y + m\right) \ , \quad p_0^2 = \omega^2 + p_z^2 \, . \tag{5}$$

Due to the structure of the external field (2), there is an additional integral-of-motion spin operator

$$\hat{R} = \hat{H}\hat{\Pi}_z^{-1} \left[\mathbb{I} + \left(\hat{p}_z \hat{\Pi}_z^{-1}\right)^2\right]^{-1/2} \ , \tag{6}$$

which is compatible with the Hamiltonian $\left[\hat{R}, \hat{H}\right]_- = 0$ and with all previous operators, $\left[\hat{R}, \hat{\Pi}_z\right]_- = \left[\hat{R}, \hat{p}_0\right]_- = \left[\hat{R}, \hat{p}_x\right]_- = \left[\hat{R}, \hat{p}_z\right]_- = 0$. In particular, the operator (6) implies that $\psi_n(y)$ is a solution of the eigenvalue equation

$$\hat{R}\psi_n(X) = e^{-ip_0 t + ip_x x + ip_z z} R\psi_n(y) \ , \quad R\psi_n(y) = s\psi_n(y) \ ,$$
$$R = \Upsilon \gamma^0 \left(\Sigma_z + \frac{s p_z}{\omega} \gamma^3\right) \ , \quad \Upsilon = \frac{1}{\sqrt{1 + p_z^2/\omega^2}} \, . \tag{7}$$

As a result, the complete set of commuting operators is $\hat{p}_x$, $\hat{p}_z$, $\hat{\Pi}_z$, $\hat{R}$ and the corresponding quantum numbers are $n = (p_x, p_z, \omega, s)$.

The set of equations (5) and (7) are simultaneously satisfied choosing $\psi_n(y)$ in the form

$$\psi_n(y) = (\mathbb{I} + sR)\left[\hat{\pi}_z + \mathbb{I}(\mu B_z(y) + s\omega)\right]\varphi_{n,\chi}(y)\upsilon_\kappa^{(\chi)}, \tag{8}$$

where $\upsilon_\kappa^{(\chi)}$ belongs to a set of four constant spinors, satisfying the eigenvalue equations

$$i\gamma^1\upsilon_\kappa^{(\chi)} = \chi\upsilon_\kappa^{(\chi)}, \quad \gamma^0\gamma^2\upsilon_\kappa^{(\chi)} = \kappa\upsilon_\kappa^{(\chi)}, \quad \chi = \pm 1, \quad \kappa = \pm 1, \tag{9}$$

and the orthonormality conditions $\upsilon_{\kappa'}^{(\chi')\dagger}\upsilon_\kappa^{(\chi)} = \delta_{\chi'\chi}\delta_{\kappa'\kappa}$. As for the scalar functions $\varphi_{n,\chi}(y)$, they are solutions of the second-order ordinary differential equation:

$$\left\{-\frac{d^2}{dy^2} - [s\omega + \mu B_z(y)]^2 + \pi_x^2 + i\mu\chi B_z'(y)\right\}\varphi_{n,\chi}(y) = 0, \quad \pi_x^2 = m^2 + p_x^2. \tag{10}$$

The potential energy of a neutral fermion interacting with the field is $U_s(y) = sU(y)$, where $U(y) = -\mu B_z(y)$. To facilitate subsequent discussions, it is convenient to select a fixed sign for particle magnetic moment. From now on, we choose a fermion with a negative magnetic moment as the main particle, $\mu = -|\mu|$. Because the field (2) increases monotonically with y, the maximum potential energy that may be experienced by the fermion is determined by the magnitude of the "step" $\mathbb{U}$

$$\mathbb{U} \equiv U_{\mathrm{R}} - U_{\mathrm{L}} = 2\varrho|\mu|B' > 0, \tag{11}$$

which is the difference between the asymptotic values $U_{\mathrm{R}} = U(+\infty) = |\mu|\varrho B'$, $U_{\mathrm{L}} = U(-\infty) = -|\mu|\varrho B'$ and is positive, by definition[a]. At remote distances– where the field can be considered homogeneous and no longer accelerates particles– the term proportional to χ in Eq. (10) is absent. Therefore, solutions of Eq. (10) have well-defined "left" ${}_\zeta\varphi_{n,\chi}(y)$ and "right" ${}^\zeta\varphi_{n,\chi}(y)$ asymptotic forms:

$$\begin{aligned} {}_\zeta\varphi_{n,\chi}(y) &= {}_\zeta\mathcal{N}\exp\left(i\zeta\left|p^{\mathrm{L}}\right|y\right), \quad \zeta = \mathrm{sgn}\left(p^{\mathrm{L}}\right), \quad y \to -\infty, \\ {}^\zeta\varphi_{n,\chi}(y) &= {}^\zeta\mathcal{N}\exp\left(i\zeta\left|p^{\mathrm{R}}\right|y\right), \quad \zeta = \mathrm{sgn}\left(p^{\mathrm{R}}\right), \quad y \to +\infty. \end{aligned} \tag{12}$$

Here, ${}_\zeta\mathcal{N}$, ${}^\zeta\mathcal{N}$ are normalization constants, $\left|p^{\mathrm{L/R}}\right|$ are y-components of fermions momenta at remote regions

$$\left|p^{\mathrm{L/R}}\right| = \sqrt{[s\pi_s(\mathrm{L/R})]^2 - \pi_x^2}, \quad \pi_s(\mathrm{L/R}) = \omega - sU_{\mathrm{L/R}}, \tag{13}$$

and $\pi_s(\mathrm{L/R})$ are their transverse kinetic energies at remote areas. Correspondingly, asymptotically-"left" ${}_\zeta\psi_n(X) = \exp(-ip_0t + ip_xx + ip_zz)\,{}_\zeta\psi_n(y)$ and asymptotically-"right" ${}^\zeta\psi_n(X) = \exp(-ip_0t + ip_xx + ip_zz)\,{}^\zeta\psi_n(y)$ sets of DP spinors are solutions of the eigenvalue equations

$$\begin{aligned} \hat{p}_y\,{}_\zeta\psi_n(X) &= \zeta\left|p^{\mathrm{L}}\right|\,{}_\zeta\psi_n(X), \quad \hat{h}_\perp^{\mathrm{kin}}\,{}_\zeta\psi_n(X) = s\pi_s(\mathrm{L})\,{}_\zeta\psi_n(X), \quad y \to -\infty, \\ \hat{p}_y\,{}^\zeta\psi_n(X) &= \zeta\left|p^{\mathrm{R}}\right|\,{}^\zeta\psi_n(X), \quad \hat{h}_\perp^{\mathrm{kin}}\,{}^\zeta\psi_n(X) = s\pi_s(\mathrm{R})\,{}^\zeta\psi_n(X), \quad y \to +\infty, \end{aligned} \tag{14}$$

[a]The labels "L" and "R" mean "asymptotic left region $y \to -\infty$" and "asymptotic right region $y \to +\infty$", respectively.

where $\hat{h}_{\perp}^{\mathrm{kin}} = \hat{\Pi}_z - \mathbb{I}\,|\mu|\,B_z(y)$ is the one-particle transverse kinetic energy operator.

Substituting the field (2) into Eq. (10) and performing a simultaneous change of variables

$$\varphi_{n,\chi}(y) = \xi^{\rho}(1-\xi)^{\sigma} f(\xi)\ , \quad \xi(y) = \frac{1}{2}\left[1+\tanh(y/\varrho)\right]\ , \tag{15}$$

we may convert Eq. (10) to the form of the differential equation for the Gauss Hypergeometric Function[38]

$$\xi(1-\xi) f'' + \left[c - (a+b+1)\,\xi\right] f' - abf = 0\,, \tag{16}$$

provided the parameters ρ, σ, a, b, and c are:

$$\begin{aligned} a &= \frac{1}{2}(1-\chi) - \frac{i\varrho}{2}\left(\mathbb{U} + \left|p^{\mathrm{L}}\right| - \left|p^{\mathrm{R}}\right|\right)\ , \\ b &= \frac{1}{2}(1+\chi) + \frac{i\varrho}{2}\left(\mathbb{U} + \left|p^{\mathrm{R}}\right| - \left|p^{\mathrm{L}}\right|\right)\ , \\ c &= 1 - i\varrho\left|p^{\mathrm{L}}\right|\ , \quad \rho = -\frac{i}{2}\varrho\left|p^{\mathrm{L}}\right|\ , \quad \sigma = \frac{i}{2}\varrho\left|p^{\mathrm{R}}\right|\ . \end{aligned} \tag{17}$$

Among the 24 Hypergeometric functions satisfying Eq. (16),[38] we select those that tend to unity when $y \to \mp\infty$. Solutions meeting this property are proportional to Hypergeometric functions of type $F(a', b'; c'; \xi)$ and $F(a'', b''; c''; 1-\xi)$. For example, a possible set of exact solutions to Eq. (10) behaving asymptotically like Eqs. (12) is

$$\begin{aligned} {}_{\zeta}\varphi_{n,\chi}(y) &= {}_{\zeta}\mathcal{N}\exp\left(i\zeta\left|p^{\mathrm{L}}\right| y\right)\left[1+\exp(2y/\varrho)\right]^{-i\varrho\left(\zeta\left|p^{\mathrm{L}}\right|+\left|p^{\mathrm{R}}\right|\right)/2}\ {}_{\zeta}u(\xi)\ , \\ {}^{\zeta}\varphi_{n,\chi}(y) &= {}^{\zeta}\mathcal{N}\exp\left(i\zeta\left|p^{\mathrm{R}}\right| y\right)\left[1+\exp(-2y/\varrho)\right]^{i\varrho\left(\left|p^{\mathrm{L}}\right|+\zeta\left|p^{\mathrm{R}}\right|\right)/2}\ {}^{\zeta}u(\xi)\ , \end{aligned} \tag{18}$$

where

$$\begin{aligned} &{}_{-}u(\xi) = F(a,b;c;\xi)\ , \quad {}_{+}u(\xi) = F(a+1-c, b+1-c; 2-c; \xi)\ , \\ &{}^{-}u(\xi) = F(a,b;a+b+1-c;1-\xi)\ , \ {}^{+}u(\xi) = F(c-a, c-b; c+1-a-b; 1-\xi)\,. \end{aligned} \tag{19}$$

With the aid of these solutions, we may finally introduce the sets of DP spinors

$$\begin{aligned} {}_{\zeta}\psi_n(X) &= e^{-i(p_0 t - p_x x - p_z z)}\left(\mathbb{I} + sR\right)\left\{\hat{\pi}_z + \mathbb{I}\left[s\omega - |\mu|\,B_z(y)\right]\right\}\ {}_{\zeta}\varphi_{n,\chi}(y)\,\upsilon_{\kappa}^{(\chi)}\,, \\ {}^{\zeta}\psi_n(X) &= e^{-i(p_0 t - p_x x - p_z z)}\left(\mathbb{I} + sR\right)\left\{\hat{\pi}_z + \mathbb{I}\left[s\omega - |\mu|\,B_z(y)\right]\right\}\ {}^{\zeta}\varphi_{n,\chi}(y)\,\upsilon_{\kappa}^{(\chi)}\,, \end{aligned} \tag{20}$$

provided the quantum numbers n obey the conditions

$$\left[s\pi_s(\mathrm{L/R})\right]^2 > \pi_x^2\,. \tag{21}$$

These inequalities ensure the nontriviality of DP spinors with real asymptotic momenta p^{L} and p^{R} in remote areas, fulfilling Eqs. (14).

To calculate the normalization constants ${}_{\zeta}\mathcal{N}$, ${}^{\zeta}\mathcal{N}$, we use the inner product on the timelike surface $y = \mathrm{const.}$,

$$\left(\psi, \psi'\right)_y = \int dt dx dz \psi^{\dagger}(X)\,\gamma^0\gamma^2\psi'(X)\ , \tag{22}$$

after imposing specific normalization conditions[b]. We assume that all processes take place within a macroscopically large space-time box, of volume TV_y, $V_y = L_x L_z$, and impose periodic boundary conditions upon DP spinors in the variables t, x, z at the boundaries. Thus, the integrals in (22) are calculated from $(-T/2, -L_x/2, -L_z/2)$ to $(+T/2, +L_x/2, +L_z/2)$ and the limits $(T, L_x, L_z) \to \infty$ are taken at the end of calculations. Under these conditions, the inner product is y-independent and we may impose the following normalization conditions:

$$\left({}_{\zeta'}\psi_{n'},\ {}_{\zeta}\psi_{n} \right)_y = \zeta \eta_{\mathrm{L}} \delta_{n'n} \delta_{\zeta'\zeta}\,, \quad \left({}^{\zeta'}\psi_{n'},\ {}^{\zeta}\psi_{n} \right)_y = \zeta \eta_{\mathrm{R}} \delta_{n'n} \delta_{\zeta'\zeta}\,, \tag{23}$$

where $\eta_{\mathrm{L/R}} = \operatorname{sgn}\left[\pi_s\left(\mathrm{L/R}\right)\right]$. It should be noted that the time independence of the magnetic field under consideration is an idealization. Physically, it is meaningful to believe that the field inhomogeneity was switched on sufficiently fast before instant t_{in}. By this time, it had time to spread to the whole area under consideration and then acted as a constant field during a large time T. It is supposed that one can ignore effects of its switching on and off. This is a kind of regularization, which could, under certain conditions, be replaced by periodic boundary conditions in t, see Refs.[34,35] for details. Evaluating the inner product (22) for each DP spinor (20) and imposing the normalization conditions (23), we obtain

$$\left|\, {}_{\zeta}\mathcal{N}\right| = \frac{\left[TV_y \Upsilon \left(1 - s\kappa\chi\Upsilon\right)\right]^{-1/2}}{2\sqrt{\left|p^{\mathrm{L}}\right| \left|\pi_s\left(\mathrm{L}\right) - s\chi\zeta \left|p^{\mathrm{L}}\right|\right|}}\,, \quad \left|\, {}^{\zeta}\mathcal{N}\right| = \frac{\left[TV_y \Upsilon \left(1 - s\kappa\chi\Upsilon\right)\right]^{-1/2}}{2\sqrt{\left|p^{\mathrm{R}}\right| \left|\pi_s\left(\mathrm{R}\right) - s\chi\zeta \left|p^{\mathrm{R}}\right|\right|}}\,. \tag{24}$$

Considering that the "left" and "right" sets of DP spinors (20) are orthonormal and complete (with respect to the inner product (22)), we may decompose one set into another with the help of some g-coefficients

$$\begin{aligned} \eta_{\mathrm{L}}\ {}^{\zeta}\psi_n\left(X\right) &= g\left({}_{+}|^{\zeta}\right)\ {}_{+}\psi_n\left(X\right) - g\left({}_{-}|^{\zeta}\right)\ {}_{-}\psi_n\left(X\right)\,, \\ \eta_{\mathrm{R}}\ {}_{\zeta}\psi_n\left(X\right) &= g\left({}^{+}|_{\zeta}\right)\ {}^{+}\psi_n\left(X\right) - g\left({}^{-}|_{\zeta}\right)\ {}^{-}\psi_n\left(X\right)\,, \end{aligned} \tag{25}$$

which, by definition, are inner products between different sets of DP spinors

$$\left({}_{\zeta}\psi_n,\ {}^{\zeta'}\psi_{n'} \right)_y = \delta_{nn'} g\left({}_{\zeta}|^{\zeta'}\right) = \delta_{nn'} g\left({}^{\zeta'}|_{\zeta}\right)^{*}\,, \tag{26}$$

and play an important role in the quantization of DP spinors with steplike magnetic fields. These coefficients link different sets of creation and annihilation operators and contains all the necessary information about vacuum instability, as shall be seen below. Substituting the identities (25) into normalization conditions (23) supply us with two important identities

$$\sum_{\zeta''=\pm} \zeta'' g\left({}^{\zeta'}|_{\zeta''}\right) g\left({}_{\zeta''}|^{\zeta}\right) = \zeta \eta_{\mathrm{L}} \eta_{\mathrm{R}} \delta_{\zeta'\zeta} = \sum_{\zeta''=\pm} \zeta'' g\left({}_{\zeta'}|^{\zeta''}\right) g\left({}^{\zeta''}|_{\zeta}\right)\,, \tag{27}$$

from which we may derive a number of identities, for example $\left|g\left({}_{+}|^{-}\right)\right|^2 = \left|g\left({}_{-}|^{+}\right)\right|^2$, $\left|g\left({}_{+}|^{+}\right)\right|^2 = \left|g\left({}_{-}|^{-}\right)\right|^2$, and $\left|g\left({}_{+}|^{+}\right)\right|^2 - \left|g\left({}_{+}|^{-}\right)\right|^2 = \eta_{\mathrm{L}}\eta_{\mathrm{R}}$.

[b]Note that for $\psi' = \psi$, the inner product (22) divided by T coincides with the definition of the current density accross the y-const. hyperplane.

3. Pair production

Besides providing conditions for the existence of solutions (20), the inequalities (21) imposes certain limitations on the quantum numbers. For critical Sauter-like magnetic steps, whose step magnitudes (11) meet the condition

$$\mathbb{U} > \mathbb{U}_{\rm c} = 2m\,, \tag{28}$$

the whole manifold of quantum numbers divides into five sub-ranges, $\Omega_k\,,\ k = 1,...,5$. Neutral fermion pair production takes place only in a well-defined bounded set of quantum numbers[32–34]

$$\Omega_3 = \{n : U_{\rm L} + \pi_x \leq s\omega \leq U_{\rm R} - \pi_x\,,\ \ \pi_{xz} \leq \mathbb{U}/2\}\ ,\ \ \pi_{xz} = \sqrt{\pi_x^2 + p_z^2}\,, \tag{29}$$

which is conventionally called *Klein zone*, Ω_3. In this subrange, $s\pi_s\,({\rm L}) \geq \pi_x$ and $s\pi_s\,({\rm R}) \leq -\pi_x$, which means that $s\eta_{\rm L} = +1$ and $s\eta_{\rm R} = -1$. As a result, there exist two linearly-independent "left" ${}_{\zeta}\psi_{n_3}\,(X)$ and "right" ${}^{\zeta}\psi_{n_3}\,(X)$ sets of DP spinors with quantum numbers within the Klein zone $n_3 = n \in \Omega_3$.

To quantize the DP field operators using sets of solutions in this subrange, we need to classify them as particle or antiparticle states and as incoming waves (waves traveling toward the "step") or outgoing waves (waves traveling outward the "step") in remote areas. The correct classification demands a careful study of the inner product on y- and t-constant hyperplanes because important quantities to the scattering problem are expressed as surface integrals on such hyperplanes. After a detailed study of these quantities, which was presented in Refs.[34,35] for charged particles and in[33] for neutral fermions, "in"-solutions (incoming waves) and "out"-solutions (outgoing waves) are

$$\text{in-solutions: } {}_{-}\psi_{n_3}\,(X)\ ,\ {}^{-}\psi_{n_3}\,(X)\ ,\ \ \text{out-solutions: } {}_{+}\psi_{n_3}\,(X)\ ,\ {}^{+}\psi_{n_3}\,(X)\ . \tag{30}$$

The above sets of solutions are complete and orthogonal with respect to the inner product on t-constant hyperplane

$$(\psi_n, \psi'_{n'}) = \int_{V_y} dxdz \int_{-K^{(\rm L)}}^{K^{(\rm R)}} dy \psi_n^{\dagger}\,(X)\,\psi'_{n'}\,(X)\ , \tag{31}$$

in which the lower/upper cutoffs $K^{(\rm L/R)}$ are macroscopic but finite parameters of the volume regularization that are situated far beyond the region of a large gradient $\partial_y B_z\,(y)$; see Ref.[34,35] for details. In particular, the inner product (31) between "in" and "out" sets of DP spinors have the form

$$\left({}_{\zeta}\psi_n,\ {}_{\zeta}\psi_{n'}\right) = \left({}^{\zeta}\psi_n,\ {}^{\zeta}\psi_{n'}\right) = \mathcal{M}_n\delta_{nn'}\ ,\ \ \left({}_{\zeta}\psi_n,\ {}^{\zeta}\psi_{n'}\right) = 0\,,\ \ n, n' \in \Omega_3\,. \tag{32}$$

where $\mathcal{M}_n = 2\left|g\left({}_{+}|{}^{-}\right)\right|^2 t^{(\rm L/R)}/T$, $t^{(\rm L/R)} = K^{(\rm L/R)}\left|\pi_s\,({\rm L/R})\,/p^{\rm L/R}\right|$. Because there are two linearly independent sets of spinors (30), the quantization is performed using two distinct "in" and "out" sets of annihilation & creation operators

$$\begin{aligned}&\text{in-set: } {}_{-}b_{n_3}\,(\text{in})\ ,\ {}_{-}b^{\dagger}_{n_3}\,(\text{in})\ ,\ {}^{-}a_{n_3}\,(\text{in})\ ,\ {}^{-}a^{\dagger}_{n_3}\,(\text{in})\ ,\\ &\text{out-set: } {}_{+}b_{n_3}\,(\text{out})\ ,\ {}_{+}b^{\dagger}_{n_3}\,(\text{out})\ ,\ {}^{+}a_{n_3}\,(\text{out})\ ,\ {}^{+}a^{\dagger}_{n_3}\,(\text{out})\ ,\end{aligned} \tag{33}$$

which, in turn, obey the following anticommutation relations

$$\left[\ {}^{-}a_{n_3'}\left(\text{in}\right),\ {}^{-}a_{n_3}^{\dagger}\left(\text{in}\right)\right]_{+}=\left[\ {}_{-}b_{n_3'}\left(\text{in}\right),\ {}_{-}b_{n_3}^{\dagger}\left(\text{in}\right)\right]_{+}=\delta_{n_3'n_3}\,,$$
$$\left[\ {}^{+}a_{n_3'}\left(\text{out}\right),\ {}^{+}a_{n_3}^{\dagger}\left(\text{out}\right)\right]_{+}=\left[\ {}_{+}b_{n_3'}\left(\text{out}\right),\ {}_{+}b_{n_3}^{\dagger}\left(\text{out}\right)\right]_{+}=\delta_{n_3'n_3}\,, \tag{34}$$

and whose annihilation operators (33) annihilate the corresponding vacuum states

$${}_{-}b_{n_3}\left(\text{in}\right)\left|0,\text{in}\right\rangle={}^{-}a_{n_3}\left(\text{in}\right)\left|0,\text{in}\right\rangle=0,\ {}_{+}b_{n_3}\left(\text{out}\right)\left|0,\text{out}\right\rangle={}^{+}a_{n_3}\left(\text{out}\right)\left|0,\text{out}\right\rangle=0. \tag{35}$$

Finally, the quantized DP field operator in the Klein zone reads

$$\begin{aligned}\hat{\Psi}\left(X\right)&=\sum_{n\in\Omega_3}\mathcal{M}_n^{-1/2}\left[\ {}^{-}a_n\left(\text{in}\right)\ {}^{-}\psi_n\left(X\right)+\ {}_{-}b_n^{\dagger}\left(\text{in}\right)\ {}_{-}\psi_n\left(X\right)\right],\\&=\sum_{n\in\Omega_3}\mathcal{M}_n^{-1/2}\left[\ {}^{+}a_n\left(\text{out}\right)\ {}^{+}\psi_n\left(X\right)+\ {}_{+}b_n^{\dagger}\left(\text{out}\right)\ {}_{+}\psi_n\left(X\right)\right].\end{aligned} \tag{36}$$

Using orthogonality relations between DP spinors (23), (32) and the relations given by Eqs. (25), one may establish a linear relation between the "in"-set of creation/annihilation operators in terms of the "out"-set and *vice-versa*. For example, two (out of four) canonical transformations have the following form

$$\begin{aligned}{}_{-}b_n^{\dagger}\left(\text{in}\right)&=-g\left({}^{+}|_{-}\right)^{-1}\ {}^{+}a_n\left(\text{out}\right)+g\left({}_{+}|^{-}\right)^{-1}g\left({}_{-}|^{-}\right)\ {}_{+}b_n^{\dagger}\left(\text{out}\right),\\{}^{+}a_n\left(\text{out}\right)&=-g\left({}_{-}|^{+}\right)^{-1}\ {}_{-}b_n^{\dagger}\left(\text{in}\right)+g\left({}^{-}|_{+}\right)^{-1}g\left({}^{+}|_{+}\right)\ {}^{-}a_n\left(\text{in}\right).\end{aligned} \tag{37}$$

With the aid of the canonical transformations (37), we may finally define vacuum instability quantities, such as the differential mean numbers of "out" particles created from the "in" vacuum,

$$N_n^{\text{cr}}=\left\langle 0,\text{in}\right|\ {}^{+}a_n^{\dagger}\left(\text{out}\right)\ {}^{+}a_n\left(\text{out}\right)\left|\text{in},0\right\rangle=\left|g\left({}_{-}|^{+}\right)\right|^{-2},\quad n\in\Omega_3\,, \tag{38}$$

and the flux density of particles created with a given s,

$$n_s^{\text{cr}}=\frac{1}{V_yT}\sum_{n\in\Omega_3}N_n^{\text{cr}}=\frac{1}{\left(2\pi\right)^3}\int dp_z\int dp_x\int dp_0N_n^{\text{cr}}\,. \tag{39}$$

The total flux density of particles created with both spin polarizations is $n^{\text{cr}}=n_{+1}^{\text{cr}}+n_{-1}^{\text{cr}}$ and the vacuum-vacuum transition probability reads:

$$P_v=\left|\langle 0,\text{out}|0,\text{in}\rangle\right|^2=\exp\left[\sum_{s=\pm1}\sum_{n\in\Omega_3}\ln\left(1-N_n^{\text{cr}}\right)\right]. \tag{40}$$

It should be noted that if the total number of created particles $N^{\text{cr}}=V_yTn^{\text{cr}}$ is small, one may neglect higher-order terms in Eq. (40) to conclude that $P_v\approx1-N^{\text{cr}}$. With the aid of this relation, we may link the total number of neutral fermions created from the vacuum with the imaginary part of an effective action S_{eff} provided it satisfies the Schwinger relation $P_v=\exp\left(-2\text{Im}S_{\text{eff}}\right)$, and it is small, so that $P_v\approx1-2\text{Im}S_{\text{eff}}$. Therefore,

$$\text{Im}S_{\text{eff}}\approx V_yTn^{\text{cr}}/2\,. \tag{41}$$

From these equations, we observe that all the information about pair creation by the external field is enclosed in $g\left({}_{-}|^{+}\right)$. To obtain this coefficient, we may use an appropriate Kummer relation[38] that connects three Gauss Hypergeometric functions appearing in one of the relations given by Eq. (25). After obtaining this coefficient and calculating its absolute square $\left|g\left({}_{-}|^{+}\right)\right|^{-2}$, we finally obtain the differential mean numbers of pairs created from the vacuum:

$$N_n^{\mathrm{cr}} = \frac{\sinh\left(\pi\varrho\left|p^{\mathrm{R}}\right|\right)\sinh\left(\pi\varrho\left|p^{\mathrm{L}}\right|\right)}{\sinh\left[\pi\varrho\left(\mathbb{U}+\left|p^{\mathrm{L}}\right|-\left|p^{\mathrm{R}}\right|\right)/2\right]\sinh\left[\pi\varrho\left(\mathbb{U}+\left|p^{\mathrm{R}}\right|-\left|p^{\mathrm{L}}\right|\right)/2\right]}\,. \tag{42}$$

Note that N_n^{cr} are positive-definite because the difference $\left|\left|p^{\mathrm{L}}\right|-\left|p^{\mathrm{R}}\right|\right|$ bounded in this subrange; $0 \leq \left|\left|p^{\mathrm{L}}\right|-\left|p^{\mathrm{R}}\right|\right| \leq \sqrt{\mathbb{U}\left(\mathbb{U}-2\pi_x\right)}$. The above expression gives the exact distribution of neutral fermions created from the vacuum by the field (2). When summed over the quantum numbers, it provides exact expressions for the flux density of the created particles (39) and the vacuum-vacuum transition probability (40). Lastly, it is noteworthy to discuss some peculiarities associated with the choice of the quantum number s and its impact on the quantization (36). As pointed out in Sec. 2, there are two species of neutral fermions, one with $s = +1$ and another with $s = -1$. In the latter case, the classification differs from the one given by Eq (30), namely ${}_{+}\psi_{n_3}(X)$, ${}^{+}\psi_{n_3}(X)$ are "in"-solutions while ${}_{-}\psi_{n_3}(X)$, ${}^{-}\psi_{n_3}(X)$ are "out"-solutions. Although this classification changes the quantization (36), it does not change the mean numbers (38). This means that the flux density of particles created with $s = -1$ equals the one with $s = +1$, $n_{+1}^{\mathrm{cr}} = n_{-1}^{\mathrm{cr}}$. Therefore, summations over s in Eqs. (39), (40) just produce an extra factor of 2 in final expressions and that is why it is enough selecting s fixed to perform specific calculations; hereafter, we select $s = +1$ for convenience. In what follows, we analyze vacuum instability quantities when the field lies in two special configurations, varying either "gradually" or "sharply" along the inhomogeneity direction.

3.1. *"Gradually"-varying field configuration*

This field configuration corresponds to the case where the amplitude B' is sufficiently large and the field inhomogeneity stretches over a relatively wide region of the space, such that the condition

$$\sqrt{\varrho\mathbb{U}/2} \gg \max\left(1, \frac{m}{\sqrt{|\mu|\,B'}}\right)\,, \tag{43}$$

is satisfied. Accordingly, the arguments of the hyperbolic functions in (42) are large, meaning that the mean numbers of pairs created acquires the following approximate form,

$$N_n^{\mathrm{cr}} \approx e^{-\pi\tau}\,, \quad \tau = \varrho\left(\mathbb{U}-\left|p^{\mathrm{R}}\right|-\left|p^{\mathrm{L}}\right|\right)\,. \tag{44}$$

The above distribution is exponentially small for large values of ω and p_x. Its most significant contribution comes from a finite range of values of quantum numbers

such that the conditions $\min\left(\pi_{+1}^2\left(\mathrm{L}\right),\pi_{+1}^2\left(\mathrm{R}\right)\right)\gg\pi_x^2$ remains valid. In this case, τ admits the following approximation

$$\tau=\frac{\left(\mathbb{U}/2\right)^2}{\left(\mathbb{U}/2\right)^2-\omega^2}\lambda+O\left(\pi_x^4/\left|\pi_{+1}\left(\mathrm{R}\right)\right|^3\right)+O\left(\pi_x^4/\left|\pi_{+1}\left(\mathrm{L}\right)\right|^3\right). \tag{45}$$

Now, we can estimate the flux density of pairs created n^{cr} for a magnetic step evolving gradually along the y-direction according to (43). To this end, it is convenient to transform the original integral over p_0 into an integral over ω through the relation between p_0, ω, and p_z discussed before, $p_0^2=\omega^2+p_z^2$. Performing such a change of variables, the flux density of the particles created by the external field in the configuration (43) has the form

$$\begin{aligned}
&n^{\mathrm{cr}}\approx\frac{4}{\left(2\pi\right)^3}\int_0^{p_z^{\max}}dp_z\int_{-p_x^{\max}}^{p_x^{\max}}dp_x\int_0^{\omega_{\max}^2}d\omega^2\frac{e^{-\pi\tau}}{\sqrt{\omega^2+p_z^2}},\\
&p_z^{\max}=\sqrt{\left(\mathbb{U}/2\right)^2-m^2},\quad p_x^{\max}=\sqrt{\left(\mathbb{U}/2\right)^2-m^2-p_z^2},\quad \omega_{\max}=\mathbb{U}/2-\pi_x.
\end{aligned} \tag{46}$$

The multiplicative factor 4 comes from the summation over s and from the fact that the integrand is symmetric in p_z. To obtain an analytical expression to N^{cr}, we formally extend the integration limits of the last two integrals to infinity. This procedure amounts to incorporating exponentially small contributions to n^{cr} since the differential mean numbers are exponentially small at large p_x and ω. In this case, we may technically interchange the order of the last two integrals in (46) and use the approximation given by Eq. (45) to discover that the flux density of the created particles is approximately given by

$$n^{\mathrm{cr}}\approx\frac{m}{\left(2\pi\right)^3}\mathbb{U}^2\sqrt{b'}e^{-\pi b'}I_{b'},\quad I_{b'}=\int_0^\infty\frac{du}{\left(u+1\right)^{5/2}}\ln\left(\frac{\sqrt{1+u}+\sqrt{1+2u}}{\sqrt{u}}\right)e^{-\pi b'u}, \tag{47}$$

where $b'=m^2/\left|\mu\right|B'$ and $\mathbb{U}=2\varrho\left|\mu\right|B'$. At last, one may use the identity $\ln\left(1-N_n^{\mathrm{cr}}\right)=-\sum_{l=1}^\infty\left(N_n^{\mathrm{cr}}\right)^l/l$ and perform integrations similar to the ones discussed before to discover that the vacuum-vacuum transition probability admits the final form

$$P_v=\exp\left(-\beta V_yTn^{\mathrm{cr}}\right),\quad \beta=\sum_{l=0}^\infty\frac{\epsilon_{l+1}}{\left(l+1\right)^{3/2}}\exp\left(-l\pi b'\right),\quad \epsilon_l=\frac{I_{b'l}}{I_{b'}}, \tag{48}$$

with n^{cr} given by Eq. (47).

It is noteworthy mentioning that relation (40)–which is well-known for strong-field QED with external electromagnetic fields–holds for the case under consideration as well. However, a direct similarity of total quantities for both cases is absent. We see that the flux density of created neutral fermion pairs and the quantity $\ln P_v^{-1}$ are quadratic in the magnitude of the step. This is a consequence of the fact that the number of states with all possible ω and p_z excited by the magnetic-field inhomogeneity is quadratic in the increment of the kinetic momentum. This is also the

reason why the flux density of created pairs and $\ln P_v^{-1}$ per unit of the length are not uniform.

3.2. *"Sharply"-varying field configuration*

A second configuration of interest is when the field (2) "sharply" steeps near the origin. Such a configuration is specified by the conditions:

$$1 \gg \sqrt{\varrho\mathbb{U}/2} \gtrsim \frac{m}{\sqrt{|\mu|\, B'}}\,. \tag{49}$$

The first inequality indicates that the gradient $\partial_y B_z\,(y)$ sharply peaks about the origin, while the second implicates that the Klein zone is relatively small. This configuration is particularly important due to a close analogy to charged pair production by the Klein step, see Ref.[39] for the review. For electric fields whose spatial inhomogeneity meets conditions equivalent to (49), it was demonstrated that the imaginary part of the QED effective action features properties similar to those of continuous phase transitions.[40,41] Recently,[42] we have demonstrated for the inverse-square electric field that this peculiarity also follows from the behavior of total quantities when the Klein zone is relatively small. Because of the condition (49), not only the parameter $\varrho\mathbb{U}/2$ is small but all parameters involving the quantum numbers p_x, p_z, and ω are small as well on account of the inequalities (29). As a result, the arguments of the hyperbolic functions in (42) are small, which means that we may expand the hyperbolic functions in ascending powers and truncate the corresponding series to first-order to demonstrate that the mean numbers admit the approximate form:

$$N_n^{\mathrm{cr}} \approx \frac{4\left|p^{\mathrm{R}}\right|\left|p^{\mathrm{L}}\right|}{\mathbb{U}^2 - \left(\left|p^{\mathrm{L}}\right| - \left|p^{\mathrm{R}}\right|\right)^2}\,. \tag{50}$$

To implement the conditions (49), we conveniently introduce the Keldysh parameter $\gamma = 2m/\mathbb{U}$ and observe that it obeys the condition $1-\gamma^2 \ll 1$ on account of (49). Next, we perform the change of variables

$$\frac{\omega}{m} = \frac{1}{2}\left(1-\gamma^2\right)(1-v)\;,\quad \frac{p_x^2}{m^2} = \left(1-\gamma^2\right) r\,, \tag{51}$$

and expand the asymptotic momenta $\left|p^{\mathrm{L/R}}\right|$ in ascending powers of $1-\gamma^2$ to learn that $\left|p^{\mathrm{R}}\right|/m = \left(1-\gamma^2\right)^{1/2}\sqrt{v-r} + O\left(\left(1-\gamma^2\right)^{3/2}\right)$, $\left|p^{\mathrm{L}}\right|/m = \left(1-\gamma^2\right)^{1/2}\sqrt{2-v-r} + O\left(\left(1-\gamma^2\right)^{3/2}\right)$. Substituting these approximations into (50) we obtain

$$N_n^{\mathrm{cr}} = \left(1-\gamma^2\right)\sqrt{(1-r)^2-(1-v)^2} + O\left(\left(1-\gamma^2\right)^2\right)\,. \tag{52}$$

We now wish to estimate the total number of pairs created from the vacuum by a sharply varying external field. In this case, it is convenient to first integrate over p_z, which is allowed as long as we swap the integration limits indicated in (46), i.e.

$p_z^{\max} = \sqrt{(\mathbb{U}/2)^2 - m^2 - p_x^2}$ and $p_x^{\max} = \sqrt{(\mathbb{U}/2)^2 - m^2}$. Calculating the integral and performing the change of variables proposed in (51), we expand the result in power series of $1-\gamma^2$ to find

$$\int_0^{p_z^{\max}} \frac{dp_z}{\sqrt{\omega^2 + p_z^2}} = -\frac{1}{2}\ln\left(1-\gamma^2\right) + 2\ln 2 + \ln\sqrt{1-r} - \ln\sqrt{(1-v)^2} + O\left(1-\gamma^2\right). \tag{53}$$

The most significant contribution to total quantities in this regime comes from the logarithm $\ln\left(1-\gamma^2\right)$, as $1-\gamma^2 \ll 1$. Neglecting higher-order terms in $1-\gamma^2$, the flux density of the particles created is approximately given by

$$n^{\mathrm{cr}} \approx \frac{\left(1-\gamma^2\right)^{7/2}\left|\ln\left(1-\gamma^2\right)\right| m^3}{(2\pi)^3} \int_0^{r_{\max}} \frac{dr}{\sqrt{r}} \int_{v_{\min}}^{v_{\max}} dv\,(1-v)\sqrt{(1-r)^2 - (1-v)^2}, \tag{54}$$

where $v_{\min} \approx r$ and $v_{\max} \approx r_{\max} \approx 1$. After straightforward integrations, the flux density of the particles created from the vacuum by a sharply varying Sauter-like magnetic step takes the approximate form

$$n^{\mathrm{cr}} \approx \frac{4}{105\pi^3} m^3 \left(1-\gamma^2\right)^{7/2}\left|\ln\left(1-\gamma^2\right)\right|. \tag{55}$$

Due to the smallness of the coefficient $\left(1-\gamma^2\right)^{7/2}$, the total number of neutral fermions pairs created from the vacuum is also small $N^{\mathrm{cr}} = V_y T n^{\mathrm{cr}}$, which means that the vacuum-vacuum transition probability is approximately given by $P_v \approx 1 - N^{\mathrm{cr}}$. We may use this result to link the flux density of pairs created (55) with the imaginary part of the effective action, given by the approximation (41).

4. Concluding remarks

Here we review our recent results on the creation of neutral fermion pairs with anomalous magnetic moments from the vacuum by Sauter-like magnetic field.[32] We show that the problem is technically analogous to the problem of charged-particle creation by an electric step, for which the nonperturbative formulation of strong-field QED exists.[34,35] To employ this formulation, we first find exact solutions of the DP equation with Sauter-like magnetic field with well-defined spin polarization and calculated all quantities characterizing the effect, in particular when the field lies in two specific configurations. When the field varies "gradually" along the inhomogeneity direction, we found that the flux density of created neutral fermion pairs is quadratic in the magnitude of the step $\mathbb{U}$. This feature is particularly different from the case of charged pair production by electric steps, in which the the flux density features a linear dependence on the magnitude of the electric step. The quadratic dependence for neutral fermions derives from the non-cartesian geometry of the parameter space formed by the quantum numbers, and it is inherent to the dynamics of neutral fermions with anomalous magnetic moments in inhomogeneous magnetic

fields. This also explains why the flux density of created pairs per unit of the length are not uniform. In particular, it means that the Schwinger method of the effective action works for the case under consideration only after a suitable parameterization. The second feature worth discussing is the behavior of total quantities when the field "sharply" varies. It is exactly the form of the Klein effect.[39] If we compare the flux density of neutral fermion pairs created with the total number of electron-positron pairs created from the vacuum by inhomogeneous electric fields (given, for example, by Eq. (88) with $d = 4$ in[42]), we observe two major differences: the first is the presence of a logarithmic coefficient $\left|\ln\left(1-\gamma^2\right)\right|$, that can be traced back to the integration over p_z (53) and therefore does not depend on the external field. To our knowledge, this term has no precedents in QED (although a logarithmic coefficient of this type may appear in scalar QED). The second, and more important, is the value of the scaling (or critical) exponent seen in (55). In contrast to QED in $3+1$ dimensions, in which $N^{\mathrm{cr}} \sim \left(1-\gamma^2\right)^3$,[40–42] the total number of neutral fermions pairs created from the vacuum features a larger exponent, $7/2$. Aside from minor numerical differences, this means that the total number (55) has an extra term $\sqrt{1-\gamma^2}\left|\ln\left(1-\gamma^2\right)\right|$, which is always less than unity in the range of values to γ within the interval $0 \leq \gamma < 1$. Formally, this indicates that backreaction effects caused by neutral fermions produced by sharply-evolving inhomogeneous magnetic fields may be significantly smaller compared to QED under equivalent conditions.

The mechanism here described raises the question about the critical magnetic field intensity, near which the phenomenon could be observed. It is possible to estimate such a value based on fermion's mass and its magnetic moment. Since $\max B_z(y) = B_z(+\infty) = \varrho B' \equiv B_{\max}$, the nontriviality of the Klein zone (29) yields the following condition

$$\mathbb{U} = 2\left|\mu\right|\varrho B' > 2m \Rightarrow B_{\max} > B_{\mathrm{cr}}\,, \quad B_{\mathrm{cr}} \equiv \frac{m}{|\mu|} \approx 1.73\times 10^8 \times \left(\frac{m}{1\,\mathrm{eV}}\right)\left(\frac{\mu_{\mathrm{B}}}{|\mu|}\right)\mathrm{G}\,, \tag{56}$$

where $\mu_{\mathrm{B}} = e/2m_e \approx 5.8\times 10^{-9}\,\mathrm{eV/G}$ is the Bohr magneton.[16] For neutrons, whose mass and magnetic moment are $m_N \approx 939.6\times 10^6\,\mathrm{eV}$, $\mu_N \approx -1.042\times 10^{-3}\mu_{\mathrm{B}}$, the critical magnetic field (56) is $B_{\mathrm{cr}} \approx 1.56\times 10^{20}\,\mathrm{G}$. More optimistic values can be estimated for neutrinos because of their light masses and small magnetic moments. For example, considering recent constraints for neutrinos effective magnetic moment $\mu_\nu \approx 2.9\times 10^{-11}\mu_{\mathrm{B}}$[18] and mass $m_\nu \approx 10^{-1}\,\mathrm{eV}$,[30] we find $B_{\mathrm{cr}} \approx 5.97\times 10^{17}\,\mathrm{G}$. Evidently, this value changes considering different values to neutrinos' magnetic moment and mass. Taking, for instance, the experimental estimate to the tau-neutrino magnetic moment $\mu_\tau \approx 3.9\times 10^{-7}\mu_{\mathrm{B}}$[17] and assuming its mass $m_{\nu_\tau} \approx 10^{-1}\,\mathrm{eV}$ we obtain a value to B_{cr} near QED critical field $B_{\mathrm{QED}} = m^2/e \approx 4.4\times 10^{13}\,\mathrm{G}$, namely $B_{\mathrm{cr}} \approx 4.44\times 10^{13}\,\mathrm{G}$. On the other hand, assuming the lower bound found in Ref.[25] $\mu_\nu \approx 10^{-14}\mu_{\mathrm{B}}$ and the same mass $m_\nu \approx 10^{-1}\,\mathrm{eV}$ we obtain a value to B_{cr} orders of magnitude larger than B_{QED}, $B_{\mathrm{cr}} \approx 1.73\times 10^{21}\,\mathrm{G}$. The critical magnetic field surprisingly increases if one considers the magnetic moment predicted by the SM,

$\mu_\nu \approx 3.2 \times 10^{-19} \mu_B \times (m_\nu/1\,\mathrm{eV})$.[27,30] Substituting this value into (56) and considering $m_\nu \approx 1\,\mathrm{eV}$ we find $B_{cr} \approx 5.41 \times 10^{26}\,\mathrm{G}$. Based on these estimates, we believe that neutral fermion pair production may occur in astrophysical enviroments, in particular during a supernova explosion or in the vicinity of magnetars, whose typical order of magnetic field intensities range from $10^{16} - 10^{18}\,\mathrm{G}$ (or up to 10^{20} G), as reported in Refs.[43–46].

We study the screening of a strong magnetic field operated by an initial huge number of $e^{\pm}$ pairs (we do not discuss here their production mechanism). The background fields configuration is of crossed fields, $\left(\vec{B} = B\,\hat{z},\ \vec{E} = E\,\hat{y}\right)$, with $E/B < 1$. In this system the following series of processes occur: 1) the electric field accelerates the pairs, which radiate high-energy synchrotron photons; 2) these synchrotron photons interact with the background magnetic field via the magnetic pair production process (MPP hereafter), i.e. $\gamma + B \rightarrow e^{+} + e^{-}$, producing additional pairs; 3) the dynamic of all the pairs around the magnetic field lines generates a current that induces a magnetic field oriented in the opposite direction to the background one and then shielding it. We get that, for instance, for an initial number of pairs $N_{\pm,0} = 10^{10}$, an initial magnetic field of 10^{12} G can be reduced by a few percent. The whole screening process described by the steps above, occurs in the short timescales $10^{-21} \leq t \leq 10^{-15}$ s, i.e. the time necessary before the particles acceleration timescale equals the synchrotron cooling timescale. Further developments (as the study of this mechanism in different geometries of the $\vec{E}$ and $\vec{B}$ fields, quantum effects in overcritical fields, other mechanisms for the production, distribution and multiplicity of the $e^{\pm}$ pairs) are necessary in order to apply this model to specific and extreme astrophysical systems (as Black Hole or Neutron Star).

Keywords: Magnetic Pair Production; Magnetic field screening; Shower processes

1. Introduction

For many years the screening of a strong electric field, operated by $e^{\pm}$ pairs created by QED processes, has been studied (e.g. see recently Ref. 1[a]). No analogous work and conclusions have been reached for a magnetic field. The main topic of this paper is to build a simple model to analyze the magnetic field screening (MFS hereafter) process owing to the motion of $e^{\pm}$ pairs in a region filled by magnetic $\vec{B}$ and electric $\vec{E}$ fields, oriented in a crossed configuration.

The basic idea of the screening process is described by the following series steps:

(1) An initial number of $e^{\pm}$ is placed in a region filled by $\vec{E}$ and $\vec{B}$, with $E/B < 1$, $B \leq B_{\rm cr} = m_e^2 c^3/(e\hbar) \approx 4.4 \times 10^{13}$ G and then $E < E_{\rm cr}$. We do not discuss here the creation process of these initial pairs (that could be, for example, the vacuum breakdown).

[a]In this paper it is shown that an electric field as high as $E \sim \alpha_f E_{\rm cr}$, with α_f the fine structure constant and $E_{\rm cr} = m_e^2 c^3/(e\hbar) \approx 1.32 \times 10^{16}$ V/cm the critical field for vacuum polarization, cannot be maintained since the creation of particle showers depletes the field

(2) The initial pairs are accelerated by $\vec{E}$ and emit radiation via the curvature/synchrotron mechanism (or their combination), due to the $\vec{B}$ field. We assume that the electric and magnetic field strength are related by the following relation

$$E(t) = \Upsilon\ B(t), \tag{1}$$

with $0 < \Upsilon \leq 1$, since we are interested in conditions of magnetic dominance.

(3) The photons create a new $e^{\pm}$ pairs via the magnetic pair production process (MPP), $\gamma + B \rightarrow e^- + e^+$.

(4) Also these new pairs are accelerated and radiate synchrotron photons. All the pairs, initial + created by the MPP process, circularize around the magnetic field lines generating a current that gives rise to an induced magnetic field, $\vec{B}_{\rm ind}$, oriented in the opposite direction with respect to the original one, thereby screening it. Because of the creation of these new charged particles and the proportionality between the strength of the fields, also the electric field is screened.

(5) This series of the processes occurs at every time t leading to the development of a particles shower.

This model can find useful application in extreme astrophysical systems, as GRBs. Indeed, following the "*inner engine*" model for GRBs[2,3] within the binary-driven hypernova (BdHN) framework (see, e.g., Refs. 4–6), these type of systems are composed by a rotating back hole, surrounded by the magnetic field and low-density ionized matter. The gravitomagnetic interaction of the rotating BH and the magnetic field induces an electric field which accelerates e^- which emit GeV photons by synchrotron radiation.[2] Then a decrease of the magnetic field leads to the decrease of the optical depth for synchrotron photons, which can reach the threshold to freely escape from the region near the BH and become observable. Therefore, from this brief introduction of the model it is easy to understand that the physical process that we present here could be necessary for the explanation of some emission in extreme astrophysical systems.

2. Model equations

Here we analyze the whole screening process for the specific configuration of perpendicular fields: $\vec{E} = E\ \hat{y}$ for the electric field and $\vec{B} = B\ \hat{z}$ for the magnetic field. In this section we just summarize the fundamental equations that describe the system. The entire set of equations and their derivation can be found in Refs. 7, 8.

In order to follow the entire screening process we have built a set of ordinary differential equations which describe, at the same time: 1) the motion of the particles; 2) the creation of new particles via the energy loss and the MPP processes; 3) the decrease of the magnetic field due to the generation of an induced magnetic field by the particles currents.

The equations of motion of a particle immersed in an EM field [b] read (see, e.g., Refs. 9, 10)

$$\frac{dp^{\alpha}}{d\tau} = m\frac{du^{\alpha}}{d\tau} = \frac{e}{c}\mathcal{F}^{\alpha\beta}u_{\beta}. \tag{2}$$

and for the radiation emitted we use the energy loss formula in quantum regime, $I = |-dE/dt|$, given in Ref. 11.

In this paper they use the parameter $\chi \equiv \varepsilon_*/2\,\varepsilon_e$ to distinguish between emission in quantum ($\chi \gtrsim 1$) and classical ($\chi < 1$) regimes, where $\varepsilon_e = \gamma m_e c^2$ is the electron energy and $\varepsilon_* = \hbar\omega^* = (3e\gamma^2/2m_e c)\sqrt{\left(\vec{E}+\vec{\beta}\times\vec{B}\right)^2 - \left(\vec{\beta}\cdot\vec{E}\right)^2}$ the critical photons energy.

The photons production rate, $\dot{N}_{\gamma}(t,\phi)$ (with ϕ the angle between the particle/photon direction and the magnetic field) can be calculated as the product between the number of pairs present at the specific time t, $N_{\pm}(t,\phi)$ and the rate of photons production via synchrotron emission, $I/\varepsilon_{\gamma}^{e}$ (with ε_{γ}^{e} the energy of synchrotron photons emitted by the $e^{\pm}$). The equation for the evolution of the number of pairs is strictly related to the one for the number of photons. Indeed, the rate of pair production $\dot{N}_{\pm}(t,\phi)$ is given by the product of the photon number N_{γ}, the attenuation coefficient for the MPP process $R_{\mathrm{A}}^{e}(t,\phi)$ times the velocity of light c.

The motion of a particle inside an electromagnetic field can be considered as the combination of an acceleration along the $z-$direction, and of a circular motion in the $x-y$ plane, around the magnetic field lines. This circular motion of the pairs produces coils traversed by the electric current. This current creates an induced magnetic field, from the Biot–Savart law, whose evolution with time is described by the following formula (calculated at the center of the coil):

$$\frac{dB_{\mathrm{z,\ ind}}}{dt} = e\frac{\beta_{\perp}(t)}{R_c(t)^2}\frac{dN_{\pm}}{dt}. \tag{3}$$

with $\beta_{\perp} = (\,\beta_x^2 + \beta_y^2\,)^{1/2}$ the perpendicular component of the particle velocity and $R_c^{-1} = \left|d\vec{\beta}/cdt\right| = \left(e/\gamma mc^2\right)\sqrt{\left(\vec{E}_{\mathrm{tot}}+\vec{\beta}\times\vec{B}_{\mathrm{tot}}\right)^2 - \left(\vec{\beta}\cdot\vec{E}_{\mathrm{tot}}\right)^2}$ the curvature radius for the particle trajectory.

We have introduced the attenuation coefficient for the magnetic pair production and we have called it R_A^e. From now on, we refer to as $\zeta \equiv R_A^e c$ the MPP rate. In Ref. 12, the expression for the pair production rate has been derived in the observer frame at rest, for strong perpendicular electric and magnetic fields ($\vec{E}\cdot\vec{B} = 0$). In order to get the expression of the MPP rate in our frame we have: 1) moved to a new K' frame, where no electric field is present, through a Lorentz transformation; 2) calculated all the necessary quantities (energy, momentum and director cosines of the photons, the component of the magnetic field perpendicular to the propagation direction of the photons, the MPP rate); 3) transforming back the rate to the

[b] We use throughout cgs-Gaussian units, in which the magnetic and electric fields share the same dimensions ($\mathrm{g}^{1/2}\ \mathrm{cm}^{-1/2}\ \mathrm{s}^{-1}$) and a -2 signature so the spacetime metric is $\eta_{\mu\nu} = (1,-1,-1,-1)$.

original frame. The expression for the MPP rate in the laboratory frame (observer at infinity, the frame where we work) assumes the following form (further details on this procedure can be found in Refs. 7, 8):

$$\zeta = 0.23 \frac{\alpha_f c}{\lambda\!\!\!^{-}_c} \frac{B_z}{B_{\rm cr}} \left(1 - \frac{E_y^2}{B_z^2}\right) \frac{\sqrt{\eta_y^2 \left(1 - \frac{E_y^2}{B_z^2}\right) + \left(\eta_x - \frac{E_y}{B_z}\right)^2}}{1 - \frac{E_y}{B_z}\eta_x} \times \exp\left\{-\frac{8}{3}\frac{mc^2}{\varepsilon_\gamma}\frac{B_{\rm cr}}{B_z}\left[\eta_y^2\left(1 - \frac{E_y^2}{B_z^2}\right) + \left(\eta_x - \frac{E_y}{B_z}\right)^2\right]^{-1/2}\right\}, \tag{4}$$

which is valid until the following condition is satisfied

$$\Psi = \frac{3}{4}\frac{e\hbar}{m\,c}\frac{B^2}{B_{\rm cr}}\gamma^2 \sqrt{{\beta_y}^2\left(1 - \frac{E^2}{B^2}\right) + \left(\frac{E}{B} - \beta_x\right)^2}\sqrt{{\eta_y}^2\left(1 - \frac{E^2}{B^2}\right) + \left(\eta_x - \frac{E}{B}\right)^2} \ll 1. \tag{5}$$

In Eq. (4) and Eq. (5) the quantities $\vec{\eta}$ are the photon director cosines, whose expression as a function of the electron velocity, polar and azimuthal angle of their emission in the comoving frame can be found in Ref. 7.

3. Results

We now present the results of the numerical integration of the set of equations described in the previous section. We have selected three values for the parameter Υ = (1/2, 1/10, 1/100). Since the proportionality between the fields is requested at any time, when $B(t)$ changes even $E(t)$ changes accordingly to keep Υ constant. These combination of these effects affect the motion of particles and, consequently, all the related processes that give rise to the screening.

The condition on Ψ in Eq. (5) brings with it three initials conditions for the background magnetic field, the electron Lorentz factor and for the emission direction of the pairs $\left(B_0,\ \gamma_0,\ \vec{\beta}_0\right)$. A further condition is necessary for the director cosines of the photons $\vec{\eta}$. Then, we need to choose the right values for these variables and parameters in order to apply the equation for the rate

We select three emission directions of the particles: 1) along the $\hat{y}$−axis; 2) along the $\hat{z}$−axis; 3) along a direction characterized by polar and azimuth angles, respectively, $\theta = 75°$ and $\phi = 30°$ (hereafter we refer to this direction as "*generic*" or "*G*"). For each direction, we have chosen the initial value of the magnetic field B_0 and, consequently, the maximum value of particles Lorentz factor γ_0, which satisfy Eq. (5). After we have integrated the set of equations that describe the entire screening process considering different number of emitted particles $N_{\pm,0} = 1,\ 10^3,\ 10^6,\ 10^{10}$ and photons $N_{\gamma,0} = 0$; $N_{\gamma,0} = 10^3$, with $N_{\pm,0} = 1$. Each numerical integration starts at $t_0 = 10^{-21}$ s and stops when the Lorentz factor of the pairs becomes 1, i.e. when the particle has lost all of its energy, at $t_f \sim 10^{-17} - 10^{-15}$ s.

In Table 1, Table 2, Table 3 we show the results we have obtained from the integrations of our set of equations describing, for all the considered initial conditions

(emission direction, B_0, γ_0, $N_{\pm,0}$, $N_{\gamma,0}$). We report the percentage variation of the magnetic field $\Delta B(\%)$, the final number of created pairs $N_{\pm,f}$ and photons $N_{\gamma,f}$. In Table 1 the results are for $\Upsilon = 1/2$, Table 2 is for $\Upsilon = 1/10$ and Table 3 for $\Upsilon = 1/100$. From Table 1, Table 2 and Table 3, we can get some interesting results. Indeed, we can see that the model (namely the system of equations we have built) is strictly correlated to the initial conditions and, in particular, to the particles emission direction and to the strength of the background magnetic field. A sufficient decrease of $\vec{B}$ is obtained when a huge initial number of particles $N_{\pm,0} \gtrsim 10^{10}$ is injected. For particles emitted along the $\hat{z}-$axis and along the *generic* direction, the stronger the background field, the higher the reduction of the field itself is. Even when they are emitted along the $\hat{y}-$axis, there is a significant reduction of $\vec{B}$, but this

Table 2. Same results of Table 1, but for $\Upsilon = 1/10$.

occurs with a lower strength of the field. These characteristics can be understood by looking on how the fundamental ingredients of the model $\left(\vec{B},\ \vec{\beta},\ \vec{\eta},\ N_{\pm}\right)$ enter in the equations and, in particular, looking at the dependence of the rate $\zeta(t)$ in Eq. (4) on $B(t)$ and $\vec{\eta}$.

In Fig. 1 is shown the variation of the parameter Ψ in Eq. (5), for three considered values of Υ and for the three directions of emission (**generic**, $\hat{y}$**-axis** and $\hat{z}$**-axis**), with $B_0 = 0.1\ B_{\rm cr}$ and $N_{\pm,\,0} = 10^6$. It is evident that the condition in Eq. (5) is well satisfied for all the analyzed cases and for all the integration time. In Fig. 2 we present the result for the screening of the magnetic field when an initial number of particles $N_{\pm,0} = 10^{10}$ is emitted along the: 1) *generic* direction with $\gamma_0 = 2.27$; 2) $\hat{z}$-axis with $\gamma_0 = 2.14$, with initial strength of the background magnetic field $B_0 = 0.3\ B_{\rm cr}$ and $\Upsilon = 1/2$.

Table 3. Same results of Table 1, but for $\Upsilon = 1/100$.

Figure 3, instead, shows the emitted photons energy for $N_{\pm,\,0} = 10^{10}$ particles emitted along the *generic* direction, for the three considered values of $\Upsilon = 1/2,\ 1/10,\ 1/100$ and for $B_0 = 0.1\ B_{cr}$.

4. Conclusions

In this work, we have built a simplified model to study the magnetic field screening process operated by a huge number of $e^{\pm}$ pairs in presence of a strong crossed electromagnetic field. The model we have built is based on two principal assumptions:

(1) We have constructed one-particle equations to describe the particles motion as a fluid. This assumption is justified considering the dynamics of the entire process and the initial conditions (the particles obey to the continuity equation and are forced to follow the same trajectory due to the high strength of the fields).
(2) Due to the proportionality between the magnetic and electric field, also the electric field is screened. This effect can be justified considering that the creation of new charged particles, via the MPP and synchrotron processes, leads to the

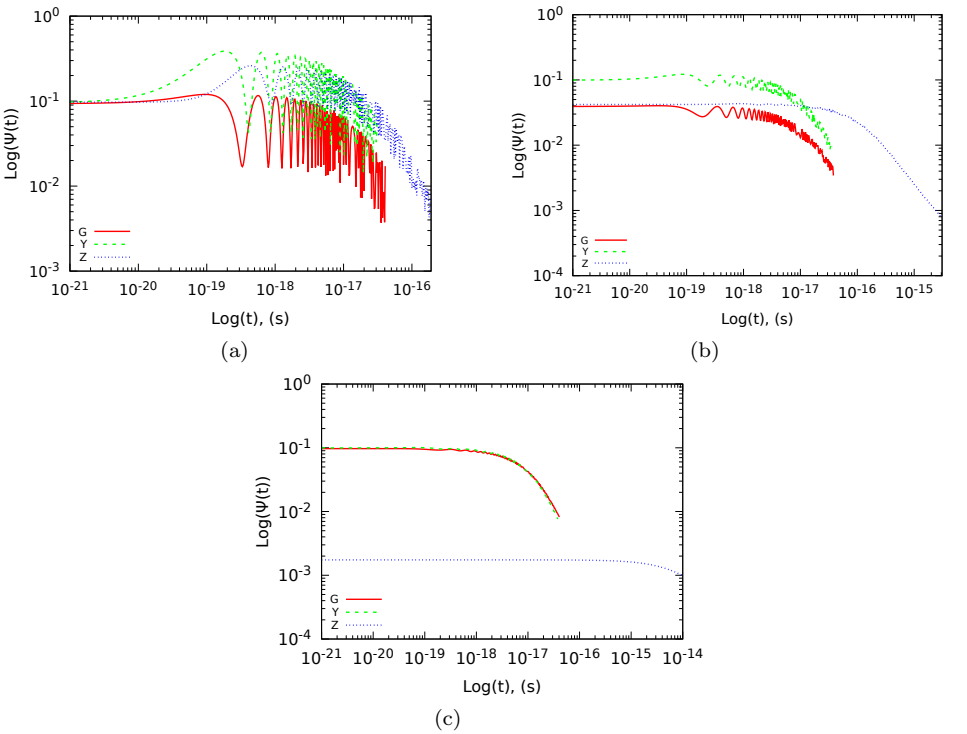

Fig. 1. Variation of the Ψ parameter, calculated for the case ϒ = 1/2 (a), 1/10 (b), 1/100 (c), for the three directions of emission (**generic**, **ŷ-axis** and **ẑ-axis**) and for an initial magnetic field strength of $B_0 = 0.1\ B_{cr}$.

formation of a current which screens the electric field too. We address to future work a more detailed treatment of this process.

We briefly summarized here the results that we got from our research. Further and more complete details can be found in Refs. 7, 8. We have obtained that the screening process occurs and the significance of the process (and, then, of the reduction of the field) depends by

(I) the number of initial pairs injected in the system: the screening is more efficient if one increases $N_{\pm,0}$ from 10^6 to 10^{10}–10^{15};
(II) the initial particles emission direction: the major effect is obtained when the particles are emitted with a higher perpendicular component of their velocity $\beta_\perp$ (namely along the *generic* and ŷ-axis directions);
(III) the parameter ϒ. For particle with lower $\beta_\perp$ (*generic* direction) a decrease of ϒ leads to a stronger screening effect. Instead, for particles with a higher $\beta_\perp$ (namely emitted along the ŷ-axis), the screening increases if ϒ decreases.

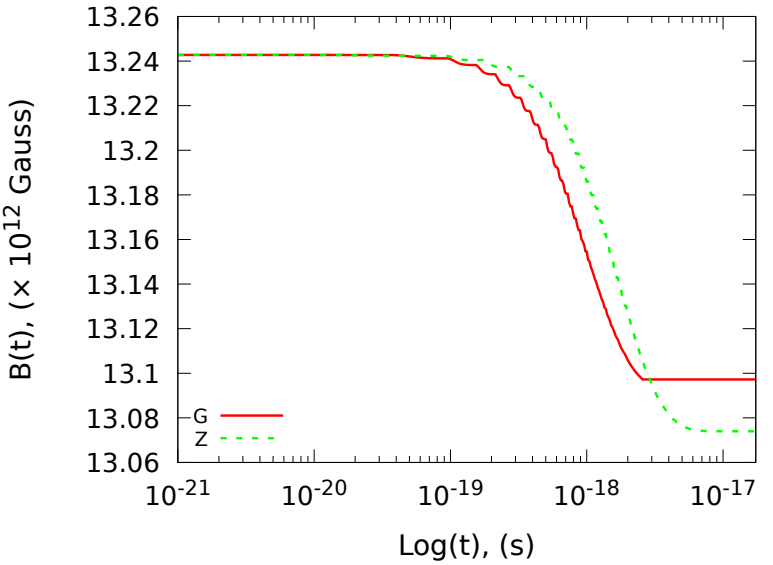

Fig. 2. Magnetic field decrease due to an initial number of particles, $N_{\pm,0} = 10^{10}$, emitted initially along the *generic* direction (with $\gamma_0 = 2.27$) and along the $\hat{z}$-axis (with $\gamma_0 = 2.14$). Here $\Upsilon = 1/2$ and $B_0 = 0.3\ B_{\rm cr}$.

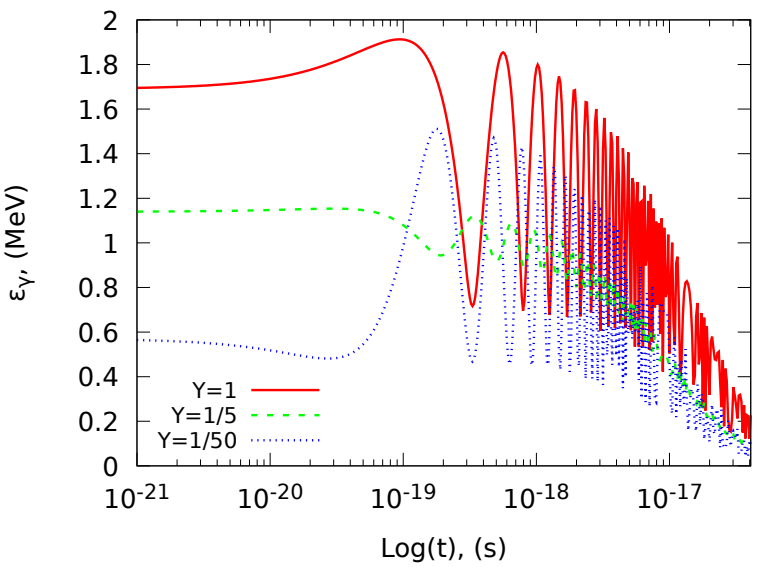

Fig. 3. Emitted photons energy, as a function of time, for $N_{\pm,0} = 10^{10}$ emitted along the *generic* direction, with $B_0 = 0.1\ B_{\rm cr}$, for $\Upsilon = 1/2,\ 1/10,\ 1/100$.

We conclude that, under the studied physical conditions, the screening effect occurs and leads to a reduction of the field up to a few percent (for the specific initial conditions considered in this work). This implies that this process needs to be taken into account in the treatment of particles dynamics in extreme astrophysical systems, as pulsars and gamma-ray bursts. This study has been the first one on this subject and, in order to apply it to real physical systems, some improvements are necessary. Future development of this work concern its extension to different configurations between the electric and magnetic fields, the extension of the treatment to the case of overcritical fields (where the entire process can be no longer treated classically). However, the present approach have helped us to clarify the main physical ingredients and the necessary conditions for the occurrence of this effect.

Particle creation by strong and time-varying backgrounds is a robust prediction of quantum field theory. Another well-established feature of field theory is that classical symmetries do not always extend to the quantized theory. When this occurs, we speak of quantum anomalies. In this contribution we discuss the entwining relationship between both predictions, relating chiral anomalies with an underlying process of particle creation. Within this context, we will also argue that the symmetry under electric-magnetic duality rotations of the source-free Maxwell theory is anomalous. This is a quantum effect, and it can be understood as the generalization of the fermion chiral anomaly to fields of spin one. This implies that the net polarization of photons propagating in a gravitational field could change in time.

Keywords: Chiral anomalies, gravitational particle creation, electromagnetic duality rotations, photon helicity

1. Introduction

Two fundamental predictions of quantum field theory in presence of strong field backgrounds were established in the sixties:

i) The spontaneous creation of particles out of the vacuum by time-varying gravitational fields. This was first discovered in the analysis of quantized fields in an expanding universe[1] and some years later applied to black holes[2] (for reviews see,[3–8] and for a historical perspective see[9,10]). It also offered a better understanding of the pair creation phenomena induced by electric fields, as explored by Heisenberg and Euler[11,12] and also Schwinger.[13]

ii) The breaking of the axial symmetry of Dirac fermions by quantum effects.[14,15] Classical symmetries of field theories may fail to survive quantization, leading to what is known in the literature as quantum anomalies (for a review see[16]). The origin of the anomalies is rooted in the renormalization mechanism need to tame the ultraviolet divergences that affect most models of quantum field theory. Renormalization in presence of an electromagnetic background can spoil the classical conservation law of the axial Noether current J_5^μ of massless charged fermions. It is codified by the Adler-Bell-Jackiw anomaly[14,15] ($\alpha = e^2/(4\pi\hbar)$ is the fine-structure

*Invited talk given at the Sixteenth Marcel Grossmann Meeting (2021), Session: Strong Electromagnetic and Gravitational Field Physics.

constant; we take $c = 1$)

$$\partial_\mu \langle 0|J_5^\mu|0\rangle = \frac{\alpha}{2\pi} F_{\mu\nu}{}^* F^{\mu\nu} \ . \tag{1}$$

The axial anomaly can also be interpreted as a low-energy phenomena in terms of particle production. A time-varying electric field creates both left-handed and right-handed fermions. The net amount of created chirality ΔQ_5 (i.e., the number of right-handed fermions N_R minus the number of left-handed fermions N_L created between t_1 and t_2)) is evaluated according to[a]

$$\Delta Q_5 = \hbar(N_R - N_L) = \int_{t_1}^{t_2} dt \int_{\Sigma_t} d\Sigma_\mu \langle 0|J_5^\mu|0\rangle = \frac{\alpha}{2\pi} \int_{t_1}^{t_2} \int_{\Sigma_t} d^4x F_{\mu\nu}{}^* F^{\mu\nu} \ . \tag{2}$$

It is important to stress that the minimum amount of created (massless) fermions is obtained in the adiabatic limit,[17] and it is just encapsulated in the creation of the chirality accounted by the anomaly. This might be somewhat surprising since the particle number is naively expected to be an adiabatic invariant[b]. The breaking of the adiabatic invariance of the particle number can then be understood as a signal of the chiral anomaly. Furthermore, the existence of the axial anomaly implies that there is necessarily a minimum amount of particle creation, even for an adiabatic process, to account for the creation of chirality. In more pedestrian words, the creation of chirality can be regarded as the "smoking gun" of the full particle creation process. We can summarize these features schematically:

$$\boxed{Quiral \ \ Anomaly \rightarrow Particle \ \ creation}$$

$$\boxed{Adiabatic \ \ Particle \ \ creation \rightarrow Quiral \ \ Anomaly}$$

The above results on the chiral anomaly can be extended to curved spacetime.[19] Expression (1) generalize to

$$\nabla_\mu \langle 0|J_5^\mu|0\rangle = \frac{\alpha}{2\pi} F_{\mu\nu}{}^* F^{\mu\nu} + \frac{\hbar}{192\pi^2} R_{\mu\nu\alpha\beta}{}^* R^{\mu\nu\alpha\beta} \ , \tag{3}$$

where $R_{\mu\nu\alpha\beta}$ is the Riemann tensor and ${}^*R^{\mu\nu\alpha\beta}$ its dual, and ∇_μ is the covariant derivative. We note that the gravitational part of the chiral anomaly persists for all type of fermions, either charged or neutral. Therefore, the chirality of (neutral) fermions fails also to be conserved in curved spacetimes for which

$$\Delta Q_5 = \frac{\hbar}{192\pi^2} \int_{t_1}^{t_2} \int_{\Sigma} d^4x \sqrt{-g} \ R_{\mu\nu\alpha\beta} \ {}^*R^{\mu\nu\alpha\beta} \tag{4}$$

is non-vanishing. This can be heuristically understood as a consequence of the universal character of gravity, as prescribed by Einstein's equivalence principle. If (4) is valid for a type of massless spin-1/2 field it must also be valid for any other type.

[a] We assume that a consistent particle interpretation is available at early and late times.
[b] It can be proved rigorously for a scalar field in an expanding universe.[1,18]

On physical grounds one can also argue that the universality of gravity suggests that these anomalies are not specific of spin 1/2 fermions. Therefore, one could also expect that a somewhat similar anomaly (also associated to an underlying particle production process) will arise for other fields admitting axial-type symmetries.

In this work we will further discuss the entwining relationship between particle creation and quantum anomalies. In particular, we are especially interested in exploring a new scenario in which (spontaneous and stimulated) particle creation can be relevant. The proposed scenario will be suggested by its link with quantum anomalies, as first explored in.[20] Our heuristic and intuitive argument is based on the universality of gravity, which suggest that the chiral anomaly for spin 1/2 fields should also be extended to the electromagnetic field. In the language of particle creation, one would also expect that a chiral gravitational configuration will create photons with different helicities in unequal amounts, in the same way as it happens, according to (4), for spin 1/2 fermions.

2. Trace and Axial anomalies for massless fermions

Free massless Dirac spinors are highly symmetric. In addition to their Poincaré invariance in Minkowski spacetime, they exhibit two extra symmetries: conformal and axial invariance. The conformal (or Weyl symmetry) implies the tracelessness of the stress-energy tensor $T_{\mu\nu}$, while the axial symmetry ($\psi \to e^{i\theta\gamma^5}\psi$) implies the conservation of the axial current $J^\mu_5 = \bar{\psi}\gamma^\mu\gamma^5\psi$. Both symmetries cannot be extended to the quantum theory when the Dirac field is coupled to an electromagnetic background. The conservation of the axial current is broken according to (1). Furthermore, the trace of the stress-energy tensor also acquires a non-vanishing vacuum expectation value[16,21,22] (for a more recent derivation, see[23])

$$\langle T^\mu_\mu \rangle = \frac{\alpha}{6\pi} F_{\mu\nu}F^{\mu\nu} \ , \tag{5}$$

which is usually interpreted in terms of the running of the coupling constant in quantum electrodynamics.[24] In the same way, neither of the two symmetries is preserved when the Dirac field is coupled to a gravitational background. One also finds a trace anomaly

$$\langle T^\mu_\mu \rangle = \frac{\hbar}{2880\pi^2}[aC_{\mu\nu\rho\sigma}C^{\mu\nu\rho\sigma} + bG + c\Box R] \ , \tag{6}$$

where $C_{\mu\nu\rho\sigma}$ is the Weyl tensor and G is the integrand of the Gauss-Bonnet topological invariant. The numerical coefficients are given by $a = -9$, $b = 11/2$, $c = 6$, and they can be obtained by different methods.[22,25] It is interesting to point out that the specific form of the trace anomaly implies that there are no massless fermions created in Friedman-Lemaître-Robertson-Walker (FLRW) universes (in this case the trace anomaly is proportional to G, up to total derivatives, and no further term proportional to R^2 appears[26]). This is fully consistent with earlier results[1] showing the absence of particle creation for fields obeying conformally invariant equations.

As remarked in the introduction one also finds an axial anomaly of the form

$$\nabla_\mu \langle J_5^\mu \rangle = \frac{\hbar}{192\pi^2} R_{\mu\nu\alpha\beta}{}^* R^{\mu\nu\alpha\beta} \ . \tag{7}$$

This anomaly can be interpreted in terms of particle creation induced by a chiral gravitational configuration (see[27] for a cosmological setting). Here we want to remark that (7) is consistent with late-time black hole emission.[2] Stationary Kerr black holes emit fermions with a helicity-dependent angular distribution,[28–30] as one could heuristically expect from the local form of the anomaly (7). Fermions with positive helicity are emitted preferentially along the direction of rotation, while fermions with negative helicity in the opposite direction.[For instance, neutrinos are preferentially emitted in the direction opposite to hole's rotation, while antineutrinos in the direction of rotation]. However, the net contribution when integrated over all angles is zero, in agreement with the vanishing of (4) for the Kerr metric. Nevertheless, in the transient process through the formation of a single Kerr black hole, as for instance the merger of two black holes (as the ones currently observed by LIGO-Virgo), the net contribution is not zero, as it has been evaluated using numerical relativity.[31] [For neutrinos/antineutrinos this means creation of matter-antimatter asymmetry]. Although the net creation of helicity is still small, due to the short duration of the process, it could be more significant in scenarios displaying an accumulative process over long periods of time. In any case, one should always take into account that the net creation of helicity represents only a lower bound of the full particle creation process. More particles could be produced without contributing to the creation of helicity.

The above discussion applies equally to the emission of photons. Right-handed photons are radiated more abundantly in the direction parallel to the axis of rotation of a Kerr black hole, and left-handed photons are emitted more abundantly in the opposite direction. This suggests the existence of an "axial anomaly" for spin-1 fields.

3. Electro-magnetic duality as an axial anomalous symmetry

Can we extend the above considerations to the electromagnetic field? Concerning the conformal symmetry, it is well-known that it is broken by quantum effects induced by the gravitational background. The trace of the renormalized stress-energy tensor can be expressed as

$$\langle T_\mu^\mu \rangle = \frac{-62\hbar}{2880\pi^2} \left(R^{\mu\nu} R_{\mu\nu} - \frac{1}{3} R^2 \right) + \frac{\hbar}{16\pi^2} c \Box R \ , \tag{8}$$

where c is an ambiguous coefficient, which depend on the particular regularization method ($c = -1/10$ for point-plitting and zeta-function regularization, and $c = 1/15$ for dimensional regularization[22]). We note again[26] that, for a FLRW universe, the trace anomaly turns out to be proportional to the integrand of the Gauss-Bonnet invariant G, up to the ambiguous and total derivative term $\Box R$. The absence of

an extra term proportional R^2 is crucial to predict the absence of massless, spin-1 particle creation in an isotropically expanding universe.

The point now is: what is the analog of axial symmetry for the free electromagnetic field? A natural candidate are the well-known electric-magnetic duality transformations, defined by

$$F^{\mu\nu} \to F'^{\mu\nu} = \sin\theta \ {}^*F^{\mu\nu} + \cos\theta \ F^{\mu\nu} \ . \tag{9}$$

The above transformations leave the action

$$S_{Maxwell} = -\frac{1}{4}\int d^4x\sqrt{-g}(\nabla_\mu A_\nu - \nabla_\nu A_\mu)(\nabla^\mu A^\nu - \nabla^\nu A^\mu) \tag{10}$$

invariant, as first proved in Refs.[32,33] in Minkowski space and in Refs.[34,35] in curved space. The associated Noether current can be expressed as

$$j^\mu_D = \frac{1}{2}[A_\nu \ {}^*F^{\mu\nu} - Z_\nu \ F^{\mu\nu}] \ , \tag{11}$$

where the auxiliary field Z_μ is defined as $\nabla_\mu Z_\nu - \nabla_\nu Z_\mu = {}^*F_{\mu\nu}$. j^μ_D is gauge invariant, but it cannot be expressed locally in terms of the field strength, in sharp contrast with the stress-energy tensor. The conserved charge[c]

$$Q_D = \int_{\Sigma_t} d\Sigma_\mu j^\mu_D \tag{12}$$

evaluates the electromagnetic helicity of a classical electromagnetic configuration.[33]

We note that Q_D can be decomposed in two contributions[37]

$$Q_D = Q_m + Q_e \ , \tag{13}$$

where

$$\begin{aligned} Q_m &= \frac{1}{2}\int_{\Sigma_t} d\Sigma_\mu A_\nu \ {}^*F^{\mu\nu} \\ Q_e &= -\frac{1}{2}\int_{\Sigma_t} d\Sigma_\mu Z_\nu \ F^{\mu\nu} \ . \end{aligned} \tag{14}$$

Q_m is the magnetic helicity and Q_e the electric helicity. Neither Q_m or Q_e are conserved quantities, in general.

At the quantum level Q_D is proportional to the difference between the number of right-handed and left-handed photons[33,38]

$$Q_D = \hbar(N_R - N_L) \ . \tag{15}$$

Therefore, this quantity is no longer conserved if the symmetry is afflicted by an anomaly. This issue was worked out in Refs.[20,39–41] from different methods and viewpoints, arguing that the symmetry under electric-magnetic duality rotations

[c] Q_D can be written in terms of a non-local integral involving only electric and magnetic fields.[36]

becomes anomalous in curved spacetime. The result is somewhat parallel to that found for spin-1/2 fields

$$\nabla_\mu \langle j_D^\mu \rangle \propto \hbar R_{\mu\nu\alpha\beta}{}^* R^{\mu\nu\alpha\beta} \ . \tag{16}$$

We want to remark here that previous works in the eighties[42–44] computed the divergence of the Pauli-Lubansky vector $K^\mu \propto A_\nu {}^* F^{\mu\nu}$ in curved space

$$\nabla_\mu \langle A_\nu \ {}^* F^{\mu\nu} \rangle = \frac{1}{2} \langle F_{\mu\nu} {}^* F^{\mu\nu} \rangle = \frac{\hbar}{96\pi^2} R_{\mu\nu\alpha\beta} {}^* R^{\mu\nu\alpha\beta} \ . \tag{17}$$

This result is indeed related to the (classically non-conserved) magnetic helicity, instead of the electromagnetic helicity. We can easily realize this from the fact that the Pauli-Lubansky vector is proportional to the current

$$j_m^\mu \equiv \frac{1}{2} A_\nu \ {}^* F^{\mu\nu} \ . \tag{18}$$

This current gives the magnetic helicity as the integral

$$Q_m(t) = \int_{\Sigma_t} d\Sigma_\mu j_m^\mu \ . \tag{19}$$

j_m^μ is not a Noether current, hence Q_m is not time-independent. The proper Noether current associated to the electro-magnetic duality symmetry involves an extra contribution $j_e^\mu \equiv -\frac{1}{2} Z_\nu F^{\mu\nu}$. This additional term is crucial to produce a classical conserved current

$$j_D^\mu = j_m^\mu + j_e^\mu \ , \tag{20}$$

which can be physically interpreted in terms of the spin-1 axial anomaly if $\nabla_\mu \langle j_D^\mu \rangle$ is different from zero. Since $\nabla_\mu \langle j_e^\mu \rangle = -\langle F^*_{\mu\nu} F^{\mu\nu} \rangle - \frac{1}{2} \langle Z_\nu \nabla_\mu F^{\mu\nu} \rangle$, one gets

$$\nabla_\mu \langle j_D^\mu \rangle = -\frac{1}{2} \langle Z_\nu \nabla_\mu F^{\mu\nu} \rangle \ . \tag{21}$$

It has been argued in[39–41] that the above vacuum expectation value is nonvanishing and that it is proportional, as expected, to $R_{\mu\nu\alpha\beta}{}^* R^{\mu\nu\alpha\beta}$, in parallel with the fermionic case. As stressed above, and in the language of particles, this would imply that the difference in the number of photons with positive and negative helicities, $N_R - N_L$, is not necessarily conserved in curved spacetimes.

Nevertheless, we want to remark that the result (17) contains an indirect signal of the electromagnetic axial anomaly found in.[39–41] If the invariance of the electromagnetic field equations under the duality transformation $F^{\mu\nu} \to F'^{\mu\nu} = \sin\theta \ {}^* F^{\mu\nu} + \cos\theta \ F^{\mu\nu}$ is strictly translated to composite quantum operators one would get

$$\langle F_{\mu\nu} {}^* F^{\mu\nu} \rangle = (\cos^2\theta - \sin^2\theta) \langle F_{\mu\nu} {}^* F^{\mu\nu} \rangle - \sin\theta \cos\theta (\langle F_{\mu\nu} F^{\mu\nu} \rangle - \langle {}^* F_{\mu\nu} {}^* F^{\mu\nu} \rangle) \ . \tag{22}$$

This would force $\langle F_{\mu\nu} {}^* F^{\mu\nu} \rangle = 0 = \langle F_{\mu\nu} F^{\mu\nu} \rangle - \langle {}^* F_{\mu\nu} {}^* F^{\mu\nu} \rangle$. Since neither $\langle F_{\mu\nu} {}^* F^{\mu\nu} \rangle$ or $(\langle F_{\mu\nu} F^{\mu\nu} \rangle - \langle {}^* F_{\mu\nu} {}^* F^{\mu\nu} \rangle)$ are zero (see[45] for a detailed discussion on this), we

should conclude that electro-magnetic duality fails for non-linear vacuum expectation values. This is the underlying reason permitting the result

$$\nabla_\mu \langle j_m^\mu \rangle + \nabla_\mu \langle j_e^\mu \rangle \neq 0 \ . \tag{23}$$

3.1. *Chiral anomalies and gravitational radiation*

We end this section by outlining an very interesting connection between chiral anomalies and gravitation radiation.[31,46] It is well-know that the right-hand side of (16), as for anomalies in gauge theories, is a total divergence. This simple fact suggests to reinterpret the result (16), or the analogous one for massless fermions, in a physically appealing manner. To evaluate the produced quirality induced by particle creation one should evaluate four-dimensional integrals of the form (4). In doing this one gets crucial contributions from the boundary of the spacetime (i.e., null infinity) involving the outgoing flux of gravitational waves. The contribution of the chiral anomaly can then be exactly related to the amount of circular polarization of the outoging gravitation radiation. Following[31,46] one gets the intriguing relation (see[46] for details)

$$\int d^4x R_{\mu\nu\lambda\sigma}{}^\star R^{\mu\nu\lambda\sigma} \propto \int_0^\infty \frac{d\omega\omega^3}{24\pi^3} \sum_{\ell m} [|h_+^{\ell m}(\omega) + i h_\times^{\ell m}(\omega)|^2 - |h_+^{\ell m}(\omega) - i h_\times^{\ell m}(\omega)|^2] \ , \tag{24}$$

where h_+, $h_\times$ are the standard gravitational waves polarization modes. The right-hand-side is related to the difference in the intensity between right and left circularly-polarized gravitational waves reaching future null infinity. This shows that a flux of circularly polarized gravitational waves triggers the spontaneous creation of quanta with net helicity. Note the similarity with the Hawking emission by rotating black holes. The angular momentum of the Kerr black hole triggers the spontaneous creation of quanta with net angular momentum.

4. Final remarks

It is well-known that spontaneous emission induces stimulated emission in presence of bosons. This is also true for gravitational particle creation.[1] One can write the simple and basic result

$$\langle N_i(t) \rangle \equiv \langle \Psi | a_i^\dagger(t) a_i(t) | \Psi \rangle = \langle N_i^0 \rangle + (1 + 2\langle N_i^0 \rangle) |\beta_i(t)|^2 \tag{25}$$

where N_i^0 is the initial number of quanta in mode i contained in the quantum state $|\Psi\rangle$ (the effect is reversed for fermions). This was also considered for black hole radiation in,[47,48] and more recently in[49,50] for non-gaussianities during inflation.

The stimulated counterpart effect is the main difference in the consequences of the axial anomaly for spin-1/2 fermions and photons. In the latter case, the presence of photons in a given mode will trigger the creation of photons of the same mode. It is not easy to evaluate quantitatively the consequences of this effect on

a macroscopic pulse of radiation. But it not difficult to guess that it will change the circular polarization of light-rays, with trajectory $x^\mu = x^\mu(\tau)$, propagating through a gravitational field with non-trivial $R_{\mu\nu\lambda\sigma}{}^\star R^{\mu\nu\lambda\sigma}(x(\tau))$. This is a quantum effect, probably very tiny, to be added to the classical gravitational redshift and the deflection of light rays by massive bodies.[51]

Constraints on the non-minimal coupling of electromagnetic fields from astrophysical observations

Susmita Jana and S. Shankaranarayanan

Strong gravity regions, like the neighborhood of black holes or neutron stars, can induce non-minimal couplings between electromagnetic fields(EM) and gravity. In these regions, gravitational fields behave as a non-linear medium in which the electromagnetic fields propagate. For a system of mass M and size R, the surface potential scales as M/R. Pulsar timing array, Double pulsar Shapiro delay, and Event horizon telescope probe that largest surface potentials $[10^{-4} - 10^{-2}]$. With many future experiments, it is possible to constrain the non-minimal coupling between electromagnetic fields and gravity. As a step in this direction, we consider the non-minimal coupling of EM field tensor through Riemann tensor for a dynamical black-hole, described by Sultana-Dyer(SD) metric. The non-minimal coupling leads to modified dispersion relations of photons, which get simplified at $\tilde{E}/\tilde{L} >> 1$ regime, where $\tilde{E}$ and $\tilde{L}$ are two conserved quantities obtained by taking into account the symmetries of the metric. We calculate polarization-dependent photon deflection angle and arrival time from these dispersion relations, which we evaluate considering different astrophysical sources of photons. We compare the analytical results with the current astrophysical observations to constraint the non-minimal coupling parameters to Riemann tensor more stringently.

Keywords: Non-minimal coupling, time-dependent black hole, strong fields; Based on.[1]

1. Introduction

The general theory of relativity has been tested in the weak-field regime with great accuracy from astrophysical observations — gravitational redshift, light deflection, and perihelion precession of planetary orbits.[2] However, it has not been verified well in strong-field regions such as near a black hole or a neutron star and many have proposed higher-order curvature corrections to GR.[3–7] Testing theories of gravity both in the strong and weak sector requires astrophysical observations, electromagnetic wave is an important source of such observations.

While testing GR through properties associated with photons we consider the minimal coupling of EM fields with gravity —Maxwell's action in curved space-time. Theories with minimal coupling are well tested in weak, but not in strong gravity regions.[8,9] Hence, the accuracy of the theories of gravity including the minimal coupling of the electromagnetic field requires investigation. To test GR in the strong-field limit it is essential to understand how does gravity interact with electromagnetic fields in such regions. One possibility is to consider coupling of the electromagnetic field tensor with the curvature of the space-time through Riemann and Ricci tensors, known as non-minimal coupling of electromagnetic fields.[3]

A model describing non-minimal coupling of electromagnetic fields with curved space-time, violating Einstein's equivalence principle, was first introduced in Ref.[3]. After that different models with more generalized actions were proposed in Refs.[4–7]. As a result, they obtained polarization-dependent photon propagation obeying distinct dispersion relations for the individual polarization modes. Whereas, minimally coupled photons follow dispersion relation $p^\mu p_\mu = 0$ irrespective of their polarization mode.

Even though non-minimal coupling in the space-time of static black hole reveals new behavior of EM waves, it is essential to study the same for a time-dependent black hole as well. One example of a time-dependent black hole is the Sultana-Dyer[10] black hole which describes a Schwarzschild black hole immersed in background FLRW space-time. In this talk we have discussed the properties of photons, non-minimally coupled to the curvature produced by a Sultana-Dyer black-hole. We expect separate dispersion relations of photons for each polarization mode, different than what was obtained for a time-independent black hole.

We also inspect the trajectory of non-minimally coupled photon for an individual mode of polarizations in the vicinity of a time-dependent black hole. In order to do so, we calculate the polarization-dependent deflection angle of a photon in Sultana Dyer space-time. We include coupling of EM field tensor with Riemann tensor only in our analysis as mentioned in.[3] From the expression of the polarization-dependent deflection angles, we constraint the value of the coupling-constant present in action. Inclusion of the dynamical black hole instead of a static one improves the bound on the coupling constant up to $\mathcal{O}(10^{10})$ for a solar-mass black hole.

2. General model

Action describing the most general model of non-minimal coupling that consists coupling of electromagnetic field tensor with Riemann, Ricci tensors and Ricci scalar is[7]:

$$\mathcal{S}_{NC} = \int d^4x\sqrt{-g}\left[\frac{R}{\kappa} - \frac{1}{4}\,F_{\mu\nu}F^{\mu\nu} + \chi^{\mu\nu\alpha\beta}\,F_{\mu\nu}F_{\alpha\beta}\right], \tag{1}$$

where,

$$\chi^{\mu\nu\alpha\beta} = \frac{q_1 R}{2}\left(g^{\mu\alpha}g^{\nu\beta} - g^{\mu\beta}g^{\nu\alpha}\right) + \frac{q_2}{2}\left(R^{\mu\alpha}g^{\nu\beta} - R^{\mu\beta}g^{\nu\alpha} + R^{\nu\beta}g^{\mu\alpha} - R^{\nu\alpha}g^{\mu\beta}\right) + \frac{\lambda}{2}R^{\mu\nu\alpha\beta}. \tag{2}$$

As mentioned earlier, the models of non-minimal coupling violate the Einstein equivalence principle(EEP), hence this model also violates EEP while being invariant under CPT and general coordinate transformation. A simpler model from the above action can be obtained by choosing $q_1 = q_2 = 0$.[11]

$$S = \int d^4x\,\sqrt{-g}\,\left(-\frac{1}{4}\,F_{\mu\nu}F^{\mu\nu} + \frac{\lambda}{2}\,R^{\mu\nu\alpha\beta}\,F_{\mu\nu}\,F_{\alpha\beta}\right). \tag{3}$$

Authors in Ref.[11] have studied properties of non-minimally coupled photon obeying this action for a spherically symmetric static black hole described by Schwarzschild metric. They have obtained non-identical modified dispersion relation for each mode of polarization followed by two polarization-dependent photon arrival times. Calculating the difference between arrival time for individual polarization they obtained constraints on the coupling coefficient λ to be $\mathcal{O}(10^{20})$ cm^2 for a Solar mass black hole.

However, in reality, the black holes are non-static — embedded in the background expanding universe. That is why in search of the imprints of a dynamical black hole we have done a similar analysis for a time-dependent black hole with mass $[M_\odot 10^{-10}, M_\odot]$.

Electromagnetic fields non minimally coupled to the curvature of space-time obey the following equation of motion,

$$\nabla_\nu F^{\mu\nu} = 2\lambda \left[R^{\mu\nu\alpha\beta} \left(\nabla_\nu F_{\alpha\beta}\right) + \left(\nabla_\alpha R^\mu_\beta\right) F^{\alpha\beta} \right]. \tag{4}$$

The LHS of the above equation contains dynamical properties of the EM field, whereas the RHS of the EoM depends on the geometry of the space-time. The first term in RHS acts as a metric-dependent momentum term which varies with the component of the electromagnetic field tensor. The second term in RHS is similar to a mass term, in this case, it differs for each value of μ. For a static black hole described by Schwarzschild or Kerr metric the term with $\nabla_\alpha R^\mu{}_\beta$ is zero in Eq. (4) as $R_{\mu\nu} = 0$ for such metrics.

Our goal is to get dispersion relation of photon that depends on photon momentum, hence it is reasonable to define a local inertial frame attached to the non-inertial one and define the photon momentum in the local inertial frame by $p_{(\mu)}$. Momentum in local frame is related to momentum in non-inertial frame (p_ν) by the relation: $p_\nu = e_\nu{}^{(\mu)}\ p_{(\mu)}$, where, $e_\nu{}^{(\mu)}$ is the tetrad connecting the two — inertial and non-inertial frames.

In the case of black-hole space-times we consider, the variations of the curvature along the spatial coordinate ($\mathcal{L}$) and the time ($\mathcal{T}$) are large compared to the wavelength and period of electromagnetic waves, i.e.

$$\mathcal{L} >> \bar{\lambda} = 1/\bar{k}, \quad T >> 1/\omega \tag{5}$$

Under the Eikonal approximation, locally we can treat the EM waves as planar and monochromatic[11]:

$$\nabla_{(\mu)} F^{(\mu)(\nu)} = p_{(\mu)}\, F^{(\mu)(\nu)} \tag{6}$$

Using this relation into Eq. (4) we get the equation that describes the dynamics of the electromagnetic field in the local inertial frame,

$$p_{(\nu)}\, F^{(\mu)(\nu)} = 2\lambda \left[R^{(\mu)(\nu)(\alpha)(\beta)}\, p_{(\nu)} F_{(\alpha)(\beta)} + \left(\nabla_{(\alpha)} R^{(\mu)}{}_{(\beta)}\right) F^{(\alpha)(\beta)} \right]. \tag{7}$$

Setting the space-time index μ to the 3-space index j followed by incorporation of the Bianchi identity in local inertial frame into the above equation leads us to the equation below.

$$\begin{aligned}&[\ p^{(\mu)}p_{(\mu)}\,\delta^{(j)}_{(k)} - p_{(k)}p^{(j)} + 4\lambda\, R^{(j)(\mu)(\nu)}{}_{(k)}\, p_{(\mu)}p_{(\nu)}\\&+ 2\lambda\,\left(\nabla_{(\alpha)}R^{(j)}{}_{(k)}\,p^{(\alpha)} - \nabla_{(k)}R^{(j)}{}_{(\alpha)}p^{(\alpha)}\right)\ ]\,F^{(0)(k)} = 0\end{aligned} \tag{8}$$

Using Eq. (7) into the above equation, the equation of motion of the EM field in the Eikonal approximation is:

$$\begin{aligned}&\Bigg[p^{(\mu)}p_{(\mu)}\,\delta^{(j)}_{(k)} + 4\lambda\left(\frac{p^{(j)}}{p_{(0)}}\epsilon^{(0)}{}_{(k)} + \epsilon^{(j)}{}_{(k)}\right)\\&+ 2\lambda\,\left(\frac{p^{(j)}}{p_{(0)}}\nabla_{(\alpha)}R^{(0)}{}_{(k)}\,p^{(\alpha)} + \nabla_{(\alpha)}R^{(j)}{}_{(k)}p^{(\alpha)}\right)\\&- 2\lambda\,\left(\frac{p^{(j)}}{p_{(0)}}\nabla_{(k)}R^{(0)}{}_{(\alpha)}\,p^{(\alpha)} + \nabla_{(k)}R^{(j)}{}_{(\alpha)}p^{(\alpha)}\right)\Bigg]F^{(0)(k)} = 0,\end{aligned} \tag{9}$$

where, $\epsilon^{(\alpha)}{}_{(\beta)} \equiv R^{(\alpha)(\mu)(\nu)}{}_{(\beta)}\,p_{(\mu)}p_{(\nu)}$ acts as a polarization tensor that generates correction to EoM according to the component of electric field.

From the above equation, one can study the trajectory of non-minimally coupled photons considering different space-time metrics. As mentioned earlier for photons in Schwarzschild and Kerr black hole terms with Ricci tensor in Eq. (9) will vanish and the EoM reduces to,

$$\left[p^{(\mu)}p_{(\mu)}\,\delta^{(j)}_{(k)} + 4\lambda\left(\frac{p^{(j)}}{p_{(0)}}\epsilon^{(0)}{}_{(k)} + \epsilon^{(j)}{}_{(k)}\right)\right]F^{(0)(k)} = 0, \tag{10}$$

Our goal is to study the effects of the curvature coupling on photon trajectory near a time-dependent black-hole and identify the differences with the same due to a static black hole. In literature the analysis has been done only for static black holes and as a result constraint on λ has also been obtained. As a step ahead, We do this analysis for a cosmological black hole described by Sultana Dyer metric.[10]

3. Sultana Dyer metric

In reality, black holes are non-static and the Sultana Dyer metric describes such a time-dependent black hole.[10] Sultana Dyer black hole metric can be interpreted as a Schwarzchild black hole immersed in the background FLRW metric:

$$ds^2 = \left(\frac{\eta}{\eta_0}\right)^4\left[-\left(1-\frac{2GM}{r}\right)\,d\eta^2\ + \frac{4GM}{r}\,d\eta dr + \left(1+\frac{2GM}{r}\right)dr^2\ +\ r^2\,d\Omega^2\right] \tag{11}$$

where η is the conformal time—related to comoving time t as, $dt = a(\eta)d\eta$; $\eta = \eta_0$ at $t = t_0$, where t_0 is current cosmic time. M is mass of the black hole.

Sultana Dyer metric has been obtained by performing conformal transformation $a(t) \propto t^{2/3}$ to the Schwarzschild metric. Thus it corresponds to black-holes in the matter-dominated epoch. The conformal transformation preserves the casual structure also, as a result, the black hole has the horizon at $r_{\rm H} = 2GM/c^2$. Sultana-Dyer space-time is sourced by two non-interacting perfect fluids — null dust and massive dust. At the horizon, $r = r_{\rm H}$ the dust particles become superluminal for time $\eta > 2r_{\rm H}$.[10]

Writing the above equation in non-geometrised unit—$\eta \to c\eta$, $r_{\rm H} \to \frac{r_{\rm H}}{c^2}$ and substituting the following dimensionless variables:

$$\tilde{r} = \frac{c^2 r}{r_{\rm H}}; \quad \tilde{\eta} \equiv H_0\, \eta; \quad \tilde{\eta}_0 \equiv H_0\, \eta_0, \tag{12}$$

in the metric we have

$$ds^2 = \alpha_0^2\ \tilde{\eta}^4 \left[-\left(1 - \frac{1}{\tilde{r}}\right)\ \beta_0^2 d\tilde{\eta}^2 + \frac{2}{\tilde{r}}\beta_0\ d\tilde{\eta} d\tilde{r} + \left(1 + \frac{1}{\tilde{r}}\right) d\tilde{r}^2 + \tilde{r}^2\ d\Omega^2 \right] = \alpha_0^2\ d\tilde{s}^2 \tag{13}$$

where H_0 is Hubble constant,

$$d\tilde{s}^2 = \tilde{\eta}^4 \left[-\left(1 - \frac{1}{\tilde{r}}\right)\ \beta_0^2 d\tilde{\eta}^2 + \frac{2}{\tilde{r}}\beta_0\ d\tilde{\eta} d\tilde{r} + \left(1 + \frac{1}{\tilde{r}}\right) d\tilde{r}^2 + \tilde{r}^2\ d\Omega^2 \right] \tag{14}$$

$$\alpha_0 = \frac{r_{\rm H}}{c^2 \tilde{\eta}_0^2} \qquad \beta_0 = \frac{c^3}{r_{\rm H}\, H_0} \tag{15}$$

From here we will be using the dimensionless line-element $d\tilde{s}$ defined in Eq. (14). This choice is suitable because the affine parameter (τ) and all the physical quantities in this space-time depend on τ.

3.1. *Conserved quantities from symmetries of the metric*

The trajectory of a null object such as a photon is being fixed by its momentum p^μ. In this work, we focus on photons moving in the orbital plane of the black hole. For the metric (13), we define the contravariant photon momentum as,

$$p^0 = \frac{d\tilde{\eta}}{d\tau}, \quad p^1 = \frac{d\tilde{r}}{d\tau}, \quad p^2 = 0, \quad p^3 = \frac{d\phi}{d\tau} \tag{16}$$

Using the metric and the relation $p_\nu = g_{\mu\nu} p^\mu$ we get the covariant form:

$$p_0 = \tilde{\eta}^4 \left(-\beta_0^2\, A \frac{d\tilde{\eta}}{d\tau} + C_1 \frac{d\tilde{r}}{d\tau} \right) := \tilde{E}; \quad p_1 = -\frac{C_1}{A}\tilde{E} + \tilde{\eta}^4 \left(\frac{C_1^2}{A} + B \right) \frac{d\tilde{r}}{d\tau} \tag{17}$$

$$p_3 = \tilde{\eta}^4 C_2 \frac{d\phi}{d\tau} := \tilde{L} \tag{18}$$

Though the metric is time-dependent it is —conformally invariant w.r.t η or $\tilde{\eta}$ and spherically symmetric. Taking into account these two symmetries it can be shown that $\tilde{E}$ and $\tilde{L}$ defined in Eq. (17) are conserved w.r.t the affine parameter τ. where, $A = (1 - \frac{1}{\tilde{r}})$, $B = (1 + \frac{1}{\tilde{r}})$, $C_1 = \frac{\beta_0}{\tilde{r}}$, $C_2 = \tilde{r}^2$.

Our goal is to see effects on the non-minimally coupled photon close to the black hole, and later it will be clear that the effects depend on $\frac{\tilde{E}}{\tilde{L}}$, which is:

$$\frac{\tilde{E}}{\tilde{L}} = \left(\frac{r_{\rm H}}{c^2\, r}\right)^2 \left(-\left(1-\frac{r_{\rm H}}{c^2\, r}\right)\beta_0^2 H_0\, \frac{d\eta}{d\phi} + \frac{\beta_0}{r}\, \frac{dr}{d\phi}\right) \tag{19}$$

Close to the black hole at radius of photon sphere, $r = 3r_{\rm H}/(2c^2)$, it can be shown that for M in the range $[M_\odot 10^{-10}, M_\odot]$ the ratio $\tilde{E}/\tilde{L} >> 1$.

4. Modified dispersion relation

As a result of the non-minimal coupling dispersion relation for photon near Schwarzschild and Sultana Dyer black hole can be obtained from Eq. (10) as[11]:

$$p^2 = \pm\, \frac{6\lambda}{r_{\rm H}^2 \tilde{r}^3}\, p_{(3)}^2. \tag{20}$$

From the above expression, we infer that the photon dispersion relation remains quadratic also as similar to the relation $p^\mu p_\mu = 0$ with $r-$dependent corrections. There $(\pm)$ sign refers to dispersion relation for $(\pm)$ polarization mode. We have verified that for the Kerr metric, describing a time-independent rotating black hole the dispersion relation remains quadratic — even in the inertial frame of reference it gives the same dispersion relation (20).

The dispersion relations for the Sultana Dyer metric will be obtained from Eq. (9). Unlike Schwarzschild and Kerr black holes, the Ricci tensor is non-zero for Sultana-Dyer black hole. Hence, the terms with the Ricci tensor and its derivative will contribute to the dispersion relation. However, it is possible to check that the contribution arising from the Ricci tensor containing terms is much smaller than the other terms in the dispersion relation. Finally, keeping only the relevant terms we obtain the dispersion relations for the local inertial frame in the Sultana-Dyer metric as:

$$-f_1\, p_{(0)}^2 + f_1\, p_{(1)}^2 + f_2\, p_{(3)}^2 + f_3\, \frac{p_{(1)} p_{(3)}^2}{p_{(0)}} = 0 \tag{21}$$

$$-f_4\, p_{(0)}^2 + f_2\, p_{(1)}^2 + f_5\, p_{(3)}^2 + 2f_3\, p_{(1)} p_{(0)} = 0\,. \tag{22}$$

where, $f_n(\tilde{r}, \tilde{\eta})$ depends on the coupling constant $\tilde{\lambda} \equiv \lambda/\alpha_0^2$ and the components of Riemann tensor in local inertial frame for Sulatana-Dyer metric — $R_{(\alpha)(\beta)(\mu)(\nu)}$. These two dispersion relations in the local frame lead to the following relations in the non-inertial frame:

$$\frac{(C_1^3 - C_1)}{B} p_1^3 + (1 - 3C_1^2)\; p_0 p_1^2 + \left(3C_1 B\, p_0^2 + \frac{(f_3 - f_2\, C_1)}{f_1\, C_2} p_3^2\right) p_1 - B^2 p_0^3 + \frac{f_2\, B}{f_1\, C_2}\, p_0 p_3^2 = 0 \tag{23}$$

$$\left(-f_4 C_1^2 - 2f_3 C_1 + f_2\right) p_1^2 + 2\,(f_3 + f_4 C_1)\, B p_0 p_1 - f_4 B^2 p_0^2 + f_5 \frac{B}{C_2} p_3^2 = 0 \tag{24}$$

It is important to note here that the above-mentioned dispersion relations for the Sultana Dyer metric are very different than the dispersion relations obtained for the Schwarzschild metric. For Schwarzschild case the dispersion relations do not contain terms with $p_0 p_1$ or $p_1 p_3^2$. Secondly, in the dispersion relations for Sultana Dyer metric terms with every component of momentum get modified whereas for Schwarzschild metric only the term with p_3 gets modified. Last point, Eq. (23) is cubic and it occurs due to the last term in Eq. (21), while for the Schwarzschild case both the dispersion relations are quadratic.

5. Results

Till now we have discussed how photon dispersion relations get modified due to the presence of non-minimal coupling in Sultana Dyer space-time as compared to Schwarzschild metric. In this part we discuss the effects of these modified dispersion relations on photon trajectory. To see the effects one needs to study the modification to the trajectory of the photon, which can be done through these astrophysical observables — 1) Photon arrival-time at the detector, 2) Photon deflection-angle at the detector. Since we are working with Sultana Dyer black hole — a time-dependent and non-diagonal metric, we prefer deflection-angle over photon arrival-time.

For verifying the existence of non-minimal coupling we have primarily two goals — 1) Put constraint on the non-minimal coupling coefficient, 2) Compare the effects on non-minimally coupled photon trajectory caused by time-independent and time-dependent black hole.

Reaching the above-mentioned goals requires derivation of the the deflection angle of photon for each polarization mode, and then their difference considering time-independent(Schwarzschild) and time-dependent(Sultana Dyer) black hole. For simplicity, we derive the difference in the deflection angle comparison at a radius of photon sphere — $\tilde{r} = 3/2$ as we are interested in the behavior of photons near the black hole.

For Schwarzschild metric at $r = (3/2)r_{\rm H}$ and $\tilde{\eta_0}$ the difference between the deflection angle for (+) and (-) polarization is,

$$\left.\frac{d\phi}{dr}\right|^{+}_{\rm Sch} - \left.\frac{d\phi}{dr}\right|^{+}_{\rm Sch} = \frac{4\beta_0\, b}{9 r_{\rm H}} \left[\left[1 - \frac{4\,\beta_0^2 b^2}{27} \left(1 - \frac{16\tilde{\lambda}}{729} \right) \right]^{-\frac{1}{2}} - \left[1 - \frac{4\,\beta_0^2 b^2}{27} \left(1 + \frac{16\tilde{\lambda}}{729} \right) \right]^{-\frac{1}{2}} \right] . \tag{25}$$

where, $b = \tilde{L}/\tilde{E}$ at fixed $\tilde{r}$ and $\tilde{\eta} = \tilde{\eta}_0$. The LHS of the above equation will be real if and only if,

$$1 - \frac{4\,\beta_0^2 b^2}{27} \left(1 \mp \frac{16\tilde{\lambda}}{729} \right) > 0\,. \tag{26}$$

From this condition, we determine the value of b, provided the values of β_0 and $\tilde{\lambda}$ are known.

Now for Sultana Dyer space-time, the difference between the polarization-dependent deflection angles can be obtained from the cubic (23) and the quadratic dispersion relation (24) separately. For the limit, $\beta_0 >> 1$ and $\tilde{E}/\tilde{L} >> 1$ both Eqs. (23) and (24) get simplified and the cubic dispersion relation becomes entirely independent of the coupling coefficient $\tilde{\lambda}$. This implies the simplified cubic dispersion relation does not hold any imprint of non-minimal coupling. Hence we stress our analysis into the quadratic dispersion relation only. From the simplified quadratic dispersion relation we get the deflection angle:

$$\frac{d\phi}{d\tilde{r}} = \frac{\tilde{L}\left(\frac{C_1^2}{A}+B\right)}{C_2\left(\frac{-\left(2f_4C_1B\tilde{E}\right)\pm\sqrt{\left(2f_4C_1B\tilde{E}\right)^2-4\left(-f_4C_1^2\right)B\tilde{L}^2\left(-f_4B\frac{\tilde{E}^2}{\tilde{L}^2}+\frac{f_5}{C_2}\right)}}{2\left(-f_4C_1^2\right)}+\frac{C_1}{A}\tilde{E}\right)}. \quad (27)$$

The difference between the deflection angle for $(\pm)$ polarizations at fixed $r = (3/2)r_{\rm H}$ and current comoving time $\tilde{\eta_0} = 3$ becomes,

$$\left.\frac{d\phi}{dr}\right|_{SD}^{+} - \left.\frac{d\phi}{dr}\right|_{SD}^{-} \sim \frac{162\,b^2\sqrt{\left(3^6-16\tilde{\lambda}\right)\left(8\tilde{\lambda}+3^6\right)}}{16\,k^3r_{\rm H}^4\left(8\tilde{\lambda}+3^6\right)}\frac{1}{\beta_0^2}. \quad (28)$$

where, $k = H_0/c$. Eqs. (25) and (28) depend on $r_{\rm H}$, β_0, b and $\tilde{\lambda}$. But it is crucial to note that in Schwarzschild space-time the difference between two deflection angles (25) depends on $b\,\beta_0$, whereas in Sultana Dyer space time (28) is proportional to b/β_0. Hence, at this point we stress that photon trajectory gets modified in different manner while travelling near a Schwarzschild or Sultana Dyer black hole. Understanding this fact better requires the value of b and $\tilde{\lambda}$.

From the condition that Eq. (28) will be real if and only if the constraint $\tilde{\lambda} < \frac{729}{16}$ is followed. As $\tilde{\lambda} = \lambda/\alpha_0^2$ we get the constraint of the coupling coefficient λ as: $\lambda < (9/16)r_{\rm H}^2$. This is another important result regarding which we like to stress the following points: First, the coupling constant λ is an intrinsic property of the field and should be independent of the parameters of the model. However, from the above expression, we see that the constraint on λ depends on the mass of the black hole. On the face of it, this might look unphysical. However, it can be pointed that the energy density of the mull dust in Sultana Dyer space-time does not remain positive for all values of η. The condition that the energy density remains positive at the photon radius translates to $\eta < 15r_{\rm H}/4$. Since, we have fixed $\eta = \eta_0$, this leads to the condition on λ. Thus, the above constraint on the coupling parameter λ ensures that the energy density of the electromagnetic field is non-negative. The table below gives the upper limit on λ for black holes with different mass ranges. Finally, it is interesting to compare the bounds on λ compared to obtained in the literature. In Ref.[11], the authors obtained constraints on λ considering photons in Schwarzschild

space-time. Considering signals from radar ranging past the Sun, the authors found $\lambda \sim 1.1 \times 10^{20}$ cm^2, which is about three orders of magnitude more stringent than the one obtained in Ref.[12]. Our analysis shows that $\lambda < 0.563 \times 10^{10}$cm^2 for the Sultana-Dyer black hole of solar-mass. Note that, in the case of signals coming from binary pulsar PSR B1534+12, the bound on $\lambda \sim 0.6 \times 10^{11}$ cm^2.[13]

Black hole mass	$r_{\rm H}$ (cm)	λ (cm^2)
Solar-mass	10^5	0.563×10^{10}
$10^{-3} M_\odot$	10^2	0.563×10^4
$10^{-5} M_\odot$	1	0.563
$10^{-10} M_\odot$	10^{-5}	0.563×10^{-10}

Now using the value of $\tilde{\lambda}$ ranging between $[0, 729/16]$ into condition (26) with the (-) sign we get the constraint $b\beta_0 < 1.8$. Similarly for the (+) sign we get the constraint as $b\beta_0 < 2.598$. However, for the constraint $b\beta_0 < 1.8$ Eq. (26) is valid for both ($\pm$) sign. From this constraint, we have fixed the value of b for a particular value of β_0, where the value of β_0 varies with the mass of the black hole.

Since we have fixed the variables $\tilde{\lambda}$, $r_{\rm H}$, β_0 and b, now we compare Eqs. (25) and (28) by evaluating their values for black holes with mass — $M_\odot$ and $10^{-5} M_\odot$. We evaluate the difference between two deflection angles in Schwarzschild and Sultana Dyer space-time considering two separate cases, 1) $b\beta_0 \sim 1$ and 2) $b\beta_0 \sim 10^{-3}$. Both these cases satisfies the condition $b\beta_0 < 1.8$. All the values has been mentioned in the table below.

Black hole mass	$b\beta_0$	$\Delta\left(\frac{d\phi}{dr}\right)_{\rm Sch}$	$\Delta\left(\frac{d\phi}{dr}\right)_{\rm SD}$
$M_\odot$	1	-1.322×10^{-5}	7.893×10^{-7}
	10^{-3}	-1.032×10^{-14}	7.893×10^{-13}
$10^{-5} M_\odot$	1	-1.322	0.079
	10^{-3}	-1.032^{-9}	7.893×10^{-8}

Inspecting the numbers in the above table we infer one more important key feature: for $b\beta_0 \sim 1$ the modulus of the difference between the deflection angles for Schwarzschild is greater than the same in Sultana Dyer space-time. However, for, $b\beta_0 \sim 10^{-3}$ the difference between the deflection angles for Sultana Dyer black hole is greater. The reason behind this behavior is that the difference between the deflection angle (28) for the Sultana Dyer black hole is proportional to b^2/β_0^2 and the same quantity (25) for the Schwarzschild black hole depends on b and β_0 differently.

As a result, we see the larger the value of b larger the effects due to Schwarzschild, and smaller the value of b the effects are larger for Sultana Dyer black hole. Another crucialfeature is that, the difference between the photon deflection angles for Schwarzschild metric is negative, while for Sultana Dyer it is always positive — that manifests two distinct signatures of two black holes. Similar behavior in the difference of deflection angles has been observed for a black hole of mass $10^{-5}M_{\odot}$ as well.

6. Conclusions and discussions

In this work, we have studied the effects of non-minimal coupling of electromagnetic fields with gravitational field near a cosmological black hole, described by Sultana Dyer metric, and compared them with the effects obtained for a Schwarzschild black hole. To our knowledge, the analysis for non-minimal coupling near a time-dependent black hole has not been explored in literature. For doing the analysis we have applied Eikonal approximation in a local inertial frame assuming that the wavelength and time period of the propagating electromagnetic wave is lesser than the variation of curvature with respect to the space-time. Our study for the Sultana Dyer metric produced a pair of modified dispersion relations which consist of corrections in all components of momentum, while for the Schwarzschild case the modification occurs only in the p_3 component. Besides that, one of the modified dispersion relations for the Sultana Dyer metric is cubic, while for the Schwarzschild metric both the dispersion relations remain quadratic. By calculating photon deflection angle for individual polarization mode in Sultana Dyer space-time we get a bound on λ for a solar mass black hole which is more stringent of order 10^{10} than the bound obtained in Ref.[11]. Through the evaluation of the difference between deflection angles for two polarizations we have found distinct signatures of two black holes — Schwarzschild and Sultana Dyer.

We hope that through observing electromagnetic emission in broad wave-band from different astrophysical events it is plausible to measure the deflection angle of electromagnetic wave and confirm the existence or non-existence of the non-minimal coupling.

For the entire work, we have assumed the time-dependent black hole to be spherically symmetric and non-rotating. To observe the signatures mentioned in this work from astrophysical observation might involve axially symmetric (like Kerr) black hole. Hence, we are investigating the possibilities to extend the analysis for a rotating black-hole space-time.

We explain a conjecture which states that the proper-time series expansion of the one-loop effective Lagrangian of quantum electrodynamics can be partially summed in all terms containing the field-strength invariants $\mathcal{F} = \frac{1}{4}F_{\mu\nu}F^{\mu\nu}(x)$, $\mathcal{G} = \frac{1}{4}\tilde{F}_{\mu\nu}F^{\mu\nu}(x)$. This summation is encapsulated in a factor with the same form as the (spacetime-dependent) Heisenberg-Euler Lagrangian density. We also discuss some implications and a possible extension in presence of gravity. We will focus on the scalar field case.

Keywords: One-loop effective Lagrangian; Partial resummation; Heisenberg-Euler Lagrangian; asymptotic expansion.

1. Introduction

In this contribution[a], we give more details on a conjecture proposed in Ref.[2], that claims that it is possible to make a factorization in the proper-time series of the one-loop effective Lagrangian of quantum electrodynamics (QED) that captures all explicit dependence on the field-strength invariants $\mathcal{F}$ and $\mathcal{G}$. The text is organized as follows. First, in Sections 1.1 and 1.2 we review some basics about the one-loop effective Lagrangian and its proper-time series expansion. We focus on the scalar QED effective Lagrangian and also on the corresponding effective Lagrangian in presence of gravity. We emphasize the existence of a modified, asymptotic expansion (also called R-summed expansion) in the gravitational scenario. In Section 2 we explain our conjecture for scalar QED (a sketch for spinor QED is given in Ref.[2]). We also check it up to order $n = 6$ (the last available coefficient in the literature). In Section 3 we explain some physical consequences that can be easily obtained using our results. Finally, in Section 4 we give a brief summary of this contribution. For simplicity, we will focus on the scalar QED case. In Appendices A and B we give the coefficients of the usual and the resummed proper-time series expansions for scalar QED.

1.1. *Heisenberg-Euler Lagrangian and the proper-time series expansion*

The Heisenberg-Euler Lagrangian captures the one-loop quantum corrections to the classical electromagnetic Lagrangian for quantum electrodynamics. It is obtained

[a]Expanded version of the talk given by S.P. in the Sixteenth Marcel Grossmann Meeting (2021).

by integrating out the matter degrees of freedom, keeping the strength of the electromagnetic background constant.[3,4] The intrinsic nonlinearities of the quantum corrections have important implications, such as pair creation from vacuum and vacuum polarization,[5] or light by light scattering or vacuum polarization (see, for example, Ref.[6] and references therein). It was originally derived by Heisenberg and Euler[7] for spinor QED in 1936. A few months later, it was obtained by Weisskopf[8] for scalar QED (see Ref.[9] for a charged spin 1 field). These two theories are regarded as the paradigm of the modern effective theories in Quantum Field Theory. From now on, we will focus on the scalar QED Heisenberg-Euler Lagrangian. It is usually written in terms of the proper time parameter s, but, apart from this, it be written in several ways. By convenience, here we use the following form borrowed from Ref.[10]:

$$\mathcal{L}^{(1)}_{scalar} = -\frac{1}{(4\pi)^2}\int_0^\infty \frac{ds}{s^3} e^{-im^2 s}\left[\det\left(\frac{esF}{\sinh(esF)}\right)\right]^{1/2}, \tag{1}$$

where $F \equiv F^{\mu}_{\ \nu}$. As we have stressed before, this result was obtained for constant electromagnetic backgrounds, but for arbitrary background configurations the form of the effective action is, in general, *unknown*.

However, it is possible to build a general, asymptotic expansion for the one-loop effective Lagrangian in terms of the proper-time parameter. Here we use the expansion given in Ref.[11], obtained via the string-inspired method in the world-line formalism (see Refs.[11–14] and also Refs.[15,16]), namely

$$\mathcal{L}^{(1)}_{scalar} = \int_0^\infty \frac{ds}{s} e^{-im^2 s} g(x; is)\ , \tag{2}$$

with

$$g(x;is) = \frac{1}{(4\pi is)^2}\sum_{n=0}^{\infty}\frac{(-is)^n}{n!}O_n(x) \longrightarrow \left\{\begin{array}{c} O_0 = 1, \quad O_1 = 0, \\ O_2 = -\frac{e^2}{6}F_{\kappa\lambda}F^{\kappa\lambda} \\ O_3 = -\frac{e^2}{20}\partial_\mu F_{\kappa\lambda}\partial^\mu F^{\kappa\lambda} \\ (\cdots) \end{array}\right\} \tag{3}$$

The expression above consist of an expansion in the number of external fields and the number of derivatives, and captures some general behaviour of the unknown formal one-loop effective Lagrangian for arbitrary backgrounds. The coefficients O_n are gauge-invariant and have mass dimension $2n$. They have been obtained up to 12th adiabatic order ($n = 6$), and their length grows substantially with n. In Appendix A can be found the complete list of coefficients. We would like to stress that this expansion presents some clear advantages with respect to other proposals. In particular, it is written in the most compact form possible. Using the Bianchi identity, the antisymmetry of $F_{\mu\nu}$ and also integration by parts, the gauge-invariant coefficients O_n have been simplified to the so-called minimal basis.[17]

1.2. *One loop effective Lagrangian in presence of gravity*

The role of the classical electromagnetic background can be replaced by a gravitational field, which is naturally coupled to quantized matter fields. In other words, it is possible to obtain quantum corrections to the Einstein-Hilbert Lagrangian induced by a quantum scalar field. In general, the form of the effective action is not known, but it is also possible to make an asymptotic expansion of it,[18] as in the previous case.

In this context, the expansion of the one-loop effective Lagrangian is usually obtained in terms of the Schwinger proper-time expansion of the Feynman propagator,[5] closely connected to the heat-kernel expansion and related techniques.[19] Specifically, the one loop effective Lagrangian in terms of the heat-kernel reads

$$\mathcal{L}^{(1)}_{scalar} = \int_0^\infty \frac{ds}{s} e^{-im^2 s} \langle x, s|x, 0\rangle \ . \tag{4}$$

In this expression, $\langle x', s|x, 0\rangle$ is the kernel or "transition amplitude" associated to the Feynman propagator, which obeys a Schrodinger-type equation in terms of the proper time parameter with appropriated boundary conditions, and $\langle x, s|x, 0\rangle$ represents the coincident limit $x' \to x$. In general, the kernel admits a general asymptotic expansion in terms of the proper time parameter, i.e.,

$$\langle x, s|x, 0\rangle = \frac{1}{(4\pi is)^2} \sum_{n=0}^{\infty} (is)^n a_n(x). \tag{5}$$

The coefficients $a_n(x)$ are called DeWitt coefficients. These quantities of mass dimension $2n$ are local, covariant and gauge invariant.[18,20] We recall here that for QED, the expansion $g(x; is)$ [see Eq. (5)] coincides with the heat kernel expansion, up to total derivatives

$$g(x; is) = \langle x, s|x, 0\rangle + total\ derivatives. \tag{6}$$

Although the general form of the gravitational one-loop effective Lagrangian is not known, there is one special case where it can be evaluated exactly[21]: the Static Einstein Universe. In this case, the kernel $\langle x, s|x, 0\rangle$ reads

$$\langle x, s|x, 0\rangle = \frac{e^{-i(\xi - \frac{1}{6})Rs}}{(4\pi is)^2}. \tag{7}$$

where R is the Ricci scalar and ξ is the coupling constant to the scalar field. This is a non-perturbative result, that involves all powers of the proper time parameter s. From this result, Parker and Toms proposed in 1985 a new asymptotic expansion for the kernel,[22] defined as

$$\langle x, s|x, 0\rangle = \frac{e^{-i(\xi - \frac{1}{6})R(x)s}}{(4\pi is)^2} \sum_{n=0}^{\infty} (is)^n \bar{a}_n(x). \tag{8}$$

The new adiabatic expansion in terms of the coefficients $\bar{a}_n(x)$ has an important advantage with respect to the previous one: it does not contain any term that vanishes when $R(x)$ is replaced by zero (see Ref.[23] for detailed proof). In other words, the non-perturbative exponential factor captures the exact dependence on the Ricci scalar in the generic Schwinger-DeWitt asymptotic expansion. This factorization has some important physical consequences, related, for example, to the effective dynamics of the Universe[24] or to the curvature dependence in the running of the gauge coupling constants.[25]

The key idea is that, from a solvable case, it is possible to extract a non-perturbative factor in the general asymptotic expansion of the one-loop effective Lagrangian that completely captures its dependence with the curvature scalar $R(x)$. In this context, a natural question arises: is it possible to find a similar factorization for the QED Lagrangian?

2. The conjecture

Based on the gravitational case, we propose the following conjecture for the electromagnetic case[2]: *The proper-time asymptotic expansion of the QED effective Lagrangian admits an exact resummation in all terms involving the field-strength invariants* $\mathcal{F} = \frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ *and* $\mathcal{G} = \frac{1}{4}\tilde{F}_{\mu\nu}F^{\mu\nu}$. *The form of the factor is just the Heisenberg-Euler Lagrangian for QED, where the electric and magnetic fields depend arbitrarily on space-time coordinates*, namely

$$\mathcal{L}^{(1)}_{scalar} = \int_0^\infty \frac{ds}{s} e^{-im^2 s} \left[\det\left(\frac{esF(x)}{\sinh(esF(x))} \right) \right]^{1/2} \bar{g}(x; is) \tag{9}$$

[to compare with (5)], where the new asymptotic expansion $\bar{g}(x; is)$ reads

$$\bar{g}(x; is) = \frac{1}{(4\pi is)^2} \sum_{n=0}^{\infty} \frac{(-is)^n}{n!} \bar{O}_n(x), \tag{10}$$

and where the coefficients $O_n(x)$ do not have terms that vanish when the electromagnetic invariants $\mathcal{F}(x)$ and $\mathcal{G}(x)$ are replaced by zero. The asymptotic expansions $g(x; is)$ and $\bar{g}(x; is)$ are related by

$$g(x; is) = \left[\det\left(\frac{esF(x)}{\sinh(esF(x))} \right) \right]^{1/2} \bar{g}(x; is). \tag{11}$$

In summary, we have proposed a new adiabatic expansion $\bar{g}(x; is)$ that can be built from the previous one via Eq. (11), and we have conjectured that, if the pre-factor is just the Euler Heisenberg Lagrangian, the new coefficients $\bar{O}_n$ associated with the new expansion will not have terms that vanish when the electromagnetic invariants are replaced by zero.

In the last part of the section, we are going to compute the new coefficients and check that, effectively, our conjecture is satisfied. First, we should expand the

Heisenberg-Euler determinant in terms of the proper time,

$$\left[\det\left(\frac{esF(x)}{\sinh(esF(x))}\right)\right]^{1/2} \sim 1 + U_2(x)(-is)^2 + U_4(x)(-is)^4 + U_6(x)(-is)^6 + \cdots, \tag{12}$$

where

$$U_2(x) = \tfrac{e^2}{12}\,\mathrm{Tr}(F^2), \tag{13}$$

$$U_4(x) = \tfrac{e^4}{288}\,\mathrm{Tr}(F^2)^2 + \tfrac{e^4}{360}\,\mathrm{Tr}(F^4), \tag{14}$$

$$U_6(x) = \tfrac{e^6}{10368}\,\mathrm{Tr}(F^2)^3 + \tfrac{e^6}{4320}\,\mathrm{Tr}(F^2)\,\mathrm{Tr}(F^4) + \tfrac{e^6}{5670}\,\mathrm{Tr}(F^6). \tag{15}$$

we note here that the trace $\mathrm{Tr}(F^{2n})$ can be always written in terms of powers of the electromagnetic invariants $\mathcal{F}$ and $\mathcal{G}$. For example, $\mathrm{Tr}(F^2) = -F_{\mu\nu}F^{\mu\nu} = -4\mathcal{F}$. Now, inserting expansions (12), (3) and (10) in Eq. (11) we find

$$O_0 + O_1 + (-is) + \frac{O_2}{2}(-is)^2 ... = (1 + U_2(-is)^2 + ...)\cdot(\bar{O}_0 + \bar{O}_1(-is) + \frac{\bar{O}_2}{2}(-is)^2 + ...) \tag{16}$$

and equating order by order we arrive to $\bar{O}_0 = 1$, $\bar{O}_1 = 0$,

$$\bar{O}_2 = O_2 - 2U_2 = 0, \tag{17}$$

$$\bar{O}_3 = O_3, \tag{18}$$

$$\bar{O}_4 = O_4 - 4!\,U_4, \tag{19}$$

$$\bar{O}_5 = O_4 - 20\,U_2 O_3, \tag{20}$$

$$\bar{O}_6 = O_6 - 6!\,U_6 - 30\,U_2\bar{O}_4. \tag{21}$$

Finally, substituting the values of the coefficients U_n and O_n in the previous equations we arrive at the explicit values of $\bar{O}_n$, which can be found in Appendix B. It is easy to see that our conjecture is satisfied. Comparing the coefficients O_n (Appendix A) with $\bar{O}_n$, one sees that all terms going with $\mathrm{Tr}(F^{2n})$ [or, equivalently, with $\mathcal{F}$ or $\mathcal{G}$] have disappeared.

2.1. *Some comments about the proper-time series expansion*

The asymptotic expansion (proper-time series expansion) that we are using here [see Eqs. (3) and (5)] is an expansion that group terms with the same mass dimension (remember that the coefficients O_n and a_n have mass dimension $2n$). This expansion is closely related with the adiabatic expansion of the scalar field modes, widely used in cosmology [see Ref.[26] for the equivalence in curved spacetime, and[27] for the adiabatic counterpart of the R-summed expansion given in (8)]. In its normal form, it is commonly used to renormalize physical quantities. It is important to recall that this expansion is not a derivative expansion (i.e., an expansion that groups terms with the same number of derivatives; see, for example, Ref.[28]). For a detailed explanation of the differences between both expansions see Ref.[3].

3. Main consequences

Our factorization, allow us to predict or reproduce some interesting physical consequences. First, it is possible to find some exactly solvable electromagnetic backgrounds. For electric and magnetic fields pointing in the $\hat{z}$ direction that depend arbitrarily on the light-cone coordinate $x^+ = (t + z)$, we find that $\bar{O}_0 = 1$ and $\bar{O}_{n>0} = 0$. Therefore, the exact form of the unrenormalized effective Lagrangian should be (in agreement with Refs.[29–31])

$$\mathcal{L}^{(1)}_{scalar} = -\frac{1}{16\pi^2}\int_0^\infty \frac{ds}{s^3} e^{-im^2 s} \frac{e^2 s^2 E(x^+)B(x^+)}{\sinh esE(x^+)\sin esB(x^+)}. \tag{22}$$

For a single electromagnetic plane wave, $\mathcal{F}(x) = 0$ and $\mathcal{G}(x) = 0$, therefore, according to our conjecture, the one-loop effective action trivially vanishes, in agreement with the result obtained in Ref.[5] by other methods. Second, our results seem to be consistent in presence of gravity. [b]. In this case, it is possible to perform a double factorization (the exponential $R(x)$ factorization is ensured[23]),

$$g(x, is) = e^{-is(\xi-\frac{1}{6})R(x)}\left[\det\left(\frac{esF(x)}{\sinh(esF(x))}\right)\right]^{1/2}\tilde{g}(x; is). \tag{23}$$

Finally, the conjecture allows us to make some general predictions regarding the Schwinger's formula for the pair production rate. The factorization suggests that the poles of the imaginary part of the one-loop effective Lagrangian are located at the same points as in the constant electric field case $\tau_n = n\pi/|eE(x)|$.

4. Summary and conclusions

The one-loop (scalar) QED effective-Lagrangian is, in general, unknown. However, it is possible to obtain an adiabatic expansion of it in terms of the functions $g(x; is)$ defined in (2). We have proposed an alternative adiabatic expansion $\bar{g}(x; is)$, which encapsulates in a global pre-factor all its dependence on the electromagnetic invariants $\mathcal{F}(x)$ and $\mathcal{G}(x)$. The form of the non-perturbative factor involved in this partial resummation is just the Heisenberg-Euler Lagrangian for QED, but with the electric and magnetic fields depending arbitrarily on spacetime coordinates. The new expansion does not contain terms that vanish when $\mathcal{F}(x)$ and $\mathcal{G}(x)$ are replaced by zero. This factorization allows us to obtain some exact solutions and seems to be consistent in presence of gravity. In this contribution, we have focused on the scalar case, but our conjecture is also valid for the spin-$\frac{1}{2}$ case. We expect our results to be consistent for non-abelian gauge backgrounds. Most of the computations in this paper have been done with the help of the xAct package of the *Mathematica Software*.[34] This work was supported in part by Spanish Ministerio de Economia, Industria y Competitividad Grants No. FIS2017-84440-C2-1-P(MINECO/FEDER, EU), No. FIS2017-91161-EXP and the project PROMETEO/2020/079 (Generalitat Valenciana). S. P. is supported by a Ph.D. fellowship, Grant No. FPU16/05287.

[b] For $\nabla_\rho F^{\mu\nu} = 0$ the factorization of the Euler-Heisenberg Lagrangian was found in Refs.[32, 33].

Appendix A

Here we give the coefficients O_n of the original expansion $g(x;is)$. $O_0 = 1$,

$$O_1 = 0,\ \ O_2 = -\tfrac{\mathbf{e^2}}{\mathbf{6}}\mathbf{F}_{\kappa\lambda}\mathbf{F}^{\kappa\lambda},\ \ O_3 = -\tfrac{e^2}{20}\partial_\mu F_{\kappa\lambda}\partial^\mu F^{\kappa\lambda}, \tag{A.1}$$

$$\begin{aligned} O_4 = {} & \tfrac{\mathbf{e^4}}{\mathbf{15}}\mathbf{F}_\kappa{}^\mu\mathbf{F}^{\kappa\lambda}\mathbf{F}_\lambda{}^\nu\mathbf{F}_{\mu\nu} + \tfrac{\mathbf{e^4}}{\mathbf{12}}\mathbf{F}_{\kappa\lambda}\mathbf{F}^{\kappa\lambda}\mathbf{F}_{\mu\nu}\mathbf{F}^{\mu\nu} \\ & -\tfrac{e^2}{70}\partial_\nu\partial_\mu F_{\kappa\lambda}\partial^\nu\partial^\mu F^{\kappa\lambda}, \end{aligned} \tag{A.2}$$

$$\begin{aligned} O_5 = {} & \tfrac{2e^4}{7}F^{\kappa\lambda}F^{\mu\nu}\partial_\lambda F_{\nu\rho}\partial_\mu F_\kappa{}^\rho - \tfrac{4e^4}{63}F_\kappa{}^\mu F^{\kappa\lambda}\partial_\lambda F^{\nu\rho}\partial_\mu F_{\nu\rho} \\ & -\tfrac{e^4}{9}F_\kappa{}^\mu F^{\kappa\lambda}F^{\nu\rho}\partial_\mu\partial_\lambda F_{\nu\rho} - \tfrac{16e^4}{63}F^{\kappa\lambda}F^{\mu\nu}\partial_\mu F_\kappa{}^\rho\partial_\nu F_{\lambda\rho} \\ & +\tfrac{5e^4}{18}F^{\kappa\lambda}F^{\mu\nu}\partial_\rho F_{\mu\nu}\partial^\rho F_{\kappa\lambda} + \tfrac{34e^4}{189}F^{\kappa\lambda}F^{\mu\nu}\partial_\nu F_{\lambda\rho}\partial^\rho F_{\kappa\mu} \\ & +\tfrac{25e^4}{189}F^{\kappa\lambda}F^{\mu\nu}\partial_\rho F_{\lambda\nu}\partial^\rho F_{\kappa\mu} + \tfrac{4e^4}{21}F_\kappa{}^\mu F^{\kappa\lambda}\partial_\rho F_{\mu\nu}\partial^\rho F_\lambda{}^\nu \\ & +\tfrac{\mathbf{e^4}}{\mathbf{12}}\mathbf{F}_{\kappa\lambda}\mathbf{F}^{\kappa\lambda}\partial_\rho\mathbf{F}_{\mu\nu}\partial^\rho\mathbf{F}^{\mu\nu} - \tfrac{e^2}{252}\partial_\rho\partial_\nu\partial_\mu F_{\kappa\lambda}\partial^\rho\partial^\nu\partial^\mu F^{\kappa\lambda}, \end{aligned} \tag{A.3}$$

We explore the question whether the presence of soft photons in a system can have direct or indirect consequences in the outcome of suitably defined quantum processes involving the system. We consider an local quantum detector with dual energy levels and coupled to the background gauge invariant charged scalar field in a flat spacetime. The de-excitation rate for downward transitions for such a system on an inertial trajectory is found to depend on the soft charges corresponding to the radial component of the electric field dressing chosen at the asymptotic boundary. While the excitation rate for upward transitions still vanishes as expected. The implications are discussed.

Keywords: Soft photon, gauge invariance, detector

1. Introduction

The BMS symmetries[1] of asymptotically flat spacetimes found by Bondi, Metzner and Sachs in 1962; the gravitational memory effect[2] first proposed by Zeldovich and Polnarev in 1974 and the Weinberg's soft theorems are related to each other through the so called Universal triad relations.[5–9] When acted upon by a BMS transformation corresponding to a BMS diffeomorphism vector at the asymptotic flat boundary or equivalently due to the passage of a gravitational wave at the asymptotic flat boundary, the vacuum state at the boundary - although classically same before and after the transformation, differs quantum mechanically in the content of soft particles and hence the soft charges defined at the boundary. Analogous to the gravitational case, there is a universal triad for the electromagnetic case as well. The electromagnetic memory effect, the $U(1)$ large gauge transformations and the Weinberg's soft photon theorem are also related to one other through analogous type connections. The significance of these universal triad relations were realised by Hawking, Perry and Strominger[3,4] to conjecture soft hair for black holes. In a recent work, a quantum version of the gravitational memory effect was shown to arise due to the BMS symmetries in a Schwarzschild spacetime.[10,11]

In the related context. we explore the question whether the presence of soft photons in a system can have direct or indirect consequences in the outcome of suitably defined quantum processes involving the system.[12] We consider a local quantum system moving on an inertial trajectory in a flat spacetime and linearly couples to a gauge invariant charged scalar field. The gauge invariant form of the field is as defined by Dirac[13] in 1955 to account for the fact that an electric charge is always accompanied by it electric field. We compute the transition rates for such a system when the system is at rest in an inertial frame and the electric field is given a soft photon dressing. Interestingly, we find that the transition rate of the local quantum system shows a de-excitation for downward transitions which depends on the soft charges corresponding to the dressed electric field. This holds true for a wide class of functions that can be chosen for the soft photon dressing of the electric field. We find that the excitation rate for upward transitions of the system vanishes as expected.

2. The local quantum system and the dressing field

We consider a flat spacetime with background electromagnetic and charged scalar fields. We then use the gauge invariant construction of a charged scalar field as defined by Dirac.[13] The 'dressed' field gauge invariant operator is defined by

$$\Phi(x) = e^{iC(x)}\phi(x), \tag{1}$$

where

$$C(x) = \int d^4x'\, f^a(x,x')A_a(x'), \tag{2}$$

Here $A_a(x')$ is the electromagnetic four vector potential and the two-point function $f^a(x,x')$ that specifies the dressing satisfies the four-dimensional Poisson's equation

$$\partial'_a f^a(x,x') = q\,\delta^4(x-x'). \tag{3}$$

Under the gauge transformation, the phase factor $e^{iC(x)}$ transforms as

$$e^{iC(x)} \to e^{iC(x)}\, e^{-iq\Omega(x)}, \tag{4}$$

Thus rendering the $\Phi(x)$ operator to be gauge invariant. The physical significance of the construction in Eq. (1) is that a charge can never be completely described without its electric field and the exponential phase factor in front of $\phi(x)$ precisely does that. The two-point function $f^a(x,x')$ contains the information about the electric field of the charge which can include soft dressing contributions in addition to the usual Coulombic electric field in the rest frame of the charge. We quantize the system by the usual standard procedures and assume the fields $A_a(x)$ and $\phi(x)$ to be free fields at the lowest order in perturbation theory.

The local quantum system is defined to be a pointlike charged two-level system moving on an pointlike trajectory $x^a(\tau)$ and parametrised by the proper time τ.

The monopole moment $m(\tau)$ of the system couples linearly to the gauge invariant scalar field operator Φ with the interaction Hamiltonian being defined as

$$\mathcal{H}_{int} = \lambda\chi(\tau)\left(m(\tau)\Phi(\tau) + m^{\dagger}(\tau)\Phi^{\dagger}(\tau)\right), \tag{5}$$

where λ is a real-valued coupling constant, $\Phi(\tau)$ is the pull-back of $\Phi(x)$ to the detector's worldline, and the real-valued switching function χ specifies how the interaction is switched on and off. One can check that the $\mathcal{H}_{int}$ is gauge invariant by construction as well as Hermitian as required for the conservation of total charge.

The time independent response function for the local quantum system on an inertial trajectory $t(\tau) = \tau$ and $\mathbf{x} = 0$ coupled to the Minkowski vacuum state in linear order of perturbation theory is determined to be

$$F(E) = \int_{-\infty}^{\infty} ds\, e^{-iEs}\, W_{\phi}(s)\, W_{A}(s), \tag{6}$$

where E is the difference between the energies of excited state and the ground state of the local quantum system. Hence $E > 0$ determines upward transitions, that is excitations, while $E < 0$ determines downward transitions, that is de-excitations. $W_{\phi}(s)$ is the pull-back of the usual charged scalar field Wightman function

$$\begin{aligned} W_{\phi}(x'', x') &= \langle 0_{\phi}|\, \phi^{\dagger}(x'')\, \phi(x')\, |0_{\phi}\rangle = \langle 0_{\phi}|\, \phi(x'')\, \phi^{\dagger}(x')\, |0_{\phi}\rangle \\ &= \int \frac{d^3\mathbf{k}}{(2\pi)^3} \frac{1}{2\omega_{\mathbf{k}}}\, e^{-i\omega_{\mathbf{k}}(t''-t')}\, e^{i\mathbf{k}\cdot(\mathbf{x}''-\mathbf{x}')}, \end{aligned} \tag{7}$$

on the detector's worldline and $W_A(s)$ is the pull-back of the electromagnetic dressing two-point function,

$$\begin{aligned} W_{A}(x'', x') = \frac{1}{|\alpha|^2 + |\beta|^2} \Big(& |\alpha|^2\, \langle 0_A|\, e^{-iC(x'')}\, e^{iC(x')}\, |0_A\rangle \\ & + |\beta|^2\, \langle 0_A|\, e^{iC(x'')}\, e^{-iC(x')}\, |0_A\rangle \Big). \end{aligned} \tag{8}$$

where α and β are fixed constants pertaining to the excited energy state of the detector more precisely defined in.[12] From the form of response function in Eq. (6), one can note that for the local quantum system considered here with the gauge invariant operator, there is an extra dependence through the $W_A(s)$ factor than in the corresponding expression of the standard detector[15] without the gauge invariance. It is this extra factor which brings the dependence of the soft photons in the de-excitation rate of the system.

3. The result

We choose the electric field dressing to have a $1/r^2$ radial dependence but allow the magnitude to have arbitrary angular dependence as well, which provides the soft photon dressing to the standard Coulombic field. The following form is chosen[14]

$$\tilde{\mathbf{f}}(\mathbf{x}, \mathbf{x}') = \frac{q}{4\pi\epsilon_0}\, \frac{g(\theta^{A'})}{|\mathbf{x} - \mathbf{x}'|^3} (\mathbf{x} - \mathbf{x}'), \tag{9}$$

where the function $g(\theta^{A'})$ depends only on the angular coordinates and it satisfies the normalisation condition $\int_0^{\pi}\int_0^{2\pi} g(\theta^A)\sin\theta\, d\theta\, d\phi = 4\pi$. The soft charge for the dressed electric field in Eq. (9) can be found to be

$$\begin{aligned} Q_\epsilon &= \int d\Omega\ \epsilon(\theta^A) \lim_{r\to\infty}\left(r^2 E^r\right) \\ &= \int d\Omega\ \epsilon(\theta^A)\ g(\theta^A), \end{aligned} \tag{10}$$

where the integral over $d\Omega$ runs over the transverse angular coordinates, $\epsilon(\theta^A)$ is a weight function and E^r is the radial component of the electric field.

The response function for the dressed field in Eq. (9) is found through the expression in Eq. (6) to be[12]

$$F(E) = \frac{(-E)\,\Theta(-E)}{2\pi} \times \frac{e^{-\tilde{Q}\gamma}\,(-E/\Lambda)^{\tilde{Q}}}{\Gamma(2+\tilde{Q})}. \tag{11}$$

where γ is the Euler-Mascheroni constant, Λ is the ultraviolet cut-off and $\tilde{Q}$ depends on the averaged squares of soft charges through

$$\tilde{Q} := \frac{q^2}{64\pi^4\epsilon_0^2}\left\{\langle Q^2_{\epsilon_1}\rangle + \langle Q^2_{\epsilon_2}\rangle + \langle Q^2_{\epsilon_3}\rangle + \langle Q^2_{\epsilon_4}\rangle\right\}. \tag{12}$$

In the limit of no soft charges, $\tilde{Q}\to 0$, the response function $F(E)$ reduces to the standard expression of the response of a detector without a gauge field coupling.[15]

$$F_{\text{Mink}}(E) = \frac{(-E)\,\Theta(-E)}{2\pi}, \tag{13}$$

In the presence of the soft charges, $\tilde{Q} > 0$, the excitation rate in Eq. (11) vanishes as expected, but the dependence of the de-excitation rate on the energy gap E gets modified through a different power dependence. We conclude that the soft charges, and hence the soft photon dressing to the electric field, do not induce spontaneous excitations in our local quantum system, but they do affect the detector's de-excitation rate. The general features of these results, in particular the vanishing of excitation rate and the dependence of the de-excitation rate on soft charges, were shown to hold for our local quantum system for a wide class of soft photon dressed electric fields defined only by their asymptotic properties.[12]

Particles are spontaneously created from the vacuum by time-varying gravitational or electromagnetic backgrounds. It has been proven that the particle number operator in an isotropically expanding universe is an adiabatic invariant. In this work we show that, in some special cases the expected adiabatic invariance of the particle number breaks down in presence of electromagnetic backgrounds. We also show a close relation between this breaking of the adiabatic invariance and the emergence of the axial anomaly.

Keywords: Particle creation, Schwinger effect, adiabatic invariance, axial anomaly.

1. Introduction

The proper understanding of the particle creation phenomena, via Bogoliubov transformations, was pioneered in the analysis of quantized fields in an isotropically expanding universe.[1–3] A fundamental issue in the study of particle creation in an expanding universe was the adiabatic invariance of the number of created particles. The particle number of a quantized field, in the limit of an infinitely slow and smooth expansion of the universe, does not change with time,[4] even if the quantized field is massless. In other words, the density of created particles by the expanding universe approach zero when the Hubble rate $\dot{a}/a$ is each time negligible even if the final amount of expansion $a(t_{final})/a(t_{initial})$ is large. Moreover, pair production can also take place in time-varying electric backgrounds,[5] and it can be regarded as a very important non-perturbative process in quantum field theory.[6]

The main purpose of this work is to generalize the analysis of the adiabatic invariance of the particle number observable in presence of an electromagnetic background. We find that, for massive fields, adiabatic invariance is, as expected, preserved (for more details see[7]). For slowly varying electromagnetic potentials no quanta is being produced, even if the change in A_μ over a long period is very large. However, in some cases and only for massless fields, the particle number is not an adiabatic invariant. We analyze the problem in detail in a two-dimensional scenario, for both scalar and Dirac fields. The main results can be easily translated to four dimensions. As a by-product of our analysis, we point out a connection between the

*Talk given by P. Beltran-Palau at the Sixteenth Marcel Grossmann Meeting (2021).

(anomalous) breaking of the adiabatic invariance of the particle number operator and the emergence of a quantum anomaly in the chiral symmetry. The requirements for the non-conservation of chirality seems to be directly related to those found for the breaking of the adiabaticity in the particle number observable. Concerning the renormalization, it is convenient in this context to use the adiabatic renormalization method[1–3] for a scalar field in a gravitational background, and recently extended for a Dirac field[8,9] and for an electric background.[10–13]

2. Brief introduction to particle creation in an expanding universe

First of all, we will introduce the phenomenon of the spontaneous particle creation in the gravitational context. It was firstly introduced by L. Parker[1,2] in the context of cosmology, and he developed the analysis for a real scalar field in an expanding universe, given by the Friedmann-Lemaitre-Robertson-Walker (FLRW) metric $ds^2 = dt^2 - a^2(t)d\vec{x}^2$. Following the prescription of the Quantum Field Theory in curved spacetimes, the gravitational field can be considered as a classical background and scalar the quantum field is described by the Klein-Gordon equation in curved space-times

$$(g^{\mu\nu}\nabla_\mu\nabla_\nu + m^2 + \xi R)\phi = 0\,, \tag{1}$$

where ξ is the coupling constant of the field with the gravitational background. We expand the quantum field as

$$\phi(t,\vec{x}) = \int \frac{d^3k}{\sqrt{2(2\pi)^3 a(t)^3}} \left(A_{\vec{k}} h_k(t) e^{i\vec{k}\vec{x}} + A^\dagger_{\vec{k}} h^*_k(t) e^{-i\vec{k}\vec{x}} \right)\,, \tag{2}$$

where $\omega_k = \sqrt{m^2 + (k/a)^2}$ and $A^\dagger_{\vec{k}}$ and $A_{\vec{k}}$ are the usual creation and annihilation operators. Introducing it into the Klein-Gordon equation we obtain the following differential equation for the modes

$$\frac{d^2 h_k}{dt^2} + \Omega_k(t)^2 h_k = 0\,, \tag{3}$$

where

$$\Omega_k(t)^2 = \omega_k^2 + \left(6\xi - \frac{3}{4}\right)\left(\frac{\dot{a}}{a}\right)^2 + \left(6\xi - \frac{3}{2}\right)\frac{\ddot{a}}{a}\,. \tag{4}$$

This is the equation of a harmonic oscillator with a time-varying frequency, which depends on the derivatives of the metric. this idea will be usefull to understand the concept of adiabatic invariance.

It is well-known that the notion of particle is not well defined when the universe is in expansion, therefore a useful strategy to analyze the phenomenon is to choose a configuration where the expansion is bounded at early and late times, as shown in Fig. 1. In this case the number of particles is well defined at early and late times, and then we can compare the difference between them.

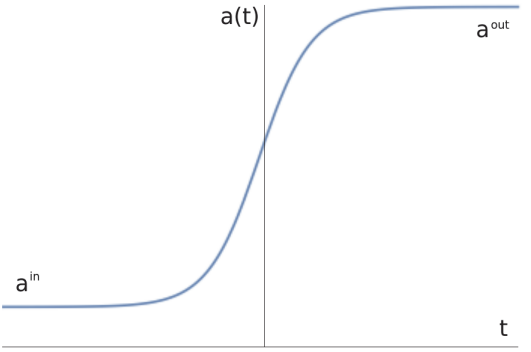

Fig. 1. Scale factor of a bounded expanding universe

We consider that at $t \to -\infty$ the vacuum expectation value of the particle number is zero, i.e., we choose the vacuum state at early times. This is analogous to choose the (normalized) positive frequency solution at early times

$$h_k^{in}(t) = \frac{1}{\sqrt{\omega_{in}}} e^{-i\omega_k^{in} t}\,, \tag{5}$$

where $\omega_k^{in} = \sqrt{m^2 + (k/a^{in})^2}$. However, the expansion of the universe induces a final state which is a combination of positive and negative frequency solutions

$$h_k^{out}(t) = \frac{1}{\sqrt{\omega_{out}}} \left(\alpha_k e^{-i\omega_k^{out} t} + \beta_k e^{i\omega_k^{out} t}\right)\,, \tag{6}$$

where $\omega_k^{in} = \sqrt{m^2 + (k/a^{out})^2}$ and α_k and β_k are the well-known Bogoliubov coefficients. It can be proven that the vacuum expectation value of the particle density at late times is not null, as a consequence of the presence of the negative frequency solution at late times. It is given by

$$\langle N^{out} \rangle = \frac{1}{(2\pi a^{out})^3} \int d^3k |\beta_k|^2\,. \tag{7}$$

Therefore, the beta coefficient gives the spectrum of momenta of the spontaneously created particles.

2.1. *Adiabatic invariance of the particle number*

Let us now introduce the concept of adiabatic invariance. As we have seen above the modes of the field follow an equation of a harmonic oscillator with time-varying frequency. In the model we are considering it would be an oscillator that starts oscillating with an specific frequency ω_k^{in} and decreases slowly its frequency tending asymptotically to ω_k^{out}. The energy of an oscillator of this kind changes in time, and is be given by the expression

$$E_k(t) = \frac{1}{2}(|\dot{h}_k(t)|^2 + \Omega_k(t)^2 |h_k(t)|^2)\,. \tag{8}$$

A main property of this kind of oscillators is that the quantity $E_k(t)/\Omega_k(t)$ is an adiabatic invariant, which means that it remains constant in the limit of an infinitely slow variation of the frequency. This limit is known as adiabatic limit. A straightforward calculation gives us the expressions of the initial and final energy in our particular case of the bounded expansion

$$E_k^{in} = \omega_k^{in} \tag{9}$$

$$E_k^{out} = \omega_k^{out}(1 + 2|\beta_k|^2)\,. \tag{10}$$

By the property mentioned above, the difference of quotients $(E^{in}/\omega_k^{in}) - (E^{out}/\omega_k^{out})$ should tend to 0 in the adiabatic limit. One can see easily that this implies necessarily that $|\beta_k|^2 \to 0$ in the adiabatic limit. This means that in the limit of an infinitely slow expansion of the universe no particles would be created by the effect of the gravity, and that's why we say that the particle number is an adiabatic invariant in this context (for more details on this concept see[4]). But there are other scenarios of particle creation in which this adiabatic invariance of the particle number can be broken, as we will see in the following sections.

3. Breaking of the adiabatic invariance by the electric field in 2D

We know that the phenomenon of particle creation is not a particular property of the gravitational field. For instance, a strong electric background can also produce spontaneously pairs particle-antiparticle from the vacuum. This phenomenon is known as the Schwinger effect.[6] A logical question we can formulate is, does the adiabatic invariance of the particle number remains when the particle production is induced by an electric field? To answer this question, we will firstly analyze the 2-dimensional case and then we will extend it to 4 dimensions. Let us consider a spatially homogeneous and time dependent classical electric field $E(t)$ acting in the unique spatial direction. For convencience we choose a particular form of this background, which is a Sauter-type[14] electric pulse given by

$$E(t) = -\frac{\rho A_0}{2}\cosh^{-2}(\rho t)\,, \tag{11}$$

shown in Fig. 2(a). It can also be described by the potential $A_\mu = (0, -A(t))$, with $E(t) = -\dot{A}(t)$, i.e.

$$A(t) = \frac{1}{2}A_0\left(\tanh(\rho t) + 1\right)\,. \tag{12}$$

This potential, analogously to the scale factor in the gravitational case, is bounded at early and late times, as shown explicitly in Fig. 2(b), starting in 0 and tending to a constant value that we denote as A_0. Note that ρ plays the role of a slowness parameter. The variation of the potential vector is slower when ρ decreases, then the adiabatic limit is equivalent to the limit $\rho \to 0$. As a first approach we will consider the 2-dimensional case for simplicity, and in the next section we will extend the results to the 4-dimensional case.

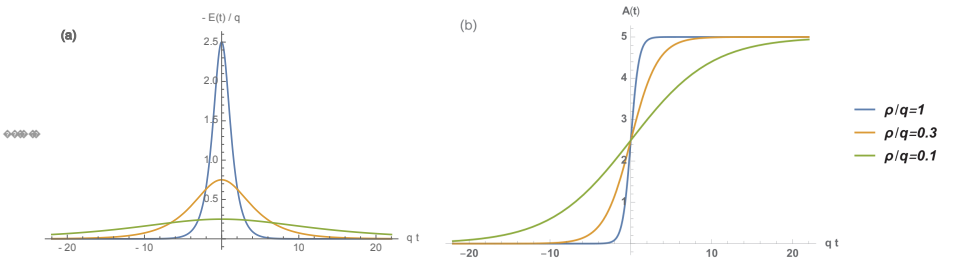

Fig. 2. (a) Sauter-type electric pulse for $A_0 = 5$ and for different values of the slowness parameter ρ. (b) Electric potential associated to the pulse for the same values of ρ. The adiabatic limit corresponds to $\rho \to 0$. The variables have been scaled with q to obtain dimensionless variables.

3.1. *Scalar field*

We will firstly analyze the case of the creation of scalar particles by an electric field. The Klein-Gordon equation for an electric background is given by

$$(D_\mu D^\mu + m^2)\phi = 0\,, \tag{13}$$

where $D_\mu \phi = (\partial_\mu + iqA_\mu)\phi$. We expand the field in terms of the usual annihilation and creation operators as

$$\phi(t,x) = \int_{-\infty}^{\infty} \frac{dk}{\sqrt{2(2\pi)}} [A_k e^{ikx} h_k(t) + B_k^\dagger e^{-ikx} h_{-k}^*(t)]\,. \tag{14}$$

Therefore the differential equation for the modes is given by

$$\ddot{h}_k(t) + \left(m^2 + (k - qA(t))^2\right) h_k(t) = 0\,. \tag{15}$$

Analogously to the gravitational case we locate the vacuum at early times, which is analogous to choose the positive frequency solution, and solving the equation we obtain at late times a combination of positive and negative frequency solutions, in terms of Bogoliubov coefficients. Finally we obtain the expression for the β_k coefficient which gives the spectrum of momenta of the created scalar particles

$$|\beta_k|^2 = \frac{\cosh\left(\pi \frac{\omega_{out} - \omega_{in}}{\rho}\right) + \cosh\left(\pi \sqrt{(\frac{qA_0}{\rho})^2 - 1}\right)}{2\sinh\left(\pi \frac{\omega_{in}}{\rho}\right)\sinh\left(\pi \frac{\omega_{out}}{\rho}\right)}\,, \tag{16}$$

where $\omega_{in} = \sqrt{k^2 + m^2}$ and $\omega_{out} = \sqrt{(k - qA_0)^2 + m^2}$. For conservation of the charge, the same amount of anti-particles will also be created with the same spectrum, but in the opposite direction, i.e., $|\beta_{-k}|^2$.

From this expression one can prove[7] that in the adiabatic limit, $\rho \to 0$, $|\beta_k|^2$ tends to 0 for massive particles, but in the massless case it tends to 1 inside the interval of momenta $k \in (0, qA_0)$, and it is 0 elsewhere. In other words, in the limit of an infinitely slow electric pulse only massless particles would be spontaneously created. Therefore, in the case of massless particles the adiabatic invariance of the particle number is broken.

The density of created particles can be obtained by integrating $|\beta_k|^2$ in all momenta. In Fig. 3 we represent the density of particles for different values of the mass in terms of the slowness parameter ρ. Note that in all the massive cases the production of particles is reduced when the process is more adiabatic, and in the limit when it is infinitely adiabatic ($\rho \to 0$) the number of particles is 0. However, in the massless case the particle density tends to a non-null value, which is given by $\langle N \rangle = \frac{|qA_0|}{\pi}$.

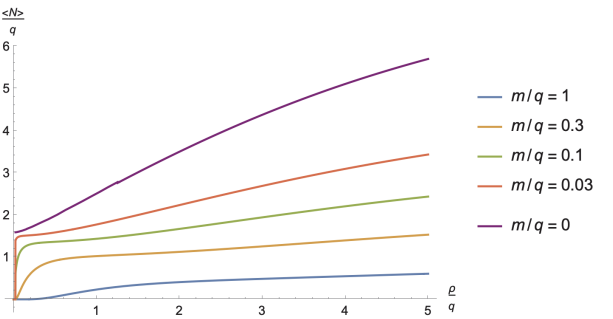

Fig. 3. Density of late-time created scalar particles as a function of the adiabaticity parameter ρ, for $A_0 = 5$ and for different values of the mass.

3.2. *Dirac field*

A Dirac field coupled to an electric background in 2 dimensions is described by the following Dirac equation

$$(i\gamma^\mu D_\mu - m)\psi = 0\,, \tag{17}$$

where γ^μ are the Dirac matrices and $D_\mu \equiv \partial_\mu - iqA_\mu$. We expand the field in terms of the creation and annihilation operators and normalized spinors as follows

$$\psi(t,x) = \int_{-\infty}^{\infty} \frac{dk}{\sqrt{2\pi}} \left[B_k e^{ikx} \begin{pmatrix} h_k^I(t) \\ -h_k^{II}(t) \end{pmatrix} + D_k^\dagger e^{-ikx} \begin{pmatrix} h_{-k}^{I*}(t) \\ h_{-k}^{I*}(t) \end{pmatrix} \right] . \tag{18}$$

The field equation is converted into the system of differential equations

$$\dot{h}_k^I - i\,(k + qA)\,h_k^I - imh_k^{II} = 0 \tag{19}$$

$$\dot{h}_k^{II} + i\,(k + qA)\,h_k^{II} - imh_k^I = 0\,. \tag{20}$$

Following a similar procedure as in the scalar case, we impose a positive frequency solution at early times and solve the equation, obtaining at late times also a negative frequency term.[7] From that expression we can obtain the Bogoloiubov coefficient that describes the spectrum of momenta of the created particles

$$|\beta_k|^2 = \frac{\cosh\left(\pi\frac{\omega_{out}-\omega_{in}}{\rho}\right) - \cosh\left(\pi\frac{qA_0}{\rho}\right)}{2\sinh\left(\pi\frac{\omega_{in}}{\rho}\right)\sinh\left(\pi\frac{\omega_{out}}{\rho}\right)}\,. \tag{21}$$

Note that $|\beta_k|^2 \leq 1$ in accordance with the the Pauli's exclusion principle. As for the scalar field, in the adiabatic limit $\rho \to 0$ this expression tends to 0 in the massive case, but in the massless case instead $|\beta_k|^2 = 1$ inside the interval $k \in (0, qA_0)$. Therefore, the adiabatic invariance is also broken for massless Dirac fermions. To clarify this idea, in Fig. 4 we show the density of particles, after integrating in all momenta, in terms of ρ for different masses. Note that, unlike the scalar case, the density of particles in the massless case is the same ($\langle N \rangle = |qA_0|/\pi$) for any value of ρ, i.e., it only depends on the final value of the electric potential, not on its form.

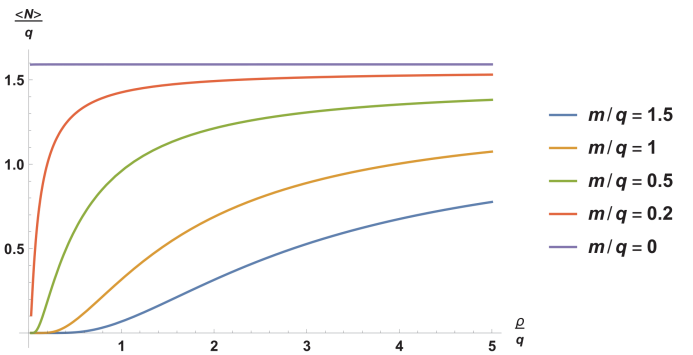

Fig. 4. Density of late-time created Dirac fermions as a function of the adiabaticity parameter ρ, for $A_0 = 5$ and for different values of the mass.

3.3. *Relation with the axial anomaly*

This breaking of the adiabatic invariance is closely related with the axial anomaly, which is also manifested in the creation of massless particles. Let us analyze this relation. It is well-known that the classical axial symmetry of the massless Dirac field is broken when considering it as a quantum field, which is known as axial anomaly. In 2 dimensions this anomaly can be expressed by[15]

$$\partial_\mu \langle j_A^\mu \rangle_{ren} = -\frac{q}{2\pi} \epsilon^{\mu\nu} F_{\mu\nu} = \frac{q\dot{A}}{\pi}\,, \tag{22}$$

where $\langle j_A^\mu \rangle$ is the 4-vector that contains the axial charge and current. Note that its divergence gives a non-vanishing value, unlike in the classical case.

In 2 dimensions it is easy to see the relation of this phenomenon with the creation of particles, since the chirality of a particle is linked to its electric charge and the direction of its movement. For instance, a positive charged particle moving in the positive direction of movement would have right-handed chirality. The created particles by the electric field are produced in pairs with opposite charge and opposite direction of movement, therefore both particles of every pair will have the same

chirality, creating a net chiral charge. In fact, the created pairs generate a electric current, which in 2 dimensions is directly proportional to the chiral charge. This observable can be calculated by using adiabatic renormalization, and the result of the total chiral charge of the created massless Dirac fermions is

$$\langle j^0_A \rangle_{ren} = \frac{qA(t)}{\pi}\,. \tag{23}$$

(for more details on the adiabatic renormalization method for Dirac fields see[10, 12, 13]) Note that this expression coincides with the one obtained by integrating (22), i.e., the chiral charge created by the massless fermions is the one predicted by the axial anomaly. This anomaly remains even if the background changes infinitely slow, just like the creation of massless particles as we have seen in the previous section. Then we can see the close relation between the axial anomaly and the breaking of the adibatic invariance. It is also interesting to remark that for massless scalar fields in 2 dimensions one can define an analogue axial anomaly, and it can be proven to be also compatible with the particle production effect.

4. Generalization to 4 dimensions

In this section we will generalize the previous results to the 4-dimensional case, and will analyze the influence of the introduction of a magnetic background apart from the electric one. We will choose the electric field acting in the direction z. We will not give the explicit details of the calculation but a summary of it, since it is analogue to the one in 2D. In fact one can see that the differential equations for the modes (and therefore the expression of β_k) can be related with the 2D ones by changing k by k_3 and the mass by an effective mass, which depends on the case. This simplifies a lot the analysis, since we know for the previous analysis that the breaking of the adiabatic invariance (i.e. $|\beta_{\vec{k}}| \neq 0$ when $\rho \to 0$) is given when this effective mass (m_{eff}) is 0.

If we consider only an electric background, the effective mass is $m^2_{eff} = m^2 + k_1^2 + k_2^2$, and then for $m = k_1 = k_2 = 0$ the Bogoliubov coefficient would tend to a non-null value when $\rho \to 0$. But since the momentum is a continuous quantum number and the density of particles is obtained by the integration in all momenta, the amount of created particles with this specific momentum is diluted in the infinite space, and the total particle density vanishes in the adiabatic limit. And then the adiabatic invariance is preserved in this case.

But the situation changes when adding a classical magnetic background. We choose for simplicity a constant magnetic field in the same direction as the electric one. In this case the perpendicular momentum k_1 is quantized in the well known Landau levels. For the scalar field the effective mass is $m^2_{eff} = m^2 + (2n+1)|qB|$, where n denote the Landau levels. This quantity never vanishes, and then the adiabatic invariance is preserved. On the other hand, for the Dirac field the effective mass is $m^2_{eff} = m^2 + 2n|qB|$, which vanishes for $m = 0$ and in the ground level

$n = 0$. In this case the particle number is obtained by the summation of all levels, and then the contribution of $n = 0$ is not diluted. Therefore in this case the particle density does not vanish in the adiabatic limit, which means that there is a breaking of the adiabatic invariance.

We can also see in this cases the close relation between this phenomenon and the axial anomaly. On one hand, in 4 dimensions this anomaly appears in the same conditions as the breaking of the adiabatic invariance, which are massless fermions in presence of not perpendicular electric and magnetic background fields. On the other hand, the chiral charge of the created massles fermions is given by

$$\langle j^0_A \rangle_{ren} = -\frac{q^2}{2\pi^2} \int_{-\infty}^{t} dt' \vec{E}(t')\vec{B}\,, \tag{24}$$

which has been obtained by using adiabatic renormalization. This expression coincides with the axial anomaly in 4 dimensions. And finally, the only mode that contributes to the chiral charge created by the axial anomaly is the lower one, $n = 0$, which is also the one that produces the breaking of the adiabatic invariance, as seen before.

5. Summary and conclusions

We have analyzed the adiabatic invariance of the particle density spontaneously created by an electromagnetic background. This property, which is verified in the case of a gravitational background, is broken in some cases when the background is an electromagnetic field. Specifically for massless scalar and Dirac fields in 2 dimensions in presence of an electric background, and for massless Dirac fields in 4 dimensions in presence of non perpendicular electric and magnetic background fields. We have also seen that there is a close relation between the breaking of the adiabatic invariance and the axial anomaly since both phenomena emerge in the same cases. Morover the amount of chiral charge produced by the creation of massless particles that remains in the adiabatic limit coincides with the expected one by the axial anomaly.

Dynamics of relativistic electrons in non-uniform magnetic fields and its applications in quantum computing and astrophysics

Srishty Aggarwal* and Banibrata Mukhopadhyay

Department of Physics, Indian Institute of Science, Bengalore, Karnataka 560012, India
**E-mail: srishtya@iisc.ac.in*

We explore the two-dimensional motion of relativistic electrons when they are trapped in magnetic fields having spatial power-law variation. Its impacts include lifting of degeneracy that emerged in the case of the constant magnetic field, special alignment of Landau levels of spin-up and spin-down electrons depending on whether the magnetic field is increasing or decreasing from the centre, splitting of Landau levels of electrons with zero angular momentum from that of positive one and the change in the equation of state of matter. Landau quantization (LQ) in variable magnetic fields has interdisciplinary applications in a variety of disciplines ranging from condensed matter to quantum information. As examples, we discuss the increase in quantum speed of the electron in presence of spatially increasing magnetic field; and the attainment of super Chandrasekhar mass of white dwarfs by taking into account LQ and Lorentz force simultaneously.

Keywords: Landau quantization; Non-uniform magnetic field; Dirac equation; Chandrasekhar-limit; Quantum speed limit

1. Introduction

Landau Quantization (LQ) is the phenomenon of the quantization of the cyclotron orbits of charged particles in presence of magnetic field. LQ has been widely discussed for uniform magnetic fields both in non-relativistic[1] as well as relativistic[2] cases. It leads to many interesting effects like quantum Hall effect, de Has Van Alphen effect, Shubnikov oscillations, modification to the equation of state (EOS) and change in the neutron drip line. The modified EOS was later proved to be useful in explaining the mass of super Chandrasekhar white dwarfs.[3]

However, a complete uniform magnetic field is an idealistic realization. What if it is non-uniform as in astrophysical systems and plasmas? In white dwarfs, neutron stars and even main sequence stars, the magnetic field varies drastically from centre to surface. Plasma can act as a source of both increasing and decreasing magnetic fields depending on its properties. Even in laboratories, fluctuations in the magnetic field are a common sight. This motivates us to initiate the exploration of the dynamics of a relativistic electron in presence of strictly spatially variable magnetic fields.[4]

We show different arrangements of the energy levels of an electron when it is trapped in variable magnetic fields. Further, we explore its applications in the fields of quantum information by showing an increase in quantum speed of an electron in presence of a spatially increasing magnetic field, and astrophysics, in the magnetized white dwarfs.

2. Solution of Dirac equation in presence of magnetic fields

The Dirac equation in the presence of magnetic field for an electron of mass m_e and charge q $(-e)$ is given by

$$i\hbar\frac{\partial\Psi}{\partial t} = \left[c\boldsymbol{\alpha}\cdot\left(-i\hbar\nabla - \frac{q\mathbf{A}}{c}\right) + \beta m_e c^2\right]\Psi, \tag{1}$$

where $\boldsymbol{\alpha}$ and β are Dirac matrices, $\mathbf{A}$ is the vector potential, $\hbar$ is the reduced Planck constant and c is the speed of light. For stationary states, we can write

$$\Psi = e^{-i\frac{Et}{\hbar}}\begin{bmatrix}\chi\\ \phi\end{bmatrix}, \tag{2}$$

where ϕ and χ are 2-component spinors.

Therefore, the decoupled equation for χ obtained from Eq. (1) is

$$(E^2 - m_e^2c^4)\chi = \left[c^2\left(\pi^2 - \frac{q\hbar}{c}\boldsymbol{\sigma}\cdot\mathbf{B}\right)\right]\chi, \tag{3}$$

where $\boldsymbol{\pi} = -i\hbar\nabla - q\mathbf{A}/c$.

We choose a simple power law variation of the magnetic field in compliance with Maxwell's equations as

$$\mathbf{B} = B_0\rho^n\hat{z}, \tag{4}$$

in cylindrical coordinates (ρ, ϕ, z). Such a field profile can take into account the uniformity in magnetic field when $n = 0$ as well as an increase and a decrease in fields with respect to radial coordinate with $n > 0$ and $n < 0$ respectively, satisfying other physics intact. Using a gauge freedom for the vector potential $\mathbf{A}$, we choose

$$\mathbf{A} = B_0\frac{\rho^{n+1}}{n+2}\hat{\phi} = A\hat{\phi}. \tag{5}$$

Let

$$\chi = e^{i\left(m\phi + \frac{p_z}{\hbar}z\right)}R_{\pm}(\rho). \tag{6}$$

Since the electron is confined to a plane perpendicular to the direction of magnetic field (z-direction), $p_z = 0$. By substituting χ from Eq. (6) into Eq. (3), and dividing it by $m_e^2c^2$, Eq. (3) becomes

$$\begin{aligned}\alpha R_{\pm}(\rho) = &-\lambda_e^2\left[\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho} - \frac{m^2}{\rho^2}\right]\tilde{R}_{\pm}\\ &+\left[\left(\frac{kB_0\rho^{n+1}}{n+2}\right)^2 + k\lambda_e\left(-\frac{2m}{n+2}\pm 1\right)B_0\rho^n\right]R_{\pm},\end{aligned} \tag{7}$$

where α is the eigenvalue of the problem and is equal to $\epsilon^2 - 1$, $\epsilon = E/m_ec^2$, $\lambda_e = \hbar/m_ec$ and $k = e/m_ec^2$. Further, choosing $R_{\pm}(\rho) = u_{\pm}(\rho)/\sqrt{\rho}$, the above equation is reduced to

$$\alpha u_{\pm} = \left(-\lambda_e^2\frac{\partial^2}{\partial\rho^2} + V_{eff}\right)u_{\pm}, \tag{8}$$

such that

$$V_{eff} = -\lambda_e^2 \left[\frac{1}{4\rho^2} - \frac{m^2}{\rho^2}\right] + \left(\frac{kB_0\rho^{n+1}}{n+2}\right)^2 + k\lambda_e \left(-\frac{2m}{n+2} \pm 1\right) B_0\rho^n. \qquad (9)$$

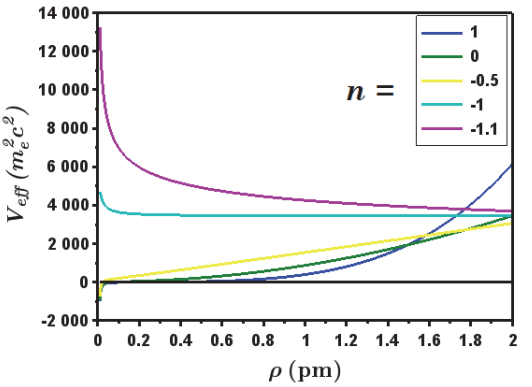

Fig. 1. The variation of effective potential for different n for $B_0 = 10^{15}$ G pm^{-n}. The black horizontal line represents $V_{eff} = 0$. Various potentials at $\rho = 1$ pm from bottom to top represent $n = 1, 0, -0.5, -1$ and -1.1 respectively.

The variation of V_{eff} for different n is shown in Fig. 1. It can be seen that V_{eff} is completely repulsive for n less than or equal to -1, whose solution will depend on the distance from the source (origin of the system) upto which a particle can move. Therefore, the energy eigenvalues for such cases depend upon where we put a hard wall making the system equivalent to confining the electron in a box. However, we do not want to apply any such restrictions on the electron. We, therefore, limit our analysis to the cases with n greater than -1.

We use "Shooting and Matching" method to solve Eq. (8). For computational analysis, we choose ρ and B_0 in the units of picometer (pm) and G pm$^{-\mathrm{n}}$ respectively.

For uniform magnetic field, i.e. $n = 0$, the eigenvalue of level ν is given by

$$\alpha_\nu = 2k\lambda_e B_0 \left(\nu + \frac{|m|}{2} - \frac{m}{2} + \frac{1}{2} \pm \frac{1}{2}\right), \qquad (10)$$

where 'm' is the azimuthal quantum number.[1] One can easily see from Eq. (10) that ground state eigenvalue (α_0) is 0 and all the other energy levels are doubly degenerate. Also, energies are same for $m \geq 0$, which turn out to be

$$E^2 = p_z^2c^2 + m_e^2c^4 \left(1 + 2\nu\frac{B_0}{B_c}\right), \qquad (11)$$

where $B_c = m_e^2c^3/e\hbar$, the Schwinger limit of pair production.

3. Eigenspectra and dispersion relations

3.1. $m = 0$

Figures 2 and 3 show the eigenspectra for different n, obtained from Eq. (7) by taking $m = 0$. On comparison of the eigenlevels without Zeeman effect (yellow-solid lines in the left) in Fig. 2, it can be observed that the spacing between the eigenlevels increases for $n > 0$, remains same if $n = 0$ and decreases for $n < 0$, from ground to higher levels. It owes to the chosen magnetic field variation in the region. If the magnetic field is spatially increasing, it has low strength near the centre and becomes strong near the outer boundary. Hence, the lower levels have lesser spacing, and the gap between consecutive levels increases for higher levels. The opposite is true for a decaying field profile.

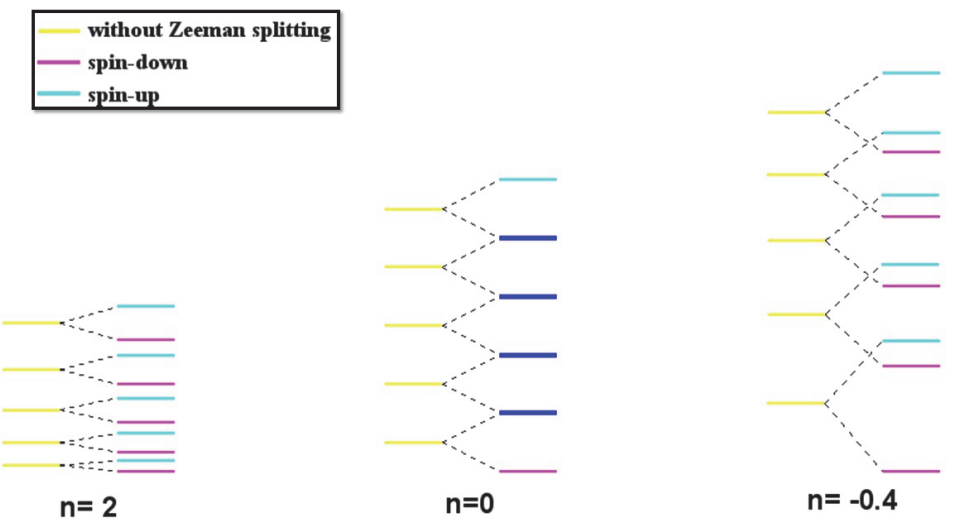

Fig. 2. Comparison of eigenlevels and the splitted states of $+\sigma.B$ and $-\sigma.B$ for $n = 2, 0$ and -0.4.

Breaking of degeneracy that arose in uniform magnetic field takes place for both increasing and decreasing magnetic fields if Zeeman effect is included. However, the alignment of levels for spin-up and spin-down electrons is quite different for these two cases as shown in Fig. 2. While the spin pattern for $n > 0$ is *dududu...*, it becomes *ddudud...* for $n < 0$ until $n = -0.6$, as can be inferred from Fig. 3. Below -0.6, the spin pattern is highly ambiguous, say for $n = -0.8$, it is *dddudud...*, whereas for $n = -0.9$, it changes to *ddddudud....* Here, d and u denote the levels for spin-down and spin-up electrons respectively. It is remarkable that the ground level for the spin-down electron always lies at 0 for all n.

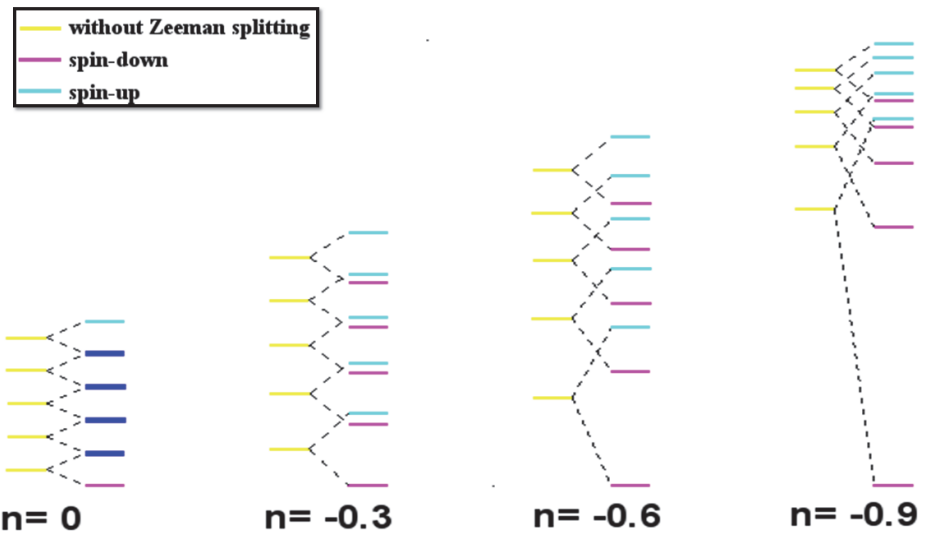

Fig. 3. Comparison of eigenlevels and the splitted states of $+\sigma.B$ and $-\sigma.B$ for $n = 0$ and when n is negative.

One can, thus, obtain the desired spacing between the eigenlevels using non-uniform magnetic fields. For example, we can prepare a system with electrons confined to lower levels in a decaying magnetic field, say with $n = -0.8$ or -0.9. Such a system will then have only spin-down electrons due to the availability of lower levels for the same. Thus, we can achieve a single spin system using such variable magnetic fields. Also, a spin-based transition can be observed in presence of increasing magnetic fields, if we restrict the energy of electron between spin-up ground level and spin-down first excited state energies.

Table 1. The values of the constants of Eq. (12) for various n. Here B_0 in Eq. (12) is chosen in the units of 10^{15} G pm^{-n}

n	C_3	C_5
−0.5	195.66	0.484
−0.4	134.63	0.486
−0.3	97	0.488
−0.2	72.5	0.4934
−0.1	56	0.50
0	44.42	0.50
1	10.95	0.5156
2	5.72	0.50
3	3.965	0.51
4	3.15	0.51

We obtain a general expression for the eigenvalue of a level ν for arbitrary n using trial and error method, given by[4]

$$\alpha_{\nu\pm} = C_3\, B_0^{\frac{2}{n+2}}\, (\nu + C_5)^{\frac{2+2n}{n+2}} \left[1 \pm \frac{C_5}{(\nu + C_5)}\right]. \tag{12}$$

where C_3 and C_5 are constants whose value depends on n. The values of these constants for some n are given in Table 1.

3.2. $m \neq 0$

We compare the eigenvalues between positive m ($m = 1$) and negative m ($m = -1$) with $m = 0$ for different variations in the magnetic fields. When $n = 0$, positive m does not have any impact on the eigenvalues in comparison with $m = 0$, while negative m leads to the increment in energies, as depicted in Fig. 4 as well as can be inferred from Eq. (10). The Fig. 4 shows that for variable magnetic fields, the trend with respect to negative m remains same as that for the uniform one, however, the impact of positive m changes for the varying field. While it leads to an increase in energies for $n > 0$, the energies decrease, if n is negative.

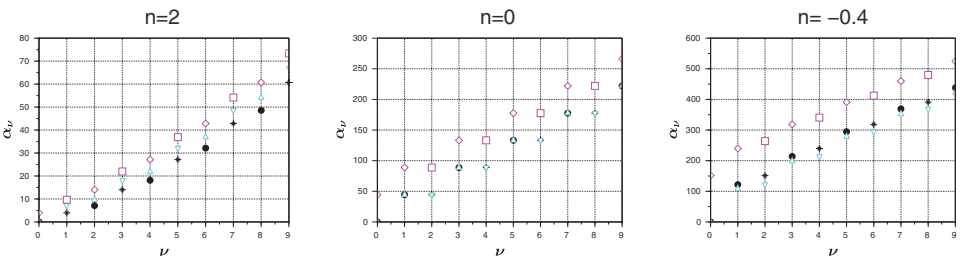

Fig. 4. The variation of eigenvalue with the eigen-index for $m = 0$ with $-\sigma.B$ (black solid circles) and $+\sigma.B$ (black asterisks); $m = +1$ with $-\sigma.B$ (cyan upward triangles) and $+\sigma.B$ (cyan downward triangles); $m = -1$ with $-\sigma.B$ (magenta diamonds) and $+\sigma.B$ (magenta squares), for $n = 2, 0$ and -0.4.

4. Finding ground state energy using variational method

We can find the upper bound of the ground state eigenvalue α_0 using the variational principle,[5] which states that

$$E_{gs} \leq \langle H \rangle, \tag{13}$$

where E_{gs} represents the ground state energy and $\langle H \rangle$ is the expectation value of Hamiltonian.

We choose the ground state wavefunction for both the spins of electron as

$$R_0 = e^{-\frac{KB_0\rho^{n+1}}{\lambda_e(n+2)^2}}. \tag{14}$$

The normalisation constant (N_0) is given by

$$N_0 = \sqrt{\frac{(n+2)}{\Gamma\left(\frac{2}{n+2}\right)}\left(\frac{2KB_0}{\lambda_e(n+2)^2}\right)^{\frac{2}{n+2}}}, \tag{15}$$

where

$$\Gamma\left(\frac{a}{b}\right) = b\int_0^\infty x^{a-1}e^{-x^b}dx.$$

Hence, the normalised wavefunction $\tilde{R}_0 = N_0 R_0$. Therefore,

$$\tilde{R}_0' = -\rho^{n+1}\frac{KB_0}{\lambda_e(n+2)}\tilde{R}_0, \tag{16}$$

and

$$\tilde{R}_0'' = -(n+1)\rho^n\frac{KB_0}{\lambda_e(n+2)}\tilde{R}_0 + \left(\frac{KB_0\rho^{n+1}}{\lambda_e(n+2)}\right)^2\tilde{R}_0. \tag{17}$$

Hence,

$$\alpha_{0_{Th}\pm} = \langle\tilde{R}_0|\,\alpha_\pm\,|\tilde{R}_0\rangle \tag{18}$$

$$= \frac{KB_0\lambda_e(1\pm1)}{\Gamma\left(\frac{2}{n+2}\right)}\left(\frac{2KB_0}{\lambda_e(n+2)^2}\right)^{-\frac{n}{n+2}}. \tag{19}$$

Thus, Eq. (19) provides an upper bound on the ground state energies for spin-down and spin-up electrons. (Eq. 19 can be obtained from Eq. 7).

Table 2. Comparison of analytical and computational α_0 values at different n for $B_0 = 10^{15}$ G pm$^{-\mathrm{n}}$.

n	$\alpha_{0_{Comp}+}$	$\alpha_{0_{Th}+}$
−0.5	225.83	256.70084
−0.4	151.124	162.464
−0.3	105.612	109.563
−0.2	76.716	77.840
−0.1	57.55	57.746
0	44.4	44.418
1	8.702	10.090
2	3.969	5.700
3	2.534	4.427
4	1.907	3.953

Note that $\alpha_{0_{Th}-}$ is zero for all n, which is the exact eigenvalue for the ground state of spin-down electron. For spin-up electron, the above expression provides the exact ground state eigenvalue only for the uniform magnetic field, but deviates for the non-uniform one. The comparison of actual α_0 obtained computationally ($\alpha_{0_{Comp}+}$) and the approximate analytical one obtained in this section ($\alpha_{0_{Th}+}$) for

spin-up electron at $B_0 = 10^{15}$ G pm^{-n} for different n is shown in Table 2. The deviation between the two values increases as one goes away from $n = 0$ in either direction. It is noteworthy that the power-law dependence of $\alpha_{0_{Th}}$ on B_0 in Eq. (19) is $2/(n+2)$ which is same as in Eq. (12), where α for a general ν is obtained using an appropriate ansatz.

5. Applications

In general, LQ in non-uniform magnetic fields can be useful in multiple domains of physics ranging from quantum information to condensed matter systems. Here, we will discuss its applications in quantum information via the increase in quantum speed of an electron and in astrophysics for the super-Chandrasekhar white dwarfs.

5.1. *Increase of quantum speed*

Quantum speed of a particle is defined as the speed of its transition from one energy level to the other. It has a direct influence on the processing speed of quantum information. The electron levels are equivalent to qubits in quantum information. Thus, if the transition between the levels takes place at higher pace, switching between the qubits will be more rapid, thereby, leading to faster processing of quantum information. Therefore, attaining higher quantum speed is one of the major requirements of the researchers in the field of quantum computation.

Assuming that the initial state of the electron is the superposition of the two consecutive states: the ground and the first excited one, given by

$$\Psi(\rho, 0) = \frac{1}{\sqrt{2}} \left[\psi_0(\rho) + \psi_1(\rho)\right], \tag{20}$$

with $m = 0$, $p_z = 0$ and the respective energies E_0 and E_1. For the transition of an electron from ground state to first excited state, the minimum time of evolution of wavefunction (T_{min}) is evaluated using Mandelstam-Tamm bound[6] as

$$T_{min} = \frac{\pi\hbar}{2\Delta H}, \tag{21}$$

where

$$\Delta H = \frac{E_1 - E_0}{2}. \tag{22}$$

The radial displacement of electron in time T_{min} is given by

$$\rho_{disp} = 2 \left| \int_0^\infty \rho D_S(\rho) d\rho \right|, \tag{23}$$

where

$$D_s(\rho) = \psi_0^\dagger \, \rho \, \psi_1. \tag{24}$$

Hence, the quantum speed of electron is

$$\tilde{\mathrm{v}} = \frac{\rho_{disp}}{T_{min}}, \tag{25}$$

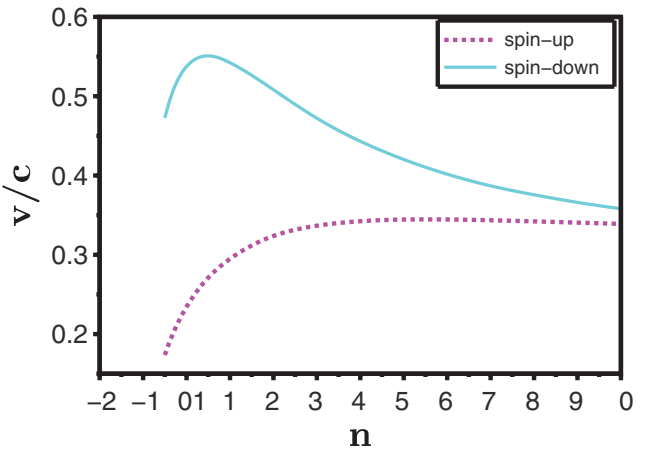

Fig. 5. Variation of quantum speed of spin-up and spin-down electrons for transition from ground state to first excited state with different n at $B_0 = 10^{16}$ G pm^{-n}.

Figure 5 illustrates the variation of the quantum speed of an electron with the change in non-uniformity index of the magnetic field in the relativistic regime. As it can be seen from the figure, the quantum speed of the electron increases with increasing n; reaches the maximum and then begins to decrease. Whereas quantum speed is maximum for $n = 1$ for spin-down electron, n has to be 6 to reach the highest speed for spin-up electron for $B_0 = 10^{16}$ G pm$^{-\mathrm{n}}$. This is associated with the varied alignment of energy levels in non-uniform magnetic fields lifting the degeneracy between $n < 0$ and $n > 0$ as shown in Fig. 2. Therefore, if a spin-up electron is trapped in a magnetic field that is spatially increasing in magnitude even linearly ($n = 1$), then we can achieve a higher speed of transition of the electron as shown in Fig. 5.

5.2. *Super-Chandrasekhar white dwarfs*

Astrophysical bodies like white dwarfs, neutron stars and magnetars are the natural sites to observe non-uniform magnetic fields, wherein, the difference between the central and the surface magnetic fields lies upto $3 - 4$ orders of magnitude or even higher.

The main impact of LQ in stellar physics is to modify the underlying EOS due to the discretization of energy levels in presence of strong magnetic fields. For a constant magnetic field, the energy levels are degenerate and the spacing between the eigenlevels is constant, but for a variable magnetic field case, the degeneracy breaks down and the spacing between levels is non-uniform, as shown in Figs. 2 and 3, which brings a considerable change in EOS in presence of non-uniform magnetic fields.

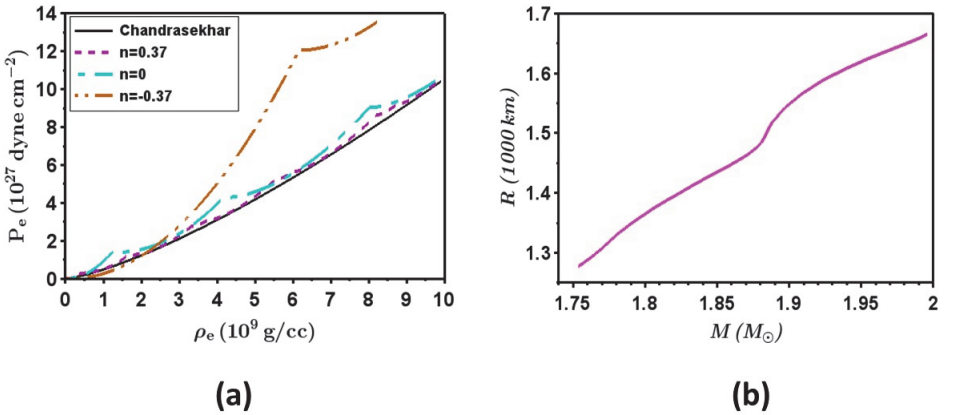

Fig. 6. (a) EOS for different n at $\epsilon_{Fmax} = 17$ for $B_0 = 2\times10^{15}\,\mathrm{G\,pm^{-n}}$. (b) Mass-radius relation of magnetized white dwarf for the magnetic field profile chosen in Eq. (33).

In a non-uniform magnetic field, the electron number density at zero temperature is given by

$$n_e = \frac{1}{(2\pi)^2\lambda_e^3}\left(\sum_{\nu=0}^{\nu=\nu_{m-}}\beta_-(\nu)x_{F-}(\nu) + \sum_{\nu=0}^{\nu=\nu_{m+}}\beta_+(\nu)x_{F+}(\nu)\right), \tag{26}$$

where '+' sign and '−' sign indicate spin-up and spin-down respectively,

$$x_{F\pm}(\nu) = \left[\epsilon_F^2 - (1+\alpha_\pm(\nu)\right]^{\frac{1}{2}} \tag{27}$$

and

$$\beta_\pm = \left(\alpha_\pm(\nu+1) - \alpha_\pm(\nu-1)\right)/2. \tag{28}$$

Note that $\nu_{m_\pm}$ is the largest integer value of ν such that

$$\alpha_{\nu_\pm} \le \epsilon_F^2 - 1. \tag{29}$$

The pressure of an electron gas at zero temperature is given by

$$P_e = \frac{m_e c^2}{(2\pi)^2\lambda_e^3}\left(\sum_{\nu=0}^{\nu=\nu_{m-}}\beta_-(\nu)(1+\alpha_-(\nu))f_2\left[\frac{x_{F-}(\nu)}{(1+\alpha_-(\nu))^{1/2}}\right] + \sum_{\nu=0}^{\nu=\nu_{m+}}\beta_+(\nu)(1+\alpha_+(\nu))f_2\left[\frac{x_{F+}(\nu)}{(1+\alpha_+(\nu))^{1/2}}\right]\right), \tag{30}$$

where

$$f_2(z) = \frac{1}{2}\left(z\sqrt{1+z^2} - ln(z+\sqrt{1+z^2})\right). \tag{31}$$

Figure 6(a) shows how the EOS changes with n at $B_0 = 2\times10^{15}\,\mathrm{G\,pm^{-n}}$. For a given ϵ_{Fmax}, the allowed number of levels decreases with decreasing n. With the

decrease in number of levels, EOS becomes stiffer and softer in high and low density regimes respectively. Although, the spatially increasing magnetic field is not common in stellar objects, we also show the change in EOS of electron in presence of an increasing magnetic field that may come handy for future explorations.

To probe the effect of LQ and Lorentz force simultaneously in white dwarfs, we choose the following sample magnetic field profile.

$$B = \begin{cases} B_0 \hat{z}, & \text{if } \rho < 850 \text{ km}, \\ B_0 \left(\frac{\rho}{1 \text{ km}}\right)^{-0.37} \hat{z}, & \text{if } 850 \text{ km} \leq \rho \leq 900 \text{ km}, \\ B_0 \left(\frac{\rho}{1 \text{ km}}\right)^{-0.99} \hat{z}, & \text{otherwise}, \end{cases} \tag{32}$$

such that the central and the surface magnetic field are 2×10^{15} G and around 10^{12} G respectively. Also, $(\mathbf{B} \cdot \nabla)\mathbf{B} = 0$ and $\nabla \cdot \mathbf{B} = 0$ for the chosen profile. Therefore, the non-rotating white dwarfs will be spherical in shape. Hence, in spherical polar coordinates with $\theta = \pi/2$, the field profile is given by

$$B = \begin{cases} -B_0 \hat{\theta}, & \text{if } r < 850 \text{ km}, \\ -B_0 \left(\frac{r}{1 \text{ km}}\right)^{-0.37} \hat{\theta}, & \text{if } 850 \text{ km} \leq r \leq 900 \text{ km}, \\ -B_0 \left(\frac{r}{1 \text{ km}}\right)^{-0.99} \hat{\theta}, & \text{otherwise}, \end{cases} \tag{33}$$

The mass and radius of a white dwarf can be obtained by solving

$$\frac{d}{dr}\left(P_e + \frac{B^2}{8\pi}\right) = -\frac{GM(r)(\rho_e + \rho_B)}{r^2}, \tag{34}$$

$$\frac{dM(r)}{dr} = 4\pi r^2 (\rho_e + \rho_B), \tag{35}$$

where ρ_B is the magnetic density, $B^2 = \mathbf{B} \cdot \mathbf{B}$, $\rho_e = n_e m_p \mu_e$, m_p is the mass of proton, μ_e is the mean molecular weight per electron and G is Newton's gravitation constant.

The mass-radius relation, shown in Fig. 6(b), depicts the existence of super-Chandrasekhar mass white dwarfs in presence of central strong magnetic field. Although, here, the surface magnetic field obtained is around 10^{12} G, the results are unaffected even if the surface magnetic field of white dwarfs is lower, say around 10^9 G which is detectable.

Here, for $r < 850$ km, since, magnetic field is uniform, EoS would be Landau quantized for the same magnetic field at $B_0 = 2 \times 10^{15}$ G. For $r \geq 850$ km, the field decays to a lower strength so that Chandrasekhar's non-magnetic EoS suffices. Only at the interface around 850 km, non-uniform field based LQ applies in EoS, but in a very tiny region. Hence practically, for the present example, LQ EOS based on non-uniform field does not play an important role in controlling the dynamics of magnetised white dwarf. However, it helps to account for the whole system including the small zone around 850 km that contains the decay of the magnetic field.

6. Summary

LQ in strictly spatially variable magnetic fields is a new venture on its own. It leads to the different alignment of energy levels of an electron as well as the breaking of spin degeneracy, depending on the variation of magnetic field. Hence, it can be useful in the multitude of fields wherein one can attain the desired spacing and alignment of levels through an appropriate non-uniformity in magnetic fields.

We have explored its application in quantum computing through an increase in quantum speed of electron in spatially increasing magnetic field. We also discuss the increase in stiffness and softenss of EOS at high and low densities in presence of non-uniform magnetic fields as compared to the case of uniform magnetic field (as well as Chandrasekhar EOS). This, we, further, use to understand the properties of magnetized white dwarfs in the small zone of rapidly decaying magnetic field.

Validity of the semiclassical approximation in 1+1 electrodynamics: Numerical solutions to the linear response equation

Ian M. Newsome
Department of Physics, Wake Forest University, Winston-Salem, NC 27109, USA
Email: newsim18@wfu.edu

From previous work,[1] the semiclassical backreaction equation in 1+1 dimensions was solved and a criterion was implemented to assess the validity of the semiclassical approximation in this case. The criterion involves the behavior of solutions to the linear response equation which describes perturbations about solutions to the semiclassical backreaction equation. The linear response equation involves a time integral over a two-point correlation function for the current induced by the quantum field and it is expected that significant growth in this two-point function (and therefore in quantum fluctuations) will result in significant growth in solutions to the linear response equation. It was conjectured for early times that the difference of two nearby solutions to the semiclassical backreaction equation, with similar initial conditions, can act as an approximate solution to the linear response equation. A comparative analysis between the approximate and numerical solutions to the linear response equation, for the critical scale for particle production, will be presented for the case of a massive, quantized spin ½ field in order to determine how robust the approximation method is for representing its solutions.

Keywords: Schwinger effect; semiclassical electrodynamics; linear response; validity.

1. Introduction

The semiclassical approximation has been utilized in a wide range of physical situations where a quantized field evolves in a classical background. The relevant scenario for the following discussion involves the decay of an electric field via the Schwinger effect.[2] The original calculation by Schwinger in 1951 involved a background field calculation in which an electric field E, that is constant in space and time, gives rise to a particle production rate due to vacuum decay. At leading one-loop order the particle production rate is proportional to a factor of $\exp\{-\pi m^2/qE\}$, from which one can define a critical scale for pair production that is $E_{\text{crit}} \sim m^2/q$.

The time evolution of the net electromagnetic field is described by the semiclassical backreaction equation and has been solved for the case of a homogeneous electric field coupled to a massive scalar or a massive spin ½ field in $1{+}1^{3-5}$ and $3{+}1^{5-7}$ dimensions. When particles are produced, they accelerate in reaction to the background electric field, creating an electric current. This current produces a counter electric field which initially damps the original background electric field, and at late times the net electric field will oscillate.

Given that the semiclassical electrodynamics model is an approximation to quantum electrodynamics, it must be asked to what extent is this an accurate

approximation? Concerning the model presented here, the semiclassical backreaction equation involves an expectation value of the current constructed from quantum fields and for this to be a satisfactory approximation to what one would measure, it is necessary that quantum fluctuations be small.

To summarize the previous work which led to the development of the numerical solution to the linear response equation presented in these proceedings, the main goals in [1] had been to study the details of the particle production process when backreaction effects were taken into account and subsequently to estimate the significance of certain types of quantum fluctuations to investigate the validity of the semiclassical approximation for 1+1 electrodynamics. This included solving the necessary backreaction equations for scalar and spin ½ fields coupled to two different classical source profiles, one which led to an asymptotically constant electric field and the other being the Sauter pulse. To wit, a criterion was implemented to assess the validity of the semiclassical approximation which had been previously applied to the process of preheating in models of chaotic inflation,[8] with an earlier version applied to semiclassical gravity.[9] This criterion involves the behavior of solutions to the linear response equation, which can be derived by perturbing the semiclassical backreaction equation about a background field solution.

In general, the linear response equation is a second order integro-differential equation which can be cumbersome to solve numerically. Therefore a method was developed[8] to approximate solutions to the linear response equation which involves the difference between solutions to the semiclassical backreaction equation with similar initial conditions. For early times, this difference is expected to act as an approximate solution to the linear response equation as long as the exact solution is relatively small.

Subsequently, an effort has been made to directly solve for the numerical solutions to the linear response equation for the case of an asymptotically constant background electric field, initially zero, coupled to a spin ½ field. For the purposes of this proceeding, the numerical solutions to the linear response equation are desired in order to determine how robust the method for approximating its solutions will be. Therefore, a comparative analysis between the numerical solutions to the linear response equation and its approximate solutions described previously will be presented in what follows, with special attention given to the critical scale for particle production.

The structure of this paper is as follows: in Sec. 2 a brief review of the system is discussed including quantization of the spin ½ field, the semiclassical backreaction equation, and the renormalization procedure used. Sec. 3 contains a review of relevant material[1] including the criterion for the validity of the semiclassical approximation with the general and specific forms of the linear response equation presented for the case of a spin ½ field coupled to a background electric field. Also, included is a discussion of the method used to approximate solutions to the linear response equation. In Sec. 4 an analysis of the numerical solutions to the linear

response equation is given, with a comparison drawn between its approximate solutions, with an emphasis on the critical scale for significant particle production. Sec. 5 includes a summary of results and discussion thereof.

2. Quantization and Renormalization of a Spin ½ Field

This section describes the model under consideration: a quantized spin ½ field which interacts with a background electric field generated by a prescribed classical source. Analysis is restriced to 1+1 Minkowski spacetime with the assumption that the background electric field is spatially homogeneous in a given reference frame, i.e. $E = E(t)$. Furthermore, the metric signature is chosen to be $(-,+)$ with $c = \hbar = 1$.

The classical action describing a spin ½ field $\psi(t,x)$ coupled to a background electric field is given by

$$S = \int d^2x \left[-\frac{1}{4} F_{\mu\nu} F^{\mu\nu} + A_\mu J_C^\mu + i\bar{\psi}\gamma^\mu D_\mu \psi - m\bar{\psi}\psi \right] . \tag{1}$$

Here $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the electromagnetic field strength tensor, m the mass of spin ½ field excitations, $D_\mu = \partial_\mu - iqA_\mu$ the gauge covariant derivative, J_C^μ a classical and conserved external source, and $\bar{\psi} = \psi^\dagger \gamma^0$. The Dirac matrices γ^μ satisfy the following anticommutation relations $\{\gamma^\mu, \gamma^\nu\} = -2\eta_{\mu\nu}$.

Variation of (1) with respect to the vector potential yields the general form of Maxwell's equation

$$-\Box A^\mu + \partial^\mu \partial_\nu A^\nu = J_C^\mu + J_Q^\mu \ . \tag{2}$$

The classical source and background electric field generated by this source is chosen to be

$$J_C = -\frac{qE_0}{(1+qt)^2} \ , \quad E_C = -\int J_C \, dt = E_0 \left(\frac{qt}{1+qt} \right) , \tag{3}$$

for $t \geq 0$ and $J_C = 0$ for $t < 0$. Note, the term J_C in (3) is the spatial component of J_C^μ. Since the classical current is initially zero, and gives rise to an electric field that is initially zero as well, there is no ambiguity in the choice of vacuum state. The source term J_Q^μ induced by the spin ½ field is given by

$$J_Q^\mu = q\bar{\psi}\gamma^\mu \psi \ . \tag{4}$$

Variation of (1) with respect to the field $\bar{\psi}$ yields the Dirac equation

$$(i\,\gamma^\mu D_\mu - m)\,\psi(t,x) = 0 \ . \tag{5}$$

In what follows, the gauge choice

$$A^\mu = (0, A(t)) \ , \tag{6}$$

will be implemented. Expanding the spin ½ field $\psi(t,x)$ in terms of a complete set of modes yields

$$\psi(t,x) = \int_{-\infty}^{\infty} dk \, \left[B_k u_k(t,x) + D_k^\dagger v_k(t,x) \right] , \tag{7}$$

with $B_k, B_k^\dagger, D_k, D_k^\dagger$ the usual creation and annihilation operators obeying the anticommutation relations $\{B_k, B_{k'}\} = \{D_k, D_{k'}^\dagger\} = \delta(k - k')$. Utilizing a particular form for the modes,[10] two independent spinor solutions can be constructed as follows

$$u_k(t,x) = \frac{e^{ikx}}{\sqrt{2\pi}} \begin{pmatrix} h_k^I(t) \\ \\ -h_k^{II}(t) \end{pmatrix}, \quad v_k(t,x) = \frac{e^{-ikx}}{\sqrt{2\pi}} \begin{pmatrix} h_{-k}^{II\,*}(t) \\ \\ h_{-k}^{I\,*}(t) \end{pmatrix}. \tag{8}$$

Using the Weyl representation of the Dirac matrices γ^μ

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \gamma^1 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \tag{9}$$

the functions $h_k^I(t)$ and $h_k^{II}(t)$ satisfy the mode equations

$$\dot{h}_k^I - i(k - qA)h_k^I - imh_k^{II} = 0\ , \tag{10a}$$

$$\dot{h}_k^{II} + i(k - qA)h_k^{II} - imh_k^I = 0\ . \tag{10b}$$

The time evolution of this system is governed by the semiclassical backreaction equation. This can be obtained by replacing J_Q^μ in (2) with its expectation value $\langle J_Q^\mu \rangle$ and then use the gauge choice (6) with (7) to yield

$$\frac{d^2}{dt^2}A(t) = -\frac{d}{dt}E(t) = J_C + \langle J_Q \rangle\ . \tag{11}$$

Due to the coupling between the classical background electric field and the quantized spin ½ field, charged spin ½ particles will be created. These particles will be accelerated by the background electric field, creating a current which generates a secondary electric field. In the semiclassical approximation, the current created from the accelerated spin ½ particles is given by $\langle J_Q \rangle$. The renormalized expression for $\langle J_Q \rangle$, evaluated in the vacuum state is[1]

$$\langle J_Q \rangle_{\rm ren} = \frac{q}{2\pi}\int_{-\infty}^{\infty} dk\ \left[|h_k^I(t)|^2 - |h_k^{II}(t)|^2 + \frac{k}{\omega} - \frac{q\,m^2}{\omega^3}A(t) \right]. \tag{12}$$

with $\omega^2 = k^2 + m^2$. Here adiabatic regularization was used to eliminate the ultraviolet divergences.[10]

3. Validity Criterion for the Semiclassical Approximation

This section gives a review of relevant material[1] required for the investigation of the solutions to the linear response equation.

Since the current term $\langle J_Q \rangle$, in part, characterizes the quantum particle production process, a natural way to determine the size of quantum fluctuations, compared to other relevant quantities, is to evaluate a two-point correlation function for the current. In general, there are a number of different correlation functions which could be used, but in order to avoid such problems as state-dependent divergences,[11]

incompatible results from various renormalization techniques,[12] or covariance issues,[9] it is useful to proceed with a two-point correlation function which emerges naturally from the semiclassical theory itself, namely $\langle [J_Q(t,x), J_Q(t^{'},x^{'})]\rangle$. This two-point function measures the extent to which the value of the current $\langle J_Q\rangle$ at two separate spacetime points commutes, thereby having the interpretation of characterizing the degree to which quantum fluctuations are introduced into the system.

Perturbing the semiclassical backreaction equation yields the linear response equation which contains this two-point correlation function and describes the time evolution of perturbations about a given semiclassical solution. A criterion for the validity of the semiclassical approximation was originally developed for semiclassical gravity[9] and modified for preheating in chaotic inflation.[8] This criterion was applied to semiclassical electrodynamics[1] and states: the semiclassical approximation will break down if any linearized gauge invariant quantity constructed from solutions to the linear response equation with finite non-singular initial data grows rapidly for some period of time. It is important to note this is a necessary, but not sufficient condition for the validity of the semiclassical approximation.

3.1. *The Linear Response Equation*

The linear response equation for semiclassical electrodynamics is found by perturbing the semiclassical backreaction equation about a given solution. From (11) this becomes

$$\frac{d^2}{dt^2}\delta A(t) = -\frac{d}{dt}\delta E(t) = \delta J_C + \delta\langle J_Q\rangle \ . \tag{13}$$

More specifically, the type of perturbation being performed is one that changes the classical current by altering the value of the classical background electric field amplitude E_0 in (3). Thus the term δJ_C is expressed as

$$\delta J_C = -\frac{q}{(1+qt)^2}\delta E_0 \ . \tag{14}$$

In conjunction with the validity criterion stated previously, it is useful to break up the solutions to the semiclassical backreaction equation into the purely classical and quantum pieces

$$E_C = -\int_{t_0}^{t} J_C(t_1)\, dt_1 \ , \tag{15a}$$

$$E_Q = E - E_C \ . \tag{15b}$$

Solutions to the linear response equation can be partitioned in the same way which allows for the statement of the validity criterion to be modified to state that if δE_Q grows rapidly during some time interval, then the semiclassical approximation is not valid.

For the case of a spin ½ field, the renormalized $\delta\langle J_Q\rangle$ term present in (13) can be expressed as[1]

$$\delta\langle J_Q\rangle_{\rm ren} = -\frac{q^2}{\pi}\delta A(t) + i\int_{-\infty}^{\infty} dx^{'}\int_{-\infty}^{t} dt^{'}\,\langle[J_Q(t,x), J_Q(t^{'},x^{'})]\rangle\,\delta A(t^{'})\ , \tag{16}$$

with the relationship

$$\int_{-\infty}^{\infty} dx^{'}\,\langle[J_Q(t,x), J_Q(t^{'},x^{'})]\rangle = \frac{4iq^2}{\pi}\int_{-\infty}^{\infty} dk\,{\rm Im}\left\{h_k^I(t)h_k^{II}(t)h_k^{I*}(t^{'})h_k^{II*}(t^{'})\right\}. \tag{17}$$

Thus (13) takes the specific form

$$\begin{aligned}\frac{d^2}{dt^2}\delta A(t) = &-\frac{q}{(1+qt)^2}\delta E_0 - \frac{q^2}{\pi}\delta A(t)\\ &-\frac{4q^2}{\pi}\int_{-\infty}^{\infty} dk\int_{-\infty}^{t} dt^{'}\,{\rm Im}\left\{h_k^I(t)h_k^{II}(t)h_k^{I*}(t^{'})h_k^{II*}(t^{'})\right\}\delta A(t^{'})\ .\end{aligned} \tag{18}$$

3.2. *Approximate Solutions to the Linear Response Equation*

A technique that was developed to approximate solutions to the linear response equation for the case of homogeneous perturbations[1] involves solving the semiclassical backreaction equation for two solutions whose initial conditions are similar. It is expected that the difference between these two solutions ΔE is an approximate solution to the linear response equation δE, for early times, as long as $\Delta E \approx \delta E$. If the difference does grow large, then the corresponding solution to the linear response equation should grow significantly as well. This would violate the criterion discussed above and thus signal a breakdown in the semiclassical approximation.

A way to measure the relative growth of two solutions E_1 and E_2 to the semiclassical backreaction equation is with the modified relative difference expression[1]

$$R = \frac{|\Delta E|}{|E_1| + |E_2|}\ , \quad \Delta E = E_2 - E_1\ . \tag{19}$$

From the semiclassical backreaction equation, it is clear the difference ΔE will be a solution of the following equation

$$-\frac{d}{dt}\Delta E = \Delta J_C + \Delta\langle J_Q\rangle\ , \tag{20}$$

with the definitions

$$\Delta J_C = J_{C,2} - J_{C,1}\ , \quad \Delta\langle J_Q\rangle = \langle J_{Q,2}\rangle - \langle J_{Q,1}\rangle\ . \tag{21}$$

For ΔE to be an approximate solution to the linear response equation, i.e. $\Delta E \approx \delta E$, it is clear that $\Delta\langle J_Q\rangle \approx \delta\langle J_Q\rangle$ must hold, since one can set $\Delta J_C = \delta J_C$ for all times.

A natural way to measure the growth of the approximate quantum contribution to the finite difference equation ΔE_Q is with a relative difference R_Q given as

$$R_Q = \frac{|\Delta E_Q|}{|E_{Q,1}| + |E_{Q,2}|} \ , \quad \Delta E_Q = E_{Q,2} - E_{Q,1} \ . \tag{22}$$

This acts as the gauge invariant quantity constructed from solutions to the linear response equation mentioned in the formal statement for the validity criterion. This difference can be compared to the relative difference R_C between corresponding classical solutions, which does not vary in time. Therefore if R_Q grows rapidly for some period of time, this signals a breakdown in the semiclassical approximation.

In Fig. 1, some results[1] are given for the quantity R_Q for a variety of different particle masses[a]. The most significant effect on the behavior of R_Q is the size of the characteristic dimensionless quantity ${}^{qE_0}/_{m^2}$. It is therefore useful to distinguish between three different regimes: (i) ${}^{qE_0}/_{m^2} \gg 1$ in which the mass is relatively small compared to the electric field, resulting a large amount of particle production, (ii) ${}^{qE_0}/_{m^2} \sim 1$ in which the mass is of the same order as the electric field, resulting in less but still significant particle production, and (iii) ${}^{qE_0}/_{m^2} \ll 1$ in which the mass is relatively large compared to the electric field, resulting in very little particle production. The critical case for particle production is defined as $E \sim E_{\text{crit}} = m^2/q$ and therefore the most relevant mass value is $m^2/q^2 = 1$.

As seen in Fig. 1, this particular mass value corresponds to the most rapid growth of R_Q based on the cases considered here, and this implies the most severe breakdown of the semiclassical approximation for this case. However, one can see that R_Q has the least amount of growth in the small mass regime and steadily increases its early time growth as the mass is increased up to the critical case. The conclusion drawn in [1], in the context of the validity criterion put forward, is that the semiclassical approximation is most greatly violated when ${}^{qE_0}/_{m^2} \sim 1$ and becomes more accurate as the particle mass is decreased (or increased since quantum fluctuations are expected to diminish due to lack of particle production in the high mass regime).

4. Numerical Solutions to the Linear Response Equation

In this section, an analysis of the numerical solution to the linear response equation for the critical case in which the characteristic quantity ${}^{qE_0}/_{m^2} = 1$ is presented. A comparison is then drawn between its approximate and numerical solutions in the context of the validity criterion stated previously.

To arrive at numerical solutions to the linear response equation, one can partition the problem into two parts. The first part involves solving the semiclassical backreaction equation, and the second involves using the output from the

[a]This is an aggregate plot built from the results and data presented in [1].

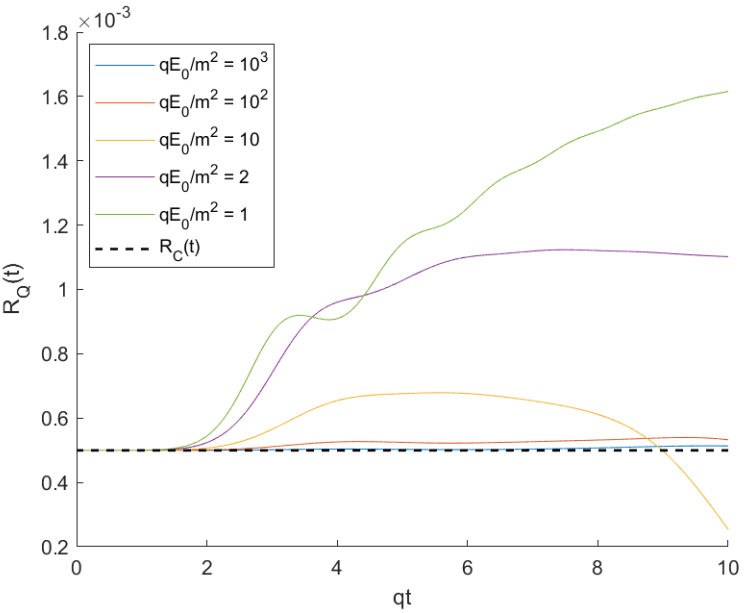

Fig. 1. Results obtained for the quantity R_Q. The values $E_{0,1}/q = 1$ and $E_{0,2}/q = 1 + 10^{-3}$ have been chosen for the solutions which comprise ΔE. The values of the characteristic quantity qE_0/m^2 for each case are shown along with the type of curve for that solution in the legend. Here $R_C(t)$ denotes the relative difference excluding quantum effects.

semiclassical backreaction equation to supply the necessary data for solving the linear response equation. Generating the solutions to the semiclassical backreaction equation involves simultaneously solving a set of three coupled differential equations, namely (10a), (10b), and (11) with (12). The solution output will be the vector potential $A(t)$, and by extension the electric field $E(t)$, and the time dependent spin ½ field modes $h_k^{I,II}(t)$. The quantities needed for solving the linear response equation (18) are the modes $h_k^{I,II}(t)$, which the two-point function in (17) depends on.

4.1. *Numerical Details*

The $|in\rangle$ state of the time dependent modes $h_k^{I,II}(t)$, prior to the classical source being turned on, is defined as positive frequency plane wave solutions to the mode equation. When the source term is turned on at $qt = 0$ and subsequently $A(t) \neq 0$, the mode solutions are altered by the presence of the background field, specifically $k \to k - qA(t)$. This leads to particle production which is measured, in part, by the quantity $\langle J_Q \rangle$. Since the two-point function $\langle [J_Q(t,x), J_Q(t^{'}, x^{'})] \rangle$ depends on these time dependent modes in a non-trivial way, the modification to the mode solutions will induce a non-zero contribution to the two-point function.

It is useful to separate the time dependent modes $h_k^{I,II}(t)$ into their real and imaginary parts

$$h_k^I = \mathrm{Re}\{h_k^I\} + i\,\mathrm{Im}\{h_k^I\}\ , \tag{23a}$$

$$h_k^{II} = \mathrm{Re}\{h_k^{II}\} + i\,\mathrm{Im}\{h_k^{II}\}\ . \tag{23b}$$

From this, the two mode equations defined in (10a) and (10b) now become four mode equations, given as

$$\mathrm{Re}\{\dot{h}_k^I\} + (k - qA)\,\mathrm{Im}\{h_k^I\} + m\,\mathrm{Im}\{h_k^{II}\} = 0\ , \tag{24a}$$

$$\mathrm{Im}\{\dot{h}_k^I\} - (k - qA)\,\mathrm{Re}\{h_k^I\} - m\,\mathrm{Re}\{h_k^{II}\} = 0\ , \tag{24b}$$

$$\mathrm{Re}\{\dot{h}_k^{II}\} - (k - qA)\,\mathrm{Im}\{h_k^{II}\} + m\,\mathrm{Im}\{h_k^I\} = 0\ , \tag{24c}$$

$$\mathrm{Im}\{\dot{h}_k^{II}\} + (k - qA)\,\mathrm{Re}\{h_k^{II}\} - m\,\mathrm{Re}\{h_k^I\} = 0\ . \tag{24d}$$

Furthermore, the quantity $\langle J_Q\rangle$ in (12) can now be expressed in the following way

$$\langle J_Q\rangle_{\mathrm{ren}} = -\frac{q^2}{\pi}A(t) + \frac{q}{2\pi}\int_{-\infty}^{\infty} dk\left[\mathrm{Re}^2\{h_k^I\} + \mathrm{Im}^2\{h_k^I\} - \mathrm{Re}^2\{h_k^{II}\} - \mathrm{Im}^2\{h_k^{II}\} + \frac{k}{\omega}\right]. \tag{25}$$

It is straightforward to now implement a numerical routine which will solve Eqs. (10) and (11).

From (17) it is clear that $\langle[J_Q(t,x), J_Q(t',x')]\rangle$ depends on the modes $h_k^{I,II}(t)$. However, the time integral present in (18) depends on both the current time t and the integration variable t'. In order to make this integral suitable for numerical evaluation, it is convenient to utilize (23a) and (23b) which allows it to be expressed as

$$\begin{aligned}
&\int_{-\infty}^{t} dt'\ \mathrm{Im}\big\{h_k^I(t)h_k^{II}(t)h_k^{I*}(t')h_k^{II*}(t')\big\}\delta A(t') \\
&\quad= \Big(\mathrm{Im}\big\{h_k^I(t)\big\}\mathrm{Im}\big\{h_k^{II}(t)\big\} - \mathrm{Re}\big\{h_k^I(t)\big\}\mathrm{Re}\big\{h_k^{II}(t)\big\}\Big) \\
&\qquad\times\int_{-\infty}^{t} dt'\ \Big(\mathrm{Re}\big\{h_k^{I*}(t')\big\}\mathrm{Im}\big\{h_k^{II*}(t')\big\} + \mathrm{Im}\big\{h_k^{I*}(t')\big\}\mathrm{Re}\big\{h_k^{II*}(t')\big\}\Big)\delta A(t') \\
&\qquad+\Big(\mathrm{Re}\big\{h_k^I(t)\big\}\mathrm{Im}\big\{h_k^{II}(t)\big\} + \mathrm{Im}\big\{h_k^I(t)\big\}\mathrm{Re}\big\{h_k^{II}(t)\big\}\Big) \\
&\qquad\times\int_{-\infty}^{t} dt'\ \Big(\mathrm{Re}\big\{h_k^{I*}(t')\big\}\mathrm{Re}\big\{h_k^{II*}(t')\big\} - \mathrm{Im}\big\{h_k^{I*}(t')\big\}\mathrm{Im}\big\{h_k^{II*}(t')\big\}\Big)\delta A(t')\ .
\end{aligned} \tag{26}$$

Here the inter-dependence of t and t', seen in the product $h_k^I(t)h_k^{II}(t)h_k^{I*}(t')h_k^{II*}(t')$, has been separated out. This allows for the time integral to be computed which then acts as the integrand for the k-integral in (18), which can be computed as well. From this the numerical solutions $\delta A(t)$ and $\delta E(t)$ to the linear response equation can be found.

4.2. *Results and Discussion*

In what follows, numerical results are presented for the critical case of ${}^{qE_0}/_{m^2} = 1$. In Fig. 2, the net electric field $E(t)$ including backreaction is plotted[1] with both the electric field contributions E_C when quantum effects are absent and E_Q generated by only quantum effects, seen in (15b) and (15a). One can see that at early times the net electric field begins to dampen compared to its classical counterpart E_C. This is due to the backreaction of the produced particles, resulting from the coupling of the spin ${}^1/_2$ field to the classical background source, causing an increase in the field E_Q.

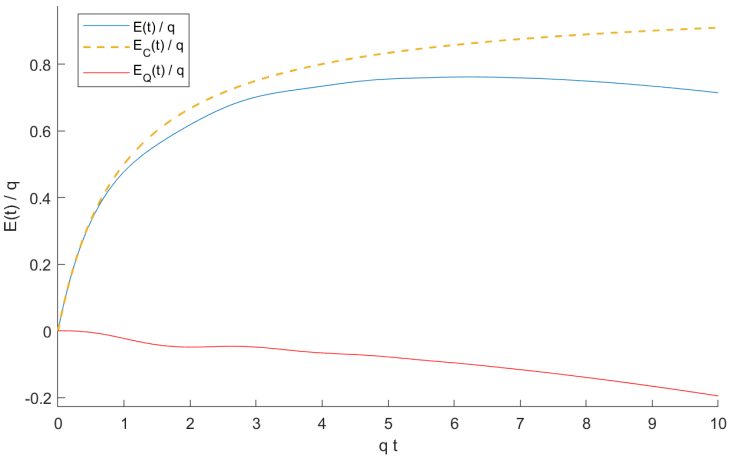

Fig. 2. A plot of the electric field including backreaction. The net electric field $E(t)$ is given by the blue curve, the electric field $E_C(t)$ with no quantum effects present is given by the yellow dashed curve, and the electric field $E_Q(t)$ generated by only quantum effects is given by the red curve.

Numerical solutions to the linear response equation are plotted in Fig. 3. The top plot shows the numerical solution δE to the linear response equation, its approximate solution given by the finite difference between two nearby semiclassical backreaction equation solutions ΔE, and the classical pieces $\delta E_C = \Delta E_C$. The bottom plot shows the purely quantum contributions to both the approximate ΔE_Q and numerical δE_Q solutions to the linear response equation. From (14) the initial value δE_0 was chosen in such a way as to equal the finite difference ΔE at early times, with this value being of order 10^{-3}.

For early times, there appears to be agreement between δE and ΔE, as well as ΔE_Q and δE_Q since the classical contribution dominates due to a lack particle production. However, near the time $qt = 1$ significant deviation between the two begins to occur, as could be measured by $(\delta E - \Delta E)/\delta E$. This deviation and subsequent late time growth in δE is driven by the dependence of $\langle [J_Q(t,x), J_Q(t^{'}, x^{'})] \rangle$

on the modes $h_k^{I,II}(t)$, whose positive frequency plane wave solutions are being altered due to the presence of the classical source term $A(t)$ having been switched on and leading to particle production. Since the critical case ${}^{qE_0}/_{m^2} = 1$ considered is a threshold case for significant particle production, above which even more particle production will occur, the growth of δE due to $\langle [J_Q(t,x), J_Q(t^{'},x^{'})] \rangle$ is expected.

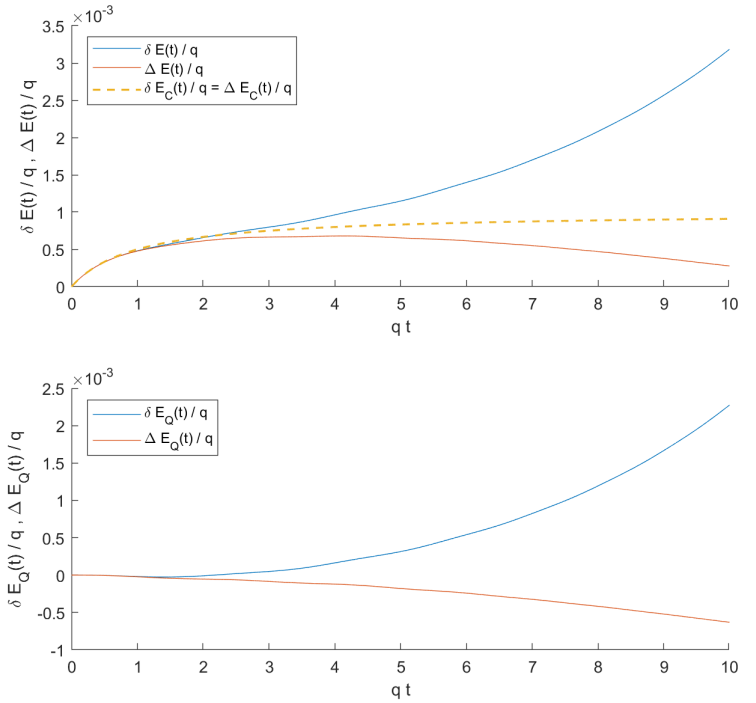

Fig. 3. The top plot shows solutions to the linear response equation, with red and blue curves representing the approximate and numerical solutions ΔE and δE, respectively, with the yellow dashed curve being the classical contribution to the solution. The bottom plot isolates the quantum contribution to the linear response equation, for both the approximate and numerical solutions ΔE_Q and δE_Q. All plots reflect the critical case of ${}^{qE_0}/_{m^2} = 1$ and were done with δE_0 and ΔE of order 10^{-3} for early times.

The time $qt = 1$ is also when one begins to notice substantial deviation between the net and classical electric fields, seen in Fig. 2, due to the presence of a nontrivial $\langle J_Q \rangle$ factor in (11) which will grow as more particles are produced. Furthermore, this time is also when one sees substantial growth of R_Q in Fig. 1 for the critical case. It therefore appears that for early times the ΔE is a good approximation to the linear response equation solution δE, and for late times $\delta E \neq \Delta E$. Comparing to the corresponding R_Q behavior, there is a breakdown in the semiclassical approximation based on the validity criterion implemented here. This was the conclusion that was

arrived at in [9], and it appears the behavior of the solutions δE as compared with the ΔE validates this conclusion.

5. Conclusions

In previous work,[1] a criterion for the validity of the semiclassical approximation was applied to the case of 1+1 semiclassical electrodynamics which involves the behavior of solutions to the linear response equation. The linear response equation depends, in part, on a two-point correlation function $\langle [J_Q(t,x), J_Q(t^{'},x^{'})\rangle$, which characterizes the quantum fluctuations introduced through the current $\langle J_Q\rangle$. Numerical solutions to the linear response equation have been obtained for 1+1 semiclassical electrodynamics using a model of the Schwinger effect in which particle production occurs in the presence of a strong, spatially homogeneous, electric field. The particle production, in the context of the system considered here, is a consequence of the coupling between a quantized spin ½ field and a classical, asymptotically constant, background electric field generated by an external source. Since the linear response equation depends on $\langle [J_Q(t,x), J_Q(t^{'},x^{'})]\rangle$, if there is rapid growth in this correlation function for some period of time, then quantum fluctuations must be significant, and will drive the growth of solutions δE to the linear response equation, resulting in a breakdown of the semiclassical approximation.

A previously developed technique to approximate solutions to the linear response equation involves the difference ΔE between two solutions to the semiclassical backreaction equation with similar initial conditions. The behavior of a quantity R_Q built from this difference of semiclassical backreaction equation solutions gives a measure for the validity of the semiclassical approximation. When R_Q grows large over some time, the corresponding linear response equation solution is expected to do so as well.

An analysis comparing the numerical δE and approximate ΔE solutions to the linear response equation has been conducted. At the critical scale, where ${}^{qE_0}/_{m^2} \sim 1$, it was found that at early times the quantity ΔE approximated the linear response equation solutions δE quite well. It was only after enough time had passed and significant particle production occurred that the numerical and approximate solutions deviated from one another. Therefore the claim that ΔE adequately approximates solutions to the linear response equation for early times is substantiated in this case. This critical scale was also the case for which the quantity R_Q had its largest growth[1] and therefore was the case considered for the purposes of this proceeding. The significant growth in both δE and R_Q signals a breakdown of the semiclassical approximation based on the validity criterion utilized here.

Regarding future work, the numerical solutions to the linear response equation will be used to further investigate the nature of how quantum fluctuations affect these solutions. More specifically, since the linear response equation involves several factors which dictate the behavior of its solutions, one of which is a term characterizing quantum fluctuations introduced through the particle production process,

having the numerical solution will allow one to isolate and investigate its respective contributions in detail.

Acknowledgements

I. M. N. would like thank Silvia Pla for sharing semiclassical backreaction numerical code and data as well as helpful discussions, Eric Grotzke for helpful discussions regarding linear response equation numerical details, Paul R. Anderson for guidance regarding the creation of this manuscript as well as helpful discussions, and Jose Navarro-Salas and Kaitlin Hill for helpful discussions. All numerical work was performed using MATLAB software with special thanks to the Distributed Environment for Academic Computing (DEAC) at Wake Forest University for providing HPC resources which contributed to the research presented in this proceeding.

Doran horizon penetrating coordinates are adopted to study specific perfect MHD processes around a Kerr black hole, focusing in particular on the physical relevance of selected electrodynamical quantities.

Keywords: Black hole physics, Relativistic MHD, Analytical solutions.

1. Introduction

General Relativity is a non linear theory which couples any physical field to gravitation described in terms of the geometry of space-time. This makes the search of exact or approximate analytical solutions for physical relevant problems an extraordinary task. Nowadays, Numerical Relativity has greatly circumvented such a problem by using the huge computational power available[1] although analytical solutions still remain fundamental to have important physical insights. The $60s$ and the $70s$ represented an important moment of rediscovery of Einstein's Theory. At that time, numerical relativity was almost unknown and Mathematical Physics techniques were widely adopted to find exact or approximate solutions. In particular, in the field of Black Holes Physics, the understanding of the electrodynamics and magnetohydrodynamics (MHD) around the recently discovered Kerr rotating black hole solution[2] was central. Due to the aforementioned difficulty associated to the non-linearity of the equations, approximate techniques of perturbative type were applied to this aim as, for instance, in the classical work by Ruffini and Wilson[3] and the one by Damour[4] (RWD) based on the properties of the geodesics in Kerr background studied by Carter.[5] In particular Ruffini and Wilson used a simplified model to describe possible charge separation processes involving the black hole and its magnetosphere. Such a studies have been recently revisited[6] by using coordinates regular on the horizon found decades later by Doran[8] and are here reviewed. Doran's work in particular generalizes classical Painlevé-Gullstrand coordinates for spherical black holes. These coordinates are horizon penetrating and are naturally associated to regular infalling physical observers. They are usually adopted in Numerical Relativity in union with the *excision* technique which allows to extend the computational domain beyond the black hole event horizon, avoiding to impose problematic boundary conditions for the partial differential equations there. Moreover, Painlevé-Gullstrand type coordinates naturally occur in Analogue Gravity in relation with acoustic black holes.[7] Summarizing, what we discuss here is the revisitation of RWD works by using useful coordinates found almost 25 years later. We will show in particular that these coordinates are the most natural ones to describe plasma physics by comoving with the fluid itself.

2. The RWD solution

RWD started from the Kerr metric in Boyer-Lindquist coordinates

$$\begin{aligned} ds^2 = &-\left(1-\frac{2Mr}{\Sigma}\right)dt^2 \; - \frac{4aMr\sin^2\theta}{\Sigma}dtd\phi + \frac{\Sigma}{\Delta}dr^2 + \Sigma d\theta^2 \\ &+ \left[r^2+a^2+\frac{2Mra^2\sin^2\theta}{\Sigma}\right]\sin^2\theta d\phi^2, \end{aligned} \tag{1}$$

with $\Sigma = r^2 + a^2\cos^2\theta$, $\Delta = r^2 - 2Mr + a^2$, a being the specific angular momentum and M the black hole mass, while the outer event horizon is located at $r_+ = M + \sqrt{M^2 - a^2}$ and Boyer-Lindquist coordinates are singular there. In the test field

approximation (no metric back reaction), neglecting pressure gradients in MHD equations as well as magnetic force terms and imposing a perfect plasma condition $F_{\mu\nu}U^{\nu} = 0$, the fluid must follow the geodesics on Kerr background studied by Carter:

$$U_{\mu;\nu}U^{\nu} = 0\,. \tag{2}$$

In particular in their works, RWD consider $U_{\phi} = 0$ and $U_t = -1$ at infinity and this implies that U_{θ} is a constant of motion. The four-velocity geodesic vector is then:

$$\begin{aligned} U^t &= \frac{\Sigma(r^2+a^2)+2Mra^2\sin^2\theta}{\Sigma\Delta}, \quad U^r = -\frac{[-\Delta U_{\theta}{}^2+2Mr(r^2+a^2)]^{\frac{1}{2}}}{\Sigma} \\ U^{\theta} &= \frac{U_{\theta}}{\Sigma}, \quad U^{\phi} = \frac{2MRa}{\Sigma\Delta}\,. \end{aligned} \tag{3}$$

Finally, requiring overall neutral stationary and axisymmetric configuration, the vector potential A_{μ} is characterized by the A_{ϕ} component only. RWD solving the simplified MHD equations found in such a a first approximation the analytical solution:

$$A_{\phi} = A(\theta_{\infty}) = A_{\phi}(\theta, r) \tag{4}$$

where

$$\theta_{\infty} = \theta - U_{\theta}\,\xi(r) \tag{5}$$

and

$$\xi(r) = \int_r^{\infty} \frac{dr'}{\sqrt{-(r'^2-2Mr'+a^2)U_{\theta}^2+2Mr'(r'^2+a^2)}}\,. \tag{6}$$

From these relations, one case easily reconstruct the entire Maxwell tensor $F_{\mu\nu}$ and obtain the associated four-current J^{μ}. Great simplification occur by choosing $U_{\theta} = 0$ because in such a case it results $A_{\phi} = F(\theta)$ with F a being an arbitrary function. Specifically, in RWD works it has been assumed the simple form $F(\theta) = A_0|\cos\theta|$ where quantity A_0 is a constant. Concerning Maxwell invariants, for this solution they have these properties:[6]

$$\frac{1}{2}F_{\mu\nu}F^{\mu\nu} = (\mathbf{B}^2 - \mathbf{E}^2) \geq 0\,, \qquad \frac{1}{4}F_{\mu\nu}{}^{*}F^{\mu\nu} = \mathbf{E}\cdot\mathbf{B} = 0\,, \tag{7}$$

so there must exist a frame in which the observer associated to the geodesics four-velocity measures a magnetic field only, while the electric one vanishes in consequence of the perfect plasma condition. In standard perfect MHD physics, both charge density and electric field disappear in a locally comoving (and corotating) plasma frame. This frame is in general not easy to be found analytically,[9] but for the RWD solution however, by using Doran coordinates, we will successfully obtain it, as now discussed.

3. Doran coordinates analysis

The transformation from Boyer-Lindquist (BL) coordinates (t, r, θ, ϕ) to Doran Painlevé-Gullstrand-like (DPG) ones (T, R, Θ, Φ) is:

$$T = t - \int^r f(r)dr \ , \qquad R = r \ , \qquad \Theta = \theta \ ,$$
$$\Phi = \phi - \int^r \frac{a}{r^2 + a^2} f(r)dr \, , \quad f(r) = -\frac{\sqrt{(2Mr)(r^2 + a^2)}}{\Delta} \, , \tag{8}$$

so Kerr solution becomes

$$\begin{aligned} ds^2 = &- \left(1 - \frac{2Mr}{\Sigma}\right) dT^2 + 2\sqrt{\frac{2Mr}{r^2 + a^2}} dT dr - \frac{2a(2Mr)}{\Sigma} \sin^2\theta dT d\Phi \\ &+ \sin^2\theta \left[r^2 + a^2 + \frac{a^2(2Mr)}{\Sigma} \sin^2\theta\right] d\Phi^2 - 2a \sin^2\theta \sqrt{\frac{2Mr}{r^2 + a^2}} dr d\Phi \\ &+ \frac{\Sigma}{r^2 + a^2} dr^2 + \Sigma d\theta^2 \, . \end{aligned} \tag{9}$$

In the following, due to some of the coordinates' coincidence, we shall denote R with r and Θ with θ again. Using the coordinates transformation above, the RWD vector potential becomes

$$A_\mu = \left[0, -a\sqrt{\frac{2Mr}{r^2 + a^2}} \frac{F(\theta)}{\Delta}, 0, F(\theta)\right] \, . \tag{10}$$

with $F(\Theta) \equiv F(\theta) = A_0 |\cos\theta|$. Concerning the geodesics, we get

$$U_\mu = \left[-1, -\frac{\sqrt{-\Delta U_\theta^2 + 2Mr(r^2 + a^2)}}{\Delta} + \frac{\sqrt{2Mr(r^2 + a^2)}}{\Delta}, U_\theta, 0\right] \, , \tag{11}$$

which in the case of interest $U_\theta = 0$ case become

$$U_\mu = [-1, 0, 0, 0] \tag{12}$$

$$U^\mu = \left[1, -\frac{\sqrt{(2Mr)(r^2 + a^2)}}{\Sigma}, 0, 0\right] \, . \tag{13}$$

The four-velocity U^μ above represents the $T = const$ normal geodesic observer. Quantity T is the local proper time of observers in free fall along trajectories characterized by constant θ and Φ. The DPG electromagnetic tensor of the $U_\theta = 0$ RWD solution field has the only non vanishing component, undefined on the equatorial plane, given by:

$$F_{\Phi\theta} = A_{\Phi,\theta} \equiv \frac{dF(\theta)}{d\theta} = -A_0 \sin\theta \frac{|\cos\theta|}{\cos\theta} \, . \tag{14}$$

Defining the orthonormal locally Lorentzian frame $e^{(a)}{}_{\mu}$ associated to the DPG normal observer discussed above:

$$e^{(0)}{}_{\mu} = [-1,0,0,0]\ , \quad e^{(1)}{}_{\mu} = \left[\sqrt{\frac{2Mr}{\Sigma}}, \sqrt{\frac{\Sigma}{r^2+a^2}}, 0, -\sqrt{\frac{2Mr}{\Sigma}} a \sin^2\theta\right]$$
$$e^{(2)}{}_{\mu} = \left[0,0,\sqrt{\Sigma},0\right]\ , \quad e^{(3)}{}_{\mu} = \left[0,0,0,\sqrt{r^2+a^2}\sin\theta\right]\ , \tag{15}$$

one can easily show that the Maxwell tensor in the frame $F_{(a)(b)} = e_{(a)}{}^{\mu} e_{(b)}{}^{\mu} F_{\mu\nu}$ has the only non vanishing component (giving a magnetic field only):

$$F_{(3)(4)} = -F_{(4)(3)} \equiv B_{(1)} \equiv B_{\hat{r}} = -\frac{A_0}{\sqrt{(r^2+a^2)\Sigma}} \frac{|\cos\theta|}{\cos\theta}\ . \tag{16}$$

Moreover, by computing the charge density $J^{\mu}U_{\mu} \equiv J_{(0)} = \rho$ measured by the same observer one easily finds that it vanishes everywhere. As anticipated, we have found the natural frame to describe this perfect MHD problem which is the comoving fluid one. Moreover by using the fact that we have horizon penetrating coordinates, we can follow the fields inside the black hole. In particular it is possible to plot the four current lines for this RWD solution given by the numerical integration of the differential equations set $dx^{\alpha}/d\lambda = J^{\alpha}$ with λ parametrising the curves.[6] To note that while in BL coordinates the current lines whirl infinite times around the event horizon without entering inside, in DPG coordinates (we remind that these are naturally associated to comoving observers) the current lines are not whirled and can be continued regularly in the interior of the black hole. Finally, the use of DPG coordinates allows one to obtain elegant expressions for studying the energetics of the RWD solution. Always in the $U_{\theta} = 0$ case, one can easily compute an important quasi-local quantity i.e. the electromagnetic energy stored outside the event horizon through a $T = \ const$ cut in space-time as measured by the DPG normal observer. This quantity is given by

$$E_{\sigma}(U) = \int_{\sigma} T^{(\mathrm{em})}_{\mu\nu} U^{\mu} d\sigma^{\nu}\ . \tag{17}$$

Here σ is a bounded hypersurface which contains a portion of spacetime while U^{μ} represents the normal observer's four-velocity. In the relation above,

$$\mathcal{E} = T^{(\mathrm{em})}_{\mu\nu} U^{\mu} U^{\nu} \equiv \frac{A_0^2}{8\pi(r^2+a^2)\Sigma} \equiv 8\pi\mathcal{F} \geq 0\,, \tag{18}$$

is the local electromagnetic energy density obtained from the $T^{(\mathrm{em})}_{\mu\nu}$ electromagnetic energy-momentum tensor in DPG coordinates, here proportional to the first Maxwell invariant. Assuming the outer boundary of σ being the 2-surface $r = \mathcal{R} = const$, we get the simple relation:

$$E_{(r_+,\mathcal{R})}(U) = \frac{A_0^2}{2a}\left[\arctan\frac{\mathcal{R}}{a} - \arctan\frac{r_+}{a}\right]\ . \tag{19}$$

4. Conclusions

We have shown that the adoption of recent modern tools is extremely useful for revisiting classical studies of the $60s$ and $70s$. We have adopted in particular the most natural object to describe the physics of Ruffini-Wilson and Damour works, represented by Kerr black hole Doran horizon penetrating coordinates with their naturally associated normal observer. We have in particular described plasma physics from the fluid comoving frame and found great simplification for the electrodynamical quantities. The limitation of the analysis here presented however rely on the $U_\theta = 0$ choice which does not allow to obtain possible charge separation processes (charge density is vanishing everywhere in this case in fact), obtained by Ruffini and Wilson by imposing $U_\theta(\theta) = -U_\theta(\pi - \theta) = const$ instead. In order to address such a more complicated problem one should require a further generalization of Doran's work for the $U_\theta \neq 0$ case first. This study is not present in the literature and deserves future studies in order to revisit also the problem of Ruffini and Wilson charge separation.

Photon-graviton conversion in a magnetic field is a process that is usually studied at tree level, but the one-loop corrections due to scalars and spinors have also been calculated. Differently from the tree-level process, at one-loop one finds the amplitude to depend on the photon polarization, leading to dichroism. However, previous calculations overlooked a tadpole contribution of the type that was considered to be vanishing in QED for decades but erroneously so, as shown by H. Gies and one of the authors in 2016. Here we compute this missing diagram in closed form, and show that it does not contribute to dichroism.

Keywords: Photon-graviton; tadpole; Einstein-Maxwell

1. Introduction: Photon-graviton conversion

Einstein-Maxwell theory contains a tree-level vertex for photon-graviton conversion in a constant electromagnetic field:

$$\frac{1}{2}\kappa h_{\mu\nu}\Big(F^{\mu\alpha}f^{\nu}{}_{\alpha}+f^{\mu}{}_{\alpha}\,F^{\nu\alpha}\Big)-\frac{1}{4}\kappa h^{\mu}_{\mu}F^{\alpha\beta}f_{\alpha\beta}. \tag{1}$$

Here $h_{\mu\nu}$ denotes the graviton, $f_{\mu\nu}$ the photon, $F^{\mu\nu}$ the external field, and κ the gravitational coupling constant.

This interaction leads to photon-graviton oscillations similar to the better-known neutrino or photon-axion oscillations[1–11] (see[12] for a recent application to gravitational waves).

In momentum space, this vertex becomes

$$\Gamma^{(\mathrm{tree})}(k,\varepsilon;F) = \epsilon_{\mu\nu}\varepsilon_\alpha \Pi^{\mu\nu,\alpha}_{(\mathrm{tree})}(k;F), \quad \Pi^{\mu\nu,\alpha}_{(\mathrm{tree})}(k;F) = -\frac{i\kappa}{2} C^{\mu\nu,\alpha} \tag{2}$$

with

$$C^{\mu\nu,\alpha} = F^{\mu\alpha}k^\nu + F^{\nu\alpha}k^\mu - \big(F\cdot k\big)^\mu \delta^{\nu\alpha} - \big(F\cdot k\big)^\nu \delta^{\mu\alpha} + \big(F\cdot k\big)^\alpha \delta^{\mu\nu}\,. \tag{3}$$

Since in a constant field the four-momentum is preserved, k^μ here is the four-momentum of the photon as well as of the graviton.

For the photon polarizations, as is customary we will use the Lorentz frame where $\mathbf{E}$ and $\mathbf{B}$ are collinear, and choose the polarization basis $\varepsilon^\alpha_\perp, \varepsilon^\alpha_\parallel$, where $\varepsilon^\alpha_\parallel$ lies in the plane spanned by k and $\mathbf{B}$ or $\mathbf{E}$, and $\varepsilon^\alpha_\perp$ is perpendicular to it. For convenience we construct also the graviton polarization tensor using the same vectors:

$$\varepsilon^{\oplus\mu\nu} = \varepsilon^{\perp\mu}\varepsilon^{\perp\nu} - \varepsilon^{\parallel\mu}\varepsilon^{\parallel\nu}, \quad \varepsilon^{\otimes\,\mu\nu} = \varepsilon^{\perp\mu}\varepsilon^{\parallel\nu} + \varepsilon^{\parallel\mu}\varepsilon^{\perp\nu}\,. \tag{4}$$

From the CP-invariance of Einstein-Maxwell theory one can then derive the following selection rules:

- For a purely magnetic field $\varepsilon^\oplus$ couples only to $\varepsilon^\perp$ and $\varepsilon^\otimes$ only to $\varepsilon^\parallel$.
- For a purely electric field $\varepsilon^\oplus$ couples only to $\varepsilon^\parallel$ and $\varepsilon^\otimes$ only to $\varepsilon^\perp$.

2. One-loop photon-graviton vacuum polarization

In[13,14] the worldline formalism was used along the lines of[15–17] to study the one-loop corrections to this amplitude due to a scalar or spinor loop, see Fig. 1.

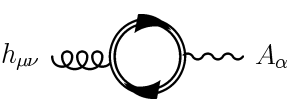

Fig. 1. One-loop correction to the photon-graviton amplitude in a constant field.

Here we employ the usual double-line notation for the full propagator in the external electromagnetic field, Fig. 2.

Fig. 2. Full scalar or spinor propagator in a constant field.

These calculations lead to the same type of two-parameter integrals as for the well-studied case of the one-loop photon vacuum polarisation in a constant field.[18–29]

Both the scalar and the spinor-loop amplitudes are UV divergent, but multiplicatively renormalizable. For example, the scalar-loop contribution in dimensional regularization displays the pole

$$\Pi^{\mu\nu,\alpha}_{\rm scal,div}(k) = \frac{ie^2\kappa}{3(4\pi)^2}\frac{1}{D-4}C^{\mu\nu,\alpha}$$

where $C^{\mu\nu,\alpha}$ is the tree level vertex (3).

For studying the relative importance of the one-loop amplitudes it is useful to normalize them by the tree-level amplitude (the "bar" on Π denotes renormalization)

$$\hat{\Pi}^{Aa}_{\rm scal,spin}(\hat{\omega},\hat{B},\hat{E}) \equiv \frac{\bar{\Pi}^{Aa}_{\rm scal,spin}(\hat{\omega},\hat{B},\hat{E})}{-\frac{i}{2}\kappa C^{Aa}} \tag{5}$$

where $A = \oplus, \otimes$ and $a = \perp, \parallel$, $\hat{\omega} = \frac{\omega}{m}$, $\hat{B} = \frac{eB}{m^2}$, $\hat{E} = \frac{eE}{m^2}$.

It then becomes obvious that the one-loop amplitudes become quantitatively relevant only for field strengths close to the critical ones $\hat{B}, \hat{E} \approx 1$. Macroscopic fields of this magnitude are known to exist only for the magnetic case, so that we will set $\hat{E} = 0$ in the following. In[14] it was shown that for this purely magnetic case the parameter integrals allow for a straightforward numerical evaluation as long as the photon energy $\hat{\omega}$ is below the pair-creation threshold $\hat{\omega}_{\rm cr}$,

$$\begin{aligned}\hat{\omega}^{\oplus\perp}_{\rm cr,scal} = \hat{\omega}^{\otimes\parallel}_{\rm cr,scal} &= 2\sqrt{1+\hat{B}}\,,\\ \hat{\omega}^{\oplus\perp}_{\rm cr,spin} &= 1+\sqrt{1+2\hat{B}}\,,\\ \hat{\omega}^{\otimes\parallel}_{\rm cr,spin} &= 2\,.\end{aligned} \tag{6}$$

There also a number of special cases were studied that allow for more explicit representations:

(1) The case of small B and arbitrary ω leads to single - parameter integrals over Airy functions.
(2) In the large B limit one finds a logarithmic growth in the field strength,

$$\hat{\Pi}^{Aa}_{\rm scal}(\hat{\omega},\hat{B}) \overset{\hat{B}\to\infty}{\sim} -\frac{\alpha}{12\pi}\ln(\hat{B})\,, \tag{7}$$

$$\hat{\Pi}^{Aa}_{\rm spin}(\hat{\omega},\hat{B}) \overset{\hat{B}\to\infty}{\sim} -\frac{\alpha}{3\pi}\ln(\hat{B})\,. \tag{8}$$

(3) In the limit of vanishing photon energy the amplitudes can be related to the corresponding one-loop effective Lagrangians:

$$\hat{\Pi}^{\oplus\perp}_{\rm scal,spin}(\hat{\omega}=0,\hat{B}) = -\frac{2\pi\alpha}{m^4}\Big(\frac{1}{\hat{B}}\frac{\partial}{\partial\hat{B}} + \frac{\partial^2}{\partial\hat{B}^2}\Big)\,\mathcal{L}^{\rm EH}_{\rm scal,spin}(\hat{B})\,, \tag{9}$$

$$\hat{\Pi}^{\otimes\parallel}_{\rm scal,spin}(\hat{\omega}=0,\hat{B}) = -\frac{4\pi\alpha}{m^4}\frac{1}{\hat{B}}\frac{\partial}{\partial\hat{B}}\,\mathcal{L}^{\rm EH}_{\rm scal,spin}(\hat{B})\,. \tag{10}$$

Here $\mathcal{L}^{\rm EH}_{\rm scal,spin}(\hat{B})$ denotes the one-loop effective Lagrangian in a constant magnetic field, obtained for the spinor QED case by Heisenberg and Euler[30] and for scalar QED by Weisskopf[31]:

$$\mathcal{L}^{\rm EH}_{\rm scal}(\hat{B}) = -\frac{m^4}{16\pi^2}\int_0^\infty \frac{d\hat{s}}{\hat{s}^3}\,\mathrm{e}^{-i\hat{s}}\left[\frac{\hat{B}\hat{s}}{\sin(\hat{B}\hat{s})} - \frac{(\hat{B}\hat{s})^2}{6} - 1\right], \tag{11}$$

$$\mathcal{L}^{\rm EH}_{\rm spin}(\hat{B}) = \frac{m^4}{8\pi^2}\int_0^\infty \frac{d\hat{s}}{\hat{s}^3}\,\mathrm{e}^{-i\hat{s}}\left[\frac{\hat{B}\hat{s}}{\tan(\hat{B}\hat{s})} + \frac{(\hat{B}\hat{s})^2}{3} - 1\right]. \tag{12}$$

3. Dichroism

For realistic parameters, the one-loop corrections turn out to be small compared to the tree-level amplitudes. However, there is also a qualitative difference to the tree-level amplitude. As has been emphasized in,[9] the tree level photon-graviton conversion does, contrary to the better known photon-axion case, not lead to a dichroism effect for photon beams. This is because both photon polarization components have equal conversion rates. This symmetry gets broken by the loop corrections. Although this effect is, of course, tiny and hardly measurable in the near future, an exhaustive analysis by Ahlers et al.[32] has shown that it is still the leading contribution to magnetic dichroism in the standard model (including standard gravity)!

4. Quantum electrodynamics in external fields

In vacuum QED, there is, of course, no one-photon amplitude because of Furry's theorem. In the presence of an external field, however, one-photon tadpole diagrams such as the one in Fig. 3 will in general be nonzero.

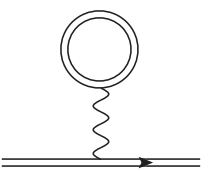

Fig. 3. Full scalar or spinor propagator in a constant field.

If the external field is constant, then the one-photon amplitude Fig. 4 can still be shown to vanish.

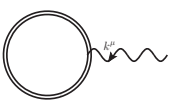

Fig. 4. One photon amplitude in a constant field.

The argument goes as follows:

(1) A constant field emits only photons with zero energy-momentum, thus there is a factor of $\delta(k)$.
(2) Because of gauge invariance, this diagram in a momentum expansion starts with the term linear in momentum.
(3) $\delta(k)k^\mu = 0$.

Since the tadpole vanishes, it has been assumed for decades that also any diagram containing it can be discarded. For example, in the book "Quantum Electrodynamics with Unstable Vacuum" by E.S. Fradkin, D.M. Gitman and S.M. Shvartsman[34] it is stated (on page 225) even more generally that, "*Thus, in the constant and homogeneous external field combined with that of a plane-wave, all the diagrams containing the causal current $\mathcal{J}^\mu(x)$ (i.e., those containing tadpoles having a causal propagator $S^c(x,y)$), are equal to zero.*"

Sometimes also additional arguments have been given; in the book "Effective Lagrangians in Quantum Electrodynamics" by Dittrich and Reuter[33] it is argued that the "handcuff" diagram of Fig. 5 vanishes because of Lorenz invariance.

Fig. 5. Handcuff diagram in a constant field.

However, in 2016 H. Gies and one of the authors[35] noted that such diagrams can give finite values because of the infrared divergence of the connecting photon propagator. In dimensional regularization, the key integral is

$$\int d^D k\, \delta^D(k) \frac{k^\mu k^\nu}{k^2} = \frac{\eta^{\mu\nu}}{D}\,. \tag{13}$$

Applying this integral to the handcuff diagram one finds a non-vanishing result, which can be expressed in the following simple way in terms of the one-loop Euler-Heisenberg Lagrangian[36]

$$\mathcal{L}^{\rm 1PR}_{\rm spin} = \frac{1}{2}\frac{\partial \mathcal{L}^{(EH)}_{\rm spin}}{\partial F^{\mu\nu}}\frac{\partial \mathcal{L}^{(EH)}_{\rm spin}}{\partial F_{\mu\nu}}$$

(the superscript "1PR" stands for "one-particle reducible"). This adds on to the standard diagram for the two-loop Euler-Heisenberg Lagrangian, studied by V.I. Ritus[39] half a century ago:

$$\mathcal{L}^{(EH)2-{\rm loop}}_{\rm spin} = \qquad + \tag{14}$$

Along the same lines, it was found in[37,38] that the one-loop tadpole contribution Fig. 3 to the scalar or spinor propagator in a constant field is also non-vanishing,

and given by

$$S^{\rm 1PR}(p) = \frac{\partial S(p)}{\partial F_{\mu\nu}} \frac{\partial \mathcal{L}^{(EH)}}{\partial F^{\mu\nu}}$$

where $S(p)$ denotes the tree-level propagator in the field.

5. Tadpole contribution to the photon-graviton amplitude

Returning to the photon-graviton amplitude in a constant field, the point of the present talk is that this amplitude, too, has a previously overlooked tadpole contribution, shown in Fig. 6.

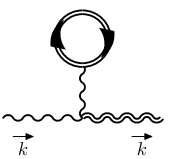

Fig. 6. Tadpole contribution to photon-graviton conversion.

Using the integral (13) it is easy to show that its contribution to the one-loop amplitudes with a scalar or spinor loop can be written as

$$\Gamma^{(\rm tadpole)}_{\rm scal}(k^\alpha, \varepsilon_\beta; \epsilon_{\mu\nu}; F_{\kappa\lambda}) = -i\frac{\alpha}{8\pi}\kappa\Big(\varepsilon\cdot F\cdot\epsilon\cdot k + \varepsilon\cdot\epsilon\cdot F\cdot k\Big) \times \int_0^\infty \frac{dz}{z}\, {\rm e}^{-\frac{m^2}{eB}z}\, \frac{\coth({\rm z}) - 1/{\rm z}}{\sinh(z)}\,, \tag{15}$$

$$\Gamma^{(\rm tadpole)}_{\rm spin}(k^\alpha, \varepsilon_\beta; \epsilon_{\mu\nu}; F_{\kappa\lambda}) = i\frac{\alpha}{4\pi}\kappa\Big(\varepsilon\cdot F\cdot\epsilon\cdot k + \varepsilon\cdot\epsilon\cdot F\cdot k\Big) \times \int_0^\infty \frac{dz}{z}\, {\rm e}^{-\frac{m^2}{eB}z}\, \frac{\coth({\rm z}) - \tanh({\rm z}) - 1/{\rm z}}{\tanh({\rm z})}\,. \tag{16}$$

Expanding out the tadpole in powers of the external field we see that the leading term, which is linear in the field (Fig. 7), is removed by the photon wave function renormalization.

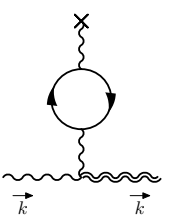

Fig. 7. Expanding the tadpole to lowest order in the field.

This gives the renormalized amplitudes

$$\Gamma^{(\text{tadpole})}_{\text{scal,ren}}(k^\alpha, \varepsilon_\beta; \epsilon_{\mu\nu}; F_{\kappa\lambda}) = -i\frac{\alpha}{8\pi}\kappa\Big(\varepsilon\cdot F\cdot\epsilon\cdot k + \varepsilon\cdot\epsilon\cdot F\cdot k\Big) \times \int_0^\infty \frac{dz}{z}\,\mathrm{e}^{-\frac{m^2}{eB}z}\left[\frac{\coth(\mathrm{z}) - 1/\mathrm{z}}{\sinh(z)} - \frac{1}{3}\right],$$

$$\Gamma^{(\text{tadpole})}_{\text{spin,ren}}(k^\alpha, \varepsilon_\beta; \epsilon_{\mu\nu}; F_{\kappa\lambda}) = i\frac{\alpha}{4\pi}\kappa\Big(\varepsilon\cdot F\cdot\epsilon\cdot k + \varepsilon\cdot\epsilon\cdot F\cdot k\Big) \times \int_0^\infty \frac{dz}{z}\,\mathrm{e}^{-\frac{m^2}{eB}z}\left[\frac{\coth(\mathrm{z}) - \tanh(\mathrm{z}) - 1/\mathrm{z}}{\tanh(\mathrm{z})} + \frac{2}{3}\right].$$

6. Comparison with the main diagram

These amplitudes are of a structure similar to what we got from the main diagram Fig. 1 in the limit of low photon energy ω, eqs. (9), (10).

However, they do not contribute to dichroism since the polarizations are still bound up in the tree-level vertex ($\varepsilon\cdot F\cdot\epsilon\cdot k + \varepsilon\cdot\epsilon\cdot F\cdot k$). Thus the above-mentioned analysis of Ahlers et al.[32] remains unaffected by the presence of the tadpole diagram.

7. Summary and outlook

- We have presented the first example of a non-vanishing diagram in Einstein-Maxwell theory involving a tadpole in a constant field.
- This diagram does not contribute to magnetic dichroism.
- A more quantitative analysis is in progress.
- In the ultra strong-field limit, the tadpoles have been shown even to dominate the (multi-loop) effective action in QED.[40] It would be interesting to extend this analysis to the Einstein-Maxwell case.

It appears that studying data from the catalogue of Gamma-Ray Bursts (GRBs) can be used to examine the birefringence phenomenon in the magnetosphere of the magnetars. By analysing the data from the McGill Online Magnetar and HEASARC Fermi Burst Catalogues, in this work we studied the angular distances between GRBs and magnetars in projection, we built their distribution map by the end of 2020, and the relative lag time periods of lights coming from GRBs and magnetars. It is confirmed that there are 29 galactic magnetars and their candidates, while the other two are located out of the Milkyway. The maximum separation angle for GRB and Magnetar projectiles was 3.76 degrees (4U0142+61 and GRB110818860), while minimum angular resolution was 0.54 degrees (SGR 1627-41 and GRB090829672). Currently, we discuss the relationship of GRB light intensity by their lag time as it would come after bending in the magnetosphere of the magnetar.

Keywords: Neutron stars; magnetars; light bending; gamma-ray bursts; birefringence.

1. Introduction

Magnetars emit a variety of electromagnetic waves ranging from gamma-ray to radio spectrum. Their bursts last from millisecond to a month.[1] Magnetar's bursts are generated by the powerful magnetic field inside of it. By taking into account the probability of boosting of core circular magnetic field covered by forceful reaction in a protoneutron star coming after a core-collapse supernova the magnetar model was created.[2] Currently there were detected 34 objects that are considered to be magnetars: 10% of them might belong to young neutron star populations.

To the date nearly thousand research articles were published on the topic of magnetars.[1] The first observational reviews on magnetars was carried out by Rea and Esposito, 2011.[3] The leading theoretical review was done by Turolla in 2015.[4] Also, both of observational and theoretical reviews were done by a group of researchers.[5,6]

*Doctoral student
†Postdoctoral associate

Historically magnetars were first presented by covering the name "Soft gamma repeaters" (SGR) and "Anomalous X-ray pulsars" (AXP).[1] The primary exposure of magnetar was done by the interplanetary space probes Venera 11 and 12 by detecting the burst activity.[7] The short-term bursts and outbursts, also continuous emissions were described by the sources of the impulsive magnetic field decays. The essential relation of SGRs to AXP was studied. It is believed that future SGRs burst activity might be detected from AXPs.[1]

It was also expected that magnetars might be prolific glitchers, described as unusual increase of rotation spin of a neutron star and they are observed basically in young neutron stars.[8,9] The first estimation of an SGR spin-down was published and the SGR 1806-20 was confirmed of a magnetar model by its sign and magnitude. Also for SGR 1900+14, as the SGR 1806-20, measurements verified that all SGRs are magnetar models.[10]

Contrary possibility of SGRs to be defined as a magnetar model was reviewed by using Einstein's observatory. They discovered a new unusual celestial bright X-ray source located at the center of the magnetar.[11] Then the new unusual celestial bright X-ray source's pulsation was estimated with the period of 3.5 s. (later it was concluded as a second harmonic of a 7-s fundamental).[11] The SGR bursts from two AXPs were explored and this confirmed Thompson and Duncans' (1996) expectations. Futhermore, the SGR bursts are one of the basic features of AXPs and, it is believed that, there is not any difference between them.[12,13]

The first catalogue of observed magnetar models and their complete characteristics were made by Olausen and Kaspi, in 2014.[14] Height scale of the known magnetar was detected to be about 20-30 pc (parsec). This height scale confirmed the magnetars to be young. Majority of magnetars from the catalog were discovered by their X-ray bursts by the sensitive all-sky monitors such as Burst Alert Telescope (BAT) onboard of Swift Gamma-Ray Burst Mission[15] and Gamma-Ray Burst Monitor (GBM)[16] onboard of Fermi Gamma-Ray Space Telescope. As well as magnetars X-ray burst activities they make X-ray pulsation in the period of range of 2-12 s.[1] Primary exploration of magnetars' glitch was carried out by Kaspi et al., 2000. One of the magnetar candidate had an unusual 6-hr period in X-ray with a different pulse and was explored in the source of the supernova remnant RCW 103, 1E 161348-5055. However, this object was considered not to be the magnetar because of their period of the bursts.[17] Another object was expected to be a magnetar by its bursts coupling with one more large X-ray flux outburst. But these bursts had long periods and this might be defined by a fall-back disc that interrupts the primarily fast-rotating neutron star.[18]

Some magnetar characteristics was detected from low-B radio pulsars from the source of SGR0418+5729.[19] The high-B radio pulsars are expected to be the magnetar by the confirmation of the exciting X-ray and soft gamma-rays are bursted by a magnetic field of neutron stars.[20,21] The relationship of magnetars to high-magnetic-field radio pulsars is expected by the research of radio pulsation from magnetars. But the magnetars' radio characters are unlike the common radio pulsars.[22,23]

Gravitational effect to the light bending is crucial in astrophysics. A weak gravitational bending effect causes gravitational lensing phenomenon, also a strong gravitational effect takes place near a compact objects, such as black holes or neutron stars.The gravitational effect of light bending near pulsars is studied by defining the angle of deflection and the flux coming to observer in a symmetrical metric of Schwarcshild.[24]

Non-linear electrodynamic bending angle based on the theory of Heisenberg-Euler and gravitational bending of a ray passing through the magnetosphere of magnetars are defined.[25] Due to this work the bending angle of light passing through the magnetars is about as a radian or 60 degree. Also the gravitational effect on the bending angle on the surface of a magnetar with the radius of about 3 km is up to 4 degree. Thus the polarisation does not effect on the gravitational bending.These non-linear electrodynamics and the gravitational bending are observable by the method of lensing. These non-linear electrodynamics and the gravitational bending are observable by the method of lensing. Additionally, it is proposed that, if the GRB comes from the nearest sources from the magnetars the scattering og light is negligible. Thus the falling of detected emission intensity will not be as deep as in the case of extra galaxies.

It appears that studying the data from the catalogue of Gamma-Ray Bursts (GRBs) can be used to study the birefringence phenomenon in the magnetosphere of the magnetars. By analysing the data from the McGill Online Magnetar and HEASARC Fermi Burst Catalogues, in this work we studied the angular distances between the nearest GRBs and magnetars in projection, built their distribution map as detected by 2020, and the relative lag time periods of lights coming from GRBs and magnetars. Currently, we discuss the relationship of GRB light intensity by their lag time as it would come after bending by the magnetosphere.

2. Methods

The effects of nonlinear electrodynamics of vacuum on the light propagation in dipole magnetic field causes the light to split into two normal modes and they can be detected in time interval of Δt.[26] It is said that the two modes of light coming to the observer can be observed in different years one by another. Initially, we should observe the detected GRBs and magnetars by their spatial distributions.

All the calculations were done in the Phyton programming platform. We downloaded the fits catalogue as a fits file from the website of HEASARC catalogue search (heasarc.gsfc.nasa.gov) in November 2020. By that time there were about 2915 gamma-ray bursts detected by Fermi GBM satellite telescope. Firstly, we defined short(less than 2 seconds) and long(more than 2 seconds) period bursts by the T90(time duration) table. It is confirmed that the long GRB bursts corresponds to core-collapse supernova stars, while the short bursts are the merges of neutron stars.[27] The number of short GRBs were 478 and the long GRBs were 2437 events.

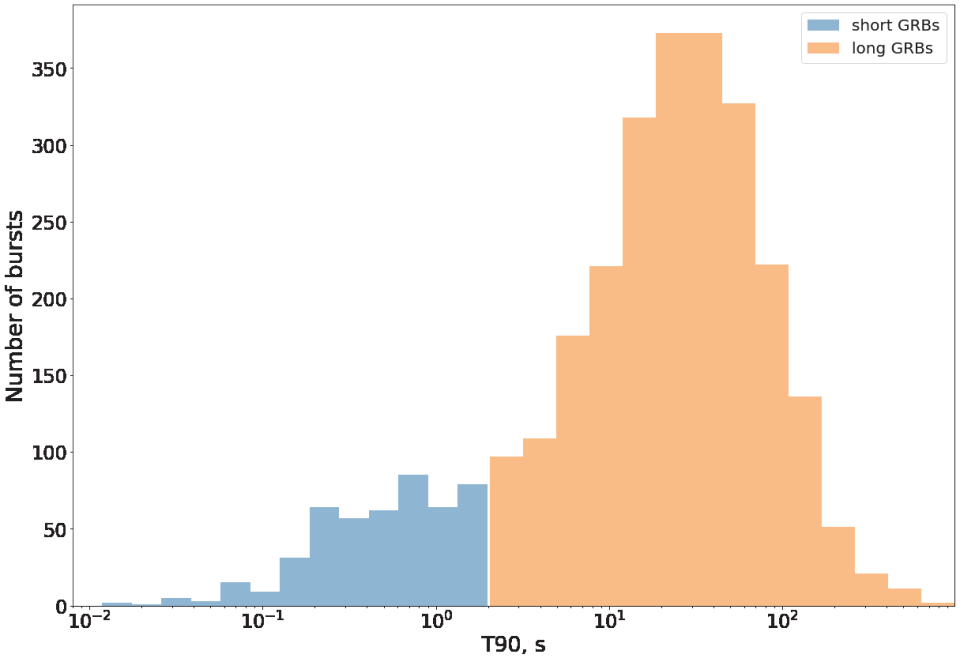

Fig. 1. The histogram of the GRBs by their periods.

In Fig. 1 we build the logarithmic histogram of the number of the bursts by their periods.[28] The minimum period of the short bursts lasted up to 0.008 s, while the maximum period was 1.984 s. Furthermore, the minimum period of the long bursts lasted up to 2.045 s, while the maximum period was 984.084 s. The majority of bursts lay between 10 and 100 s. But other short period bursts have the maximum number corresponds approximately to a second. This results are comparable with the previous works although in size by the order of magnitude.[28] As can be learned from their red shifts the bursts come from different parts of the universe. Let us define their spatial distribution.

Firstly, we took spatial coordinates from catalogue and changed them from the ecliptic into galactic (l,b) values.

We used Aitoff-Hammer projection in order to make the distribution of 2915 bursts on Fig. 2. Marked as red(long) and blue(short) dots these events isotropically distributed, which proves theis extragalactic origin. In previous works the spatial distribution were observed as an object of the definite goals. We use the spatial distribution to study the delay of light within the distribution of the observed magnetars and their candidates.

Nowadays there are 29 galactic and 2 extragalactic magnetars observed; among them there are 26 known magnetars and 5 magnetar candidates.[14] Their distribution

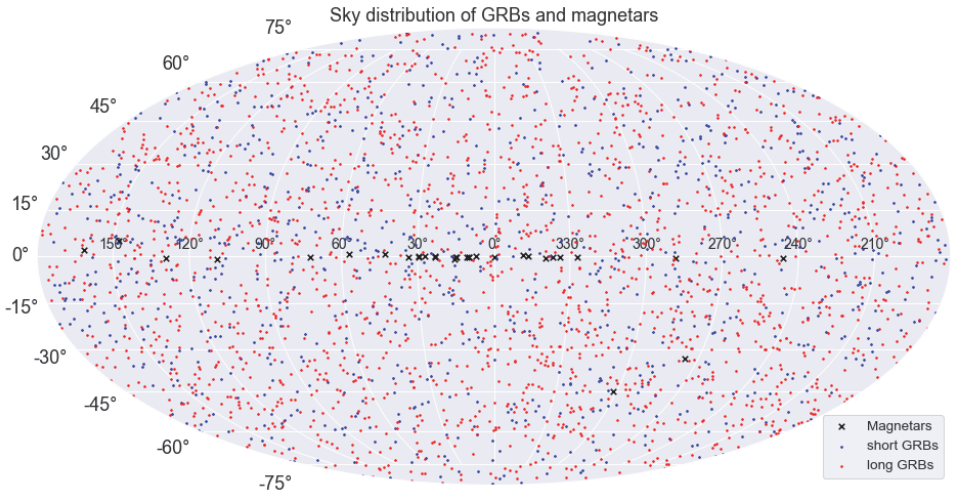

Fig. 2. The sky distribution of GRBs from HEASARC Catalogue as for November, 2020 observed by Fermi's Gamma-ray Burst Monitor (Fermi-GBM).[29]

in the Aitoff-Hammer map are made by using the McGill Online Magnetar catalog and indicated as black crosses in Fig. 2. As for GRBs we changed their coordinates into the galactic coordinates. Indeed, we could present both of the GRB and magnetars in the same map. Most of the magnetars are accumulated along the galactic plane. The other two can be seen out of the Galaxy of Milky-way.

When the light coming from the GRB passes through the magnetosphere of the magnetar it declines to some angle and the light splits into two modes.[30] This phenomena requires first to find out the relation of the spatial coordinates of the GRBs and the magnetars.

In order to illustrate the effect of the light bending we present its schematic view in Fig. 3. The light passing through the magnetars inclines to some θ angle.

If the light coming directly to the observer passes l distance, while the delayed distance is defined as: $\Delta l = (1 - \mathrm{ME} \cdot cos\alpha) \cdot \mathrm{GE}$. Here, ME is a distance between a magnetar and an observer. GE is a distance between a GRB and the Earth.

The next step is a calculation of the distance between the GRBs and the magnetars in projection. Here we take a magnetar, then we define the distance between this magnetar and the GRBs in order to find the closest pair.

Thus it is a projection distance: angular separation between the magnetar and the GRBs. Firstly, we define the difference of right ascensions of the magnetars and the GRBs, we do the same, as well as for the declination. Secondly, we define the distance between a magnetar and GRBs by the simple formula for triangle: $\Delta\ \mathrm{D} = \sqrt{RA^2 + Dec^2}$.

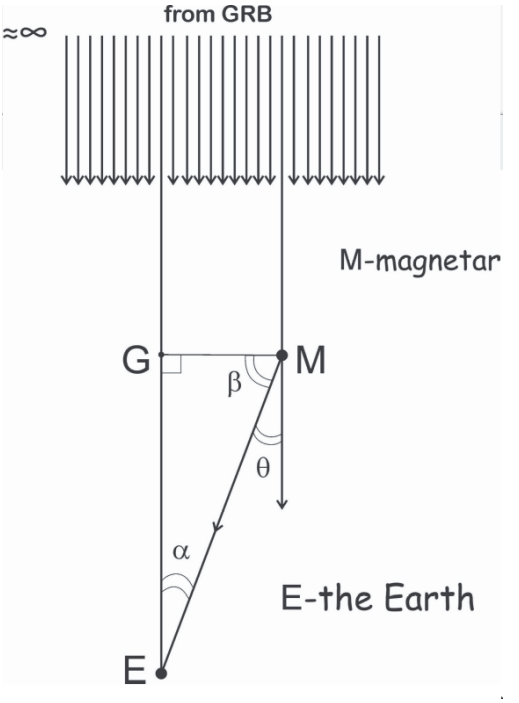

Fig. 3. Light propagation scheme.

We calculated angular distance corresponded to every 31 magnetars. Hence, every magnetars in the map surrounded by 2915 GRBs. The minimum of the angular distance corresponded to the magnetar is defined as the nearest GRB to the magnetar. As in Table 1, α is an angular projection distance for magnetars and GRBs. This results help to define the lag time of light coming to the detector by passing through the magnetar.

Delay of the GRB coming to the Earth can be defined by the distance between the magnetar and the detector. This data can be used from the McGill Online Magnetar Catalog website. We changed the units of parsec to light years and then we calculated the delayed time of light of GRB by dividing the delayed distance by the speed of light. Hopefully, we present the result in Figure 6. Here nan is a unknown data of the distance to a given magnetar. We do not use them in the future. Minimum of lag time corresponds to the magnetar of SGR 0418+5729, while the longest time is for the magnetar of CXOU J010043.1-721134. Futhermore, the errors of the distance to a magnetar should be useful for the calculation of delayed time period of the light.

Table 1. Minimum distance in projection between magnetars and GRBs.

3. Summary

By building the distribution of magnetars on galactic map, it is confirmed that there are 29 galactic magnetars and their candidates, while the other two are located out of the Milkyway. The number of GRBs we studied is 2915. The maximum separation angle for GRB and Magnetar projectiles was 3.76 degrees (4U0142+61 and GRB110818860), while minimum angular resolution was 0.54 degrees (SGR1627-41 and GRB090829672). There are five candidates of lag time period for GRBs (GRB130304658, GRB110319628, GRB141102536, GRB090829672, GRB140627401) and corresponding magnetars(SGR 0418+5729, SGR 0501+4516, 1E 1048.1-5937, SGR 1627-41, Swift J1822.3-1606) we expect to study in the future works. We discuss the relationship of GRB light intensity by their lag time as it

would come after bending by the magnetosphere. The further steps will include modelling of the front emission from GRBs passing through the magnetosphere of the given magnetar.

We study the absorption cross section of a massless test scalar field, for arbitrary frequency values, in the background of an Ayón-Beato-García electrically charged regular black hole spacetime. We show that Ayón-Beato-García regular black holes can mimic the absorption properties of Reissner-Nordström black holes in the whole frequency range, for small-to-moderate values of the normalized electric charge.

Keywords: Regular black holes; scalar field; absorption cross section.

1. Introduction

General relativity (GR) is a geometric theory of gravity that over more than one hundred years has successfully passed several experimental tests.[1–3] The observational evidences of GR[4–6] confirm the existence of black holes (BHs). These objects are characterized by a one-way membrane, called the event horizon, and in standard GR they are normally associated to a curvature singularity. Since the known laws of physics break down at such singularities, the standard GR is not able to explain the physics of a BH singular core.

An attempt to avoid the curvature singularity issues are the so-called regular BH (RBH) spacetimes,[7] i.e., singularity-free black hole geometries. The first exact charged RBH solution was proposed in 1998 by Eloy Ayón-Beato and Alberto García (ABG).[8] This solution was based on the minimal coupling between gravity and a nonlinear electrodynamics model, and describes a static and electrically charged RBH. The nonlinear electrodynamics theory can be seen as a possible generalization of Maxwell's linear electrodynamics for strong electromagnetic fields.[9]

In real astrophysical scenarios BHs are surrounded by distributions of matter.[10] Among the bosonic and fermionic distributions of matter, the simplest one is the scalar field, corresponding to spinless particles.[11] It is possible to study how BHs absorb and scatter matter fields as an attempt to better comprehend how BHs interact with their surroundings.[12–17] We present a selection of results for the massless scalar absorption by ABG RBHs, focusing in the possibility of RBHs mimic the absorption properties of standard BHs. More details on this work are presented in a previously published paper (see Ref. 18).

2. Ayón-Beato-García RBH Spacetime

The line element of the ABG solution is given by[8]

$$ds^2 = f(r)dt^2 - f(r)^{-1}dr^2 - r^2\left(d\theta^2 + \sin^2\theta\, d\varphi^2\right), \tag{1}$$

with

$$f(r) = f^{\rm ABG}(r) \equiv 1 - \frac{2Mr^2}{(r^2+Q^2)^{3/2}} + \frac{Q^2r^2}{(r^2+Q^2)^2}, \tag{2}$$

where M and Q are the mass and the electric charge of the BH, respectively. The asymptotic limits of the metric function are given by

$$\lim_{r\to 0} f^{\rm ABG}(r) \approx \ f^{\text{de Sitter}}(r) = 1 - \frac{1}{3}\left[\frac{3\left(2|Q|M - Q^2\right)}{Q^4}\right] r^2 \tag{3}$$

and

$$\lim_{r\to \infty} f^{\rm ABG}(r) \approx \ f^{\rm RN}(r) = 1 - \frac{2M}{r} + \frac{Q^2}{r^2}. \tag{4}$$

The ABG solution describes RBHs when $|Q| \leq Q_{\rm ext} \approx 0.6341M$. For $|Q| < Q_{\rm ext}$ we have a Cauchy, r_-, and an event horizon, r_+, given by

$$r_\pm = |Q|\sqrt{\left(\pm\frac{\sqrt{-\frac{9(12s^2-1)}{\sqrt{u(s)}} - 12s^2 - \frac{u(s)}{6} + \frac{9}{2}}}{2\sqrt{6}s} + \frac{\sqrt{u(s)}}{12s} + \frac{1}{4s}\right)^2 - 1}, \tag{5}$$

where $s \equiv |Q|/(2M)$ and

$$u(s) \equiv 6\left(-\frac{4(11s^2-3)s}{\sqrt[3]{g(s)}} + s\sqrt[3]{g(s)} - 4s^2 + \frac{3}{2}\right), \tag{6}$$

$$g(s) \equiv 4(74s^3 + 3\sqrt{3}\sqrt{400s^6 - 112s^4 + 47s^2 - 4} + 9s). \tag{7}$$

On the other hand, $Q = Q_{\rm ext}$ corresponds to the so-called extreme ABG RBH, for which we have only one horizon; while $Q > Q_{\rm ext}$ corresponds to a horizonless solution. The regularity of the solution at the core of the geometry is evidenced by the behavior of the scalar invariants presented in Ref. 8, which are all regular there.

3. Absorption of Massless Test Scalar Fields

3.1. *Massless scalar field*

The massless and chargeless test scalar field Φ obeys the Klein-Gordon equation:

$$\nabla_\mu\nabla^\mu\Phi = \frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}g^{\mu\nu}\partial_\nu\right)\Phi = 0. \tag{8}$$

We can decompose Φ as

$$\Phi = \sum C_{\omega l} \left(\frac{\psi_{\omega l}(r)}{r} P_l(\cos\theta) e^{-i\omega t} \right), \tag{9}$$

where $C_{\omega l}$ are constant coefficients. The indexes ω and l denote the frequency and the angular momentum of the wave, respectively, $\psi_{\omega l}(r)$ is the radial function and P_l are the Legendre Polynomials.

By inserting Eq. (9) into Eq. (8) we may find the following radial equation

$$\frac{d^2}{dr_\star^2}\psi_{\omega l} + \left[\omega^2 - V_{\rm eff}(r)\right]\psi_{\omega l} = 0, \tag{10}$$

where $\frac{dr_\star}{dr} \equiv \frac{1}{f(r)}$ is the tortoise coordinate and the effective potential $V_{\rm eff}(r)$ reads

$$V_{\rm eff}(r) \equiv f(r)\left[\frac{1}{r}\frac{df(r)}{dr} + \frac{l(l+1)}{r^2}\right]. \tag{11}$$

In Fig. 1 we present the effective potential in the background of ABG RBHs. We note that the peak of the effective potential increases as we consider higher values of the normalized charge $\alpha \equiv Q/Q_{\rm ext}$, as well as higher values of l; and for the asymptotic limits, we have $\lim_{r_\star \to \pm\infty} V_{\rm eff}(r_\star) = 0$.

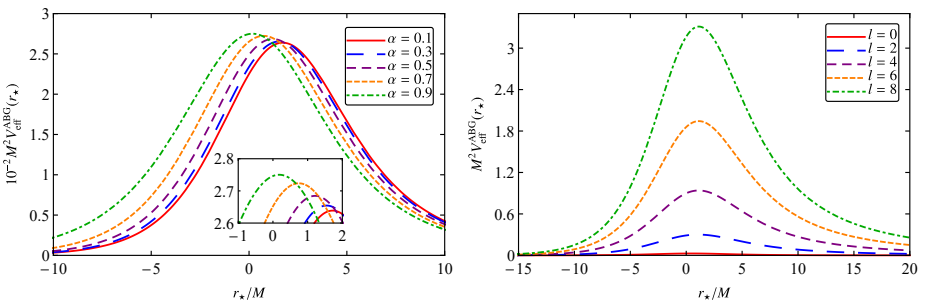

Fig. 1. The effective potential of scalar waves in the background of the ABG RBH, as a function of $r_\star$: (i) with $l = 0$, for different choices of the normalized charge α (left panel); and (ii) for different choices of l, with $\alpha = 0.8$ (right panel). The lower inset in the left panel emphasizes the peaks of the effective potential.

The appropriate boundary conditions are given by plane waves incoming from the infinite null past (the so-called *in modes*), so that the solutions of Eq. (10) reads

$$\psi_{\omega l} \sim \begin{cases} T_{\omega l} e^{-i\omega r_\star}, & r \to r_+ \ (r_\star \to -\infty), \\ e^{-i\omega r_\star} + R_{\omega l} e^{i\omega r_\star}, & r \to \infty \ (r_\star \to \infty), \end{cases} \tag{12}$$

where $T_{\omega l}$ and $R_{\omega l}$ are complex coefficients. By using the conservation of the flux, one can show that the transmission $|T_{\omega l}|^2$ and reflection $|R_{\omega l}|^2$ coefficients satisfy

$$|R_{\omega l}|^2 + |T_{\omega l}|^2 = 1. \tag{13}$$

3.2. *Absorption cross section*

By using the so-called partial-wave method, we may write the total absorption cross section (ACS) of the massless scalar wave as a sum of partial-waves contributions, given by[19]

$$\sigma = \sum_{l=0}^{\infty} \sigma_l, \tag{14}$$

where the partial ACS, σ_l, reads

$$\sigma_l = \frac{\pi}{\omega^2}(2l+1)|T_{\omega l}|^2. \tag{15}$$

There are analytic approximations for the ACS of massless test scalar fields by BHs in the low- and high-frequency regimes. In the low-frequency regime, for stationary BH geometries, the ACS tends to the surface area of the BH event horizon, namely[20,21]

$$\mathrm{A} = 4\pi r_+^2. \tag{16}$$

On the other hand, in the high-frequency regime, the absorption of a massless scalar field is governed by the geometric cross section (GCS) of null geodesics, i.e., $\sigma_{\mathrm{gcs}} = \pi b_c^2$, where b_c is the critical impact parameter. By using the so-called sinc approximation, it is possible to obtain an improvement for the high-frequency approximation, which can be expressed as[22]

$$\sigma_{\mathrm{hf}} = \sigma_{\mathrm{gcs}}\left[1 - 8\pi b_c \Lambda e^{-\pi b_c \Lambda}\mathrm{sinc}\left(2\pi b_c \omega\right)\right], \tag{17}$$

where $\mathrm{sinc}(x) \equiv \sin(x)/x$, and Λ is the Lyapunov exponent.[23]

4. Results

4.1. *Main features*

The numerical method employed to obtain the ACS consists in integrating numerically Eq. (10) from very close to the BH event horizon r_+, up to some radial position very far from the BH, with the boundary conditions in these regions given by Eq. (12).

In Fig. 2 we show the total ACS, normalized by the BH area, for distinct ABG RBHs. We note that, as $\omega \to 0$, the ratio σ/A tends to the unity. Hence, at the low-frequency limit, the numerical result for the ACS tends to the BH area, as expected.

A comparison between the horizon area of ABG and RN BHs is presented in Fig. 3. We see that for fixed values of α, ABG and RN BHs have very similar BH areas.

In Fig. 4 we compare the total ACS obtained numerically with the analytic approximations for the high-frequency regime (see Subsec. 3.2). As we can see, in this frequency regime, the total ACS obtained numerically oscillates around the

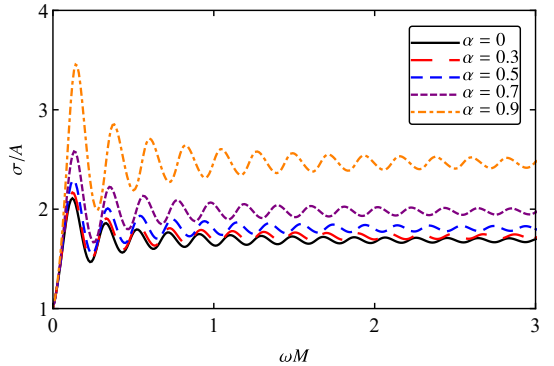

Fig. 2. The total ACS of the scalar wave for distinct ABG RBHs (divided by the BH area), as a function of ωM. We also exhibit, for comparison, the results for the Schwarzschild case ($\alpha = 0$).

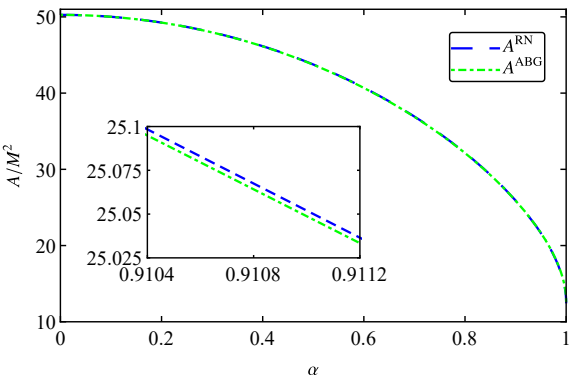

Fig. 3. The surface area of the BH event horizon of ABG and RN BHs, as a function of the normalized charge. The central inset shows the areas of ABG and RN BHs for α between 0.9104 and 0.9116, emphasizing the high similarity between the corresponding areas.

corresponding GCS and the oscillatory profile is very well reproduced by the sinc approximation. These results, combined with the ones for the low-frequency regime (cf. Fig. 2), show that our numerical results are consistent with the analytic approximations available in the literature. We also see that the total ACS of the ABG RBH diminishes as we increase α, so that the wave is more absorbed in the background of small-charge ABG RBH spacetimes. This is in accordance with the fact that the potential barrier raises as we increase α (see Fig. 1).

Examples of partial ACSs in the background of different ABG RBHs are shown in Fig. 5. We observe that the peak of the partial-wave modes diminishes as we consider higher values of the normalized electric charge and the mode $l = 0$ provides the main contributions for the ACS in the low-frequency regime.

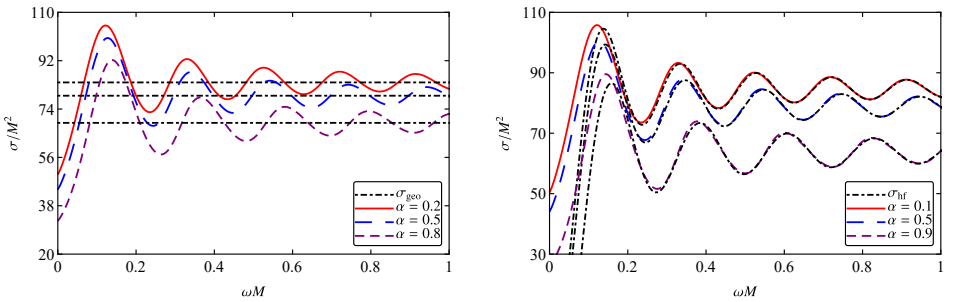

Fig. 4. Comparison of the total ACS (as a function of ωM) of the ABG RBH obtained numerically with: (i) the corresponding GCSs (left panel) and (ii) the corresponding sinc approximation (right panel), considering distinct values of α.

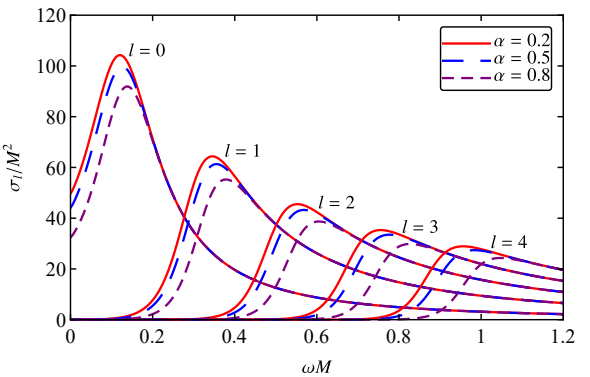

Fig. 5. Partial ACSs of the scalar wave considering different ABG RBHs (distinct values of α), as functions of ωM.

In Fig. 6 we compare the absorption results for ABG and RN BHs, considering two values of α. The total ACS of the ABG RBH is typically larger than the corresponding RN case. However, for small values of α, the total ACS of ABG and RN BH solutions can be very similar for arbitrary values of the frequency. Notice also that the zero-frequency regime of the total ACSs of ABG and RN BHs are very similar, for the same α value. This is in agreement with the behavior of their areas which are very similar for the same choices of α (cf. Fig. 3).

4.2. *RBHs as standard BHs mimickers*

We can consider the values of $(\alpha^{\rm ABG}, \alpha^{\rm RN})$ for which the corresponding GCSs coincide in order to find situations in which the absorption results of ABG and RN BHs are very similar. In Fig. 7 we display such values, which can be found up to $(\alpha^{\rm ABG}, \alpha^{\rm RN}) = (1, 0.9161)$.

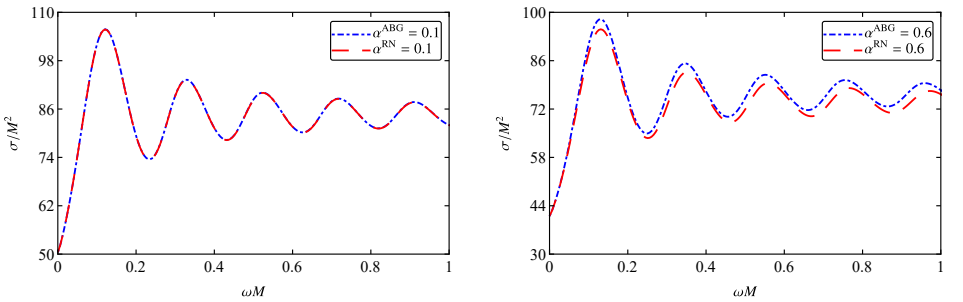

Fig. 6. The total ACSs of ABG and RN BHs as a function of ωM, for $\alpha = 0.1$ (left panel) and for $\alpha = 0.6$ (right panel).

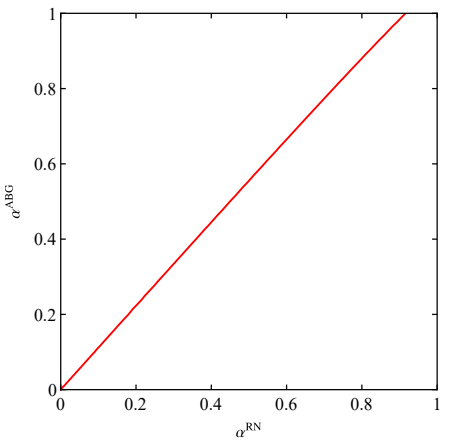

Fig. 7. The values of the normalized charges for which the GCSs of ABG and RN BHs coincide.

In Fig. 8 we exhibit the total ACSs for two pairs of $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}})$, for which the GCSs coincide. For low-to-moderate α values, the total ACSs of the ABG and RN BHs are basically indistinguishable along the whole frequency regime. This contrasts with the absorption results for massless test scalar fields in the Bardeen case,[24] for which the ACSs of Bardeen and RN BH solutions can be very similar only in the high-frequency regime.

We can define a function to estimate the percentual deviation between the BH area of each pair $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}})$, namely

$$\mathrm{A}_{\mathrm{dif}} \equiv \frac{\mathrm{A}^{\mathrm{RN}} - \mathrm{A}^{\mathrm{ABG}}}{\mathrm{A}^{\mathrm{ABG}}} 100\%. \tag{18}$$

The smaller the function $\mathrm{A}_{\mathrm{dif}}$ is, the more similar are the ABG and RN BHs areas. In Table 1 we present the corresponding BH areas, as well as $\mathrm{A}_{\mathrm{dif}}$, for several pairs $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}})$ displayed in Fig. 7. As we can see, the function $\mathrm{A}_{\mathrm{dif}}$ increases with

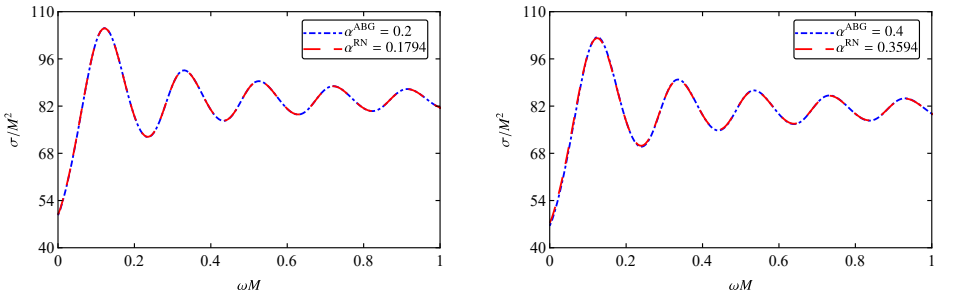

Fig. 8. The total ACS for the pairs $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}}) = (0.2, 0.1794)$ (left panel) and $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}}) = (0.4, 0.3594)$ (right panel). In both cases, the corresponding GCSs coincide.

Table 1. The BH areas and $\mathrm{A_{dif}}$ for several pairs $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}})$ shown in Fig. 7.

α^{ABG}	α^{RN}	$\mathrm{A}^{\mathrm{ABG}}/M^2$	$\mathrm{A}^{\mathrm{RN}}/M^2$	$\mathrm{A_{dif}}$
0.1516	0.1365	49.6831	49.7961	0.2274%
0.182	0.1629	49.425	49.5963	0.3453%
0.2027	0.1815	49.2219	49.4341	0.4309%
0.2852	0.2548	48.189	48.6201	0.8946%
0.318	0.2855	47.6772	48.1951	1.0863%
0.3417	0.3054	47.2708	47.8927	1.3156%
0.4003	0.3608	46.1309	46.9368	1.7469%
0.4707	0.4226	44.4976	45.6667	2.6273%
0.5003	0.4489	43.7207	45.0586	3.0601%

the increase of α. We also note that for an ABG RBH with $\alpha \lesssim 0.5$, we have that $\mathrm{A_{dif}} \lesssim 3\%$. Therefore, pairs $(\alpha^{\mathrm{ABG}}, \alpha^{\mathrm{RN}})$ that satisfy $\sigma^{\mathrm{ABG}}_{\mathrm{gcs}} = \sigma^{\mathrm{RN}}_{\mathrm{gcs}}$ correspond to very similar BH areas, as long as we consider only low-to-moderate values of α, implying that the ACSs of ABG and RN BHs are very similar also at the low-frequency regime. This also contrasts with the absorption results for massless test scalar field in the Bardeen case.[24]

5. Final Remarks

We revisited the scalar absorption of massless scalar fields by the first electrically charged ABG RBH solution,[18] presenting a selection of additional results. The height of potential barrier (related to the propagation of massless scalar waves in the background of the ABG RBH) enhances as we increase l or α. The ACSs obtained with our numerical method tend to the corresponding BH area in the low-frequency regime, as expected,[20] and, in this limit, the mode $l = 0$ provides the

main contribution to the ACS. We also obtained that the BH areas of ABG and RN BHs are very similar for certain values of α.

The total ACS of the ABG RBH, in the mid-to-high frequency limit, oscillates around the corresponding GCS and the sinc approximation provides excellent results for ACS in this regime. Therefore, considering the results in the low- and high-frequency regime, we conclude that our numerical results for the ACS agree very well with the analytic approximations. We also noted that the ABG RBH total ACS diminishes as we increase α, what is in accordance with the fact that $V_{\text{eff}}(r)$ increases as we increase α. The ABG RBH total ACS is typically larger than the RN one, for the same choice of α, but it is possible to find situations for which the total ACSs of ABG and RN BHs are very similar in the whole frequency range, mainly for small values of α. This similarity shows that it is possible that electrically charged RBHs mimic standard BHs, in what concerns the absorption of massless test scalar fields.

The progenitor evolution and the explosion mechanism of Type Ia supernovae remain unexplained. Nonetheless, substantial progress has been made over the past years with three-dimensional hydrodynamic simulations of different scenarios. Here, we review some recent work pertaining to the leading paradigms of modeling: thermonuclear explosions of white dwarf stars near and below the Chandrasekhar mass limit. We discuss implications of the different explosion channels and their predictions of observables.

Keywords: Type Ia supernovae, thermonuclear explosions, white dwarf stars, numerical simulations

1. Introduction

Despite substantial progress in theoretical modeling and numerical simulations over the past years,[1] our understanding of the physical mechanism of Type Ia supernovae remains incomplete. This has two main reasons. (i) The progenitor systems from which these explosions arise have not been identified, and therefore the initial conditions for the explosion simulations are uncertain. (ii) Modeling the explosion stage itself is a severe multi-scale multi-physics challenge and relies on assumptions and approximations. Some of these approximations could be mitigated with multi-dimensional hydrodynamical simulations. They form a cornerstone of a consistent modeling pipeline that follows a progenitor model over explosion and nucleosynthesis to the formation of observables. By avoiding tunable parameters, such a modeling pipeline facilitates a direct comparison of model predictions with astronomical data.

This allows for conclusions to be drawn on the validity of the assumed progenitor scenarios. In the following, we describe the application of this modeling pipeline to two different explosion scenarios.

2. Explosion models

Ignoring the fascinating but complex and still enigmatic evolution of progenitor systems of Type Ia supernovae, the main question to simulations is how to set up the state of the white dwarf at the onset of explosion. The two fundamental choices, a configuration close to the limit of stability, the Chandrasekhar mass, and a white dwarf below that mass limit, imply different explosion scenarios.[2] The compact structure of a near-Chandrasekhar mass object causes high densities of the material ahead of the thermonuclear burning front[3] if it propagates as a supersonic detonation. The products of such an explosion, almost exclusively iron group elements, are inconsistent with observations of Type Ia supernova. To produce the required intermediate mass elements detected in their spectra, burning has to start out as a subsonic deflagration in a white dwarf close to the Chandrasekhar mass. After some time of pre-expansion of the star, the burning front may turn into a supersonic detonation. In a sub-Chandrasekhar mass white dwarf, in contrast, the densities are lower and allow for the required intermediate-mass elements to be produced in a detonation.

For both scenarios, the actual ignition of the burning remains uncertain and is difficult to resolve in multidimensional hydrodynamic simulations.[4] Therefore, simulations often start out with an assumption on the triggering of the explosive burning.

3. Near-Chandrasekhar mass explosions

Sets of simulations have been carried out to test the impact of initial parameters on the outcome of explosions in near-Chandrasekhar mass white dwarf stars. Testing the ignition configuration[5] revealed that the number and spatial distribution of ignition sparks is the most important parameter for the strength of the deflagration. Few and asymmetrically distributed sparks lead to an incomplete disruption of the white dwarf. With very many ignition kernels (that are less likely to be realized in nature[4,6]), a complete unbinding of the star becomes possible, but the mass of ^{56}Ni produced is too low to explain the brighness of normal Type Ia supernovae. A detonation may form later and enhance the thermonuclear burning,[7] but here we restrict our discussion to cases where the flame propagation remains subsonic throughout.

Pure deflagrations in near-Chandrasekhar mass white dwarfs have been discussed as a model for the subclass of Type Iax supernovae.[8] An open question, however, remains: Can deflagrations in Chandrasekhar-mass white dwarfs cover the entire range of objects in this class, including the very faint events? To explore this,

we have carried out an extended systematic study of three-dimensional hydrodynamic explosion simulations[9] varying the distance of single-spark ignitions from the stellar center, but also other parameters such as the central density of the white dwarf at the onset of explosion, its metallicity, its carbon mass fraction, and its rotation state. This suite of models shows that it it well possible to decrease the ^{56}Ni production and thus the brightness of the modeled events to values that would match the faintest members of the Type Iax supernova class. However, inconsistencies were discovered, too. The faint events evolve to quickly in brightness. All models fall onto a strong correlation between the produced ^{56}Ni mass and the total eject mass. This correlation does not match observations and none of the initial parameters was able to perturb it significantly. For the brighter models, however, reasonable matches with observations were found. Previous claims of chemically layered ejecta structures[10] based on the "abundance tomography" method contradict the picture of Type Iax supernovae originating from deflagrations in Chandrasekhar-mass white dwarfs. Because of the intrinsic instabilities of subsonic flame propagation, such a scenario would predict well-mixed ejecta. Recent forward-modeling,[11] however, finds that the predictions of such models may still be consistent with observations.

Improvements in explosion modeling and – in particular – in the treatment of non local thermodynamic equilibrium (NLTE) effects in the radiation transfer calculations are needed to settle the question of whether deflagrations in Chandrasekhar-mass white dwarfs can explain at least the brighter Type Iax supernovae. Given the failure to model the faint events in this framework, it seems possible that not all members of the observationally-defined class of Type Iax supernovae pertain to the same physical explosion mechanism.

4. Sub-Chandrasekhar mass explosions

Explosions of white dwarf stars below the Chandrasekhar mass are an appealing model because they seem to reproduce important observational trends.[12] The question, however, is how such inert objects trigger a detonation. A classical model is that of double detonations: A helium shell is accreted on top of a carbon-oxygen white dwarf. Once massive enough, it triggers a shell detonation that initiates a secondary detonation of the carbon-oxygen core. If the helium shell is not too massive, its products do not strongly impact the observables and the match with data from normal Type Ia supernovae improves.[13–16]

We have recently explored the mechanism of triggering of the secondary core detonation and the impact of the shell detonation products on predicted observables in an extended sequence of three-dimensional hydrodynamic simulations.[17–19] This study identifies different possibilities for the core detonation initiation depending on the mass of the helium shell and the carbon-oxygen core. Although a reasonable match is obtained in the predicted observables with observational data, some shortcomings remain. These include too red spectra and too wide variations of the lightcurve width-luminosity relation with viewing angle. Some of these deficiencies

can be attributed to approximations in the treatment of NLTE effects in radiation transport,[16] but the mismatches may also call into question the explosion model itself.

5. Imprints on nucleosynthesis yields

Apart from comparing to optical observables, another approach to discriminate between and assess the validity of Type Ia supernova explosion models is by their imprints on the nucleosynthesis yields.[20] An important difference between near- and sub-Chandrasekhar mass explosion models is the production of manganese.[21] In explosive carbon burning, it can only be produced in (super-)solar ratio to iron if the densities are sufficiently high to allow for normal freeze-out from nuclear statistical equilibrium. This is the case for explosive burning in the cores of Chandrasekhar-mass white dwarfs. Alpha-rich freezeout, as occurring at lower densities in explosions of sub-Chandrasekhar mass objects, destroys the mother nucleus of ^{55}Mn, ^{55}Co, by proton captures. This produces additional ^{56}Ni at the expense of manganese. Therefore, it was concluded that a substantial fraction of Type Ia supernovae has to originate from the Chandrasekhar-mass explosion channel so that these objects can drive the manganese-over-iron trend in galactic chemical evolution towards the solar value. Our new double-detonation sub-Chandrasekhar mass explosion models,[19,20] however, show that additional manganese can be produced in the helium shell detonation. This lowers the fraction of Chandrasekhar-mass models needed to explain the galactic chemical evolution of manganese.

6. Conclusions

Three-dimensional hydrodynamic simulations help to avoid tunable parameters in the modeling of different explosion scenarios for Type Ia supernovae. The optical observables derived from such models via nucleosynthesis postprocessing[22] and radiative transfer calculations can be exposed directly to observational data. For the time being, however, the discriminative power of this approach is insufficient to identify a valid model for normal Type Ia supernovae. All considered scenarios have some advantages and some shortcomings. The reason may simply be that the correct scenario has not yet been found. Sub-Chandrasekhar mass explosions are a promising model, but in the double detonation mechanism they still fail to match some important observational properties of Type Ia supernovae. Similar explosions can, however, also be triggered by mergers of two white dwarfs.[23–26]

A similar situation is encountered with deflagrations in near-Chandrasekhar mass white dwarf stars. While this model looks promising for explaining brighter members of the Type Iax supernova class, its fainter end cannot be reproduced.

To ultimately settle the question of the origin of Type Ia supernovae, constant improvement is required in the explosion modeling as well as in the treatment of radiative transfer predicting the optical observables. Alternative observables that

may help to discriminate between models include the nucleosynthesis yields discussed here, but also spectropolarimetry data,[27–29] the search for surviving companion stars in the double degenerate progenitor model[30] and imprints of different explosion scenarios on the forming supernova remnants.[31,32]

What the progenitors of Type Ia supernovae (SNe Ia) are, whether they are near-Chandrasekhar mass or sub-Chandrasekhar mass white dwarfs, has been the matter of debate for decades. Various observational hints are supporting both models as the main progenitors. In this paper, we review the explosion physics and the chemical abundance patterns of SNe Ia from these two classes of progenitors. We will discuss how the observational data of SNe Ia, their remnants, the Milky Way Galaxy, and galactic clusters can help us to determine the essential features where numerical models of SNe Ia need to match.

Keywords: Supernova; Hydrodynamics; Nucleosynthesis; Supernova Remnant; Galactic Chemical Evolution

1. Introduction

Type Ia supernovae (SNe Ia) are well-understood as the thermonuclear explosions of carbon-oxygen white dwarfs (CO WDs).[1–3] They produce the majority of iron-peak elements in the galaxy, in particular ^{55}Mn. Their light curves can be standardized for measuring distance in the cosmological scale.[4,5] Understanding their progenitors, the explosion mechanisms and their obseravables are important for understanding the Universe in the larger scale.[6,7] In this review paper, we will explore possible progenitors of SNe Ia, whether they are the explosions of near-Chandrasekhar mass (Ch-mass) WDs or sub-Chandrasekhar mass (subCh-mass) WDs. In Table 1 we tabulate the important features to contrast between the Ch-mass and subCh-mass WDs.

The rise of the two classes of models comes from the diversity of observed SNe Ia. In the literature, a number of explosion models have been proposed to explain the normal and peculiar SNe Ia. For the Ch-mass WD, representative models include the pure turbulent deflagration model (PTD),[8–15] PTD with deflagration-detonation transition,[16–22] gravitationally confined detonation model[23–27] and pulsation reverse

detonation models.[28,29] The subCh-mass WD models include the double-detonation model,[30–38] violent merger model[39–42] and WD head-on collision model.[43–45] On top of these, unconventional models such as magnetized WDs,[46] super-Chandrasekhar mass WDs,[47] differentially rotating WDs[48,49] and interaction with dark matter gravity[50,51] have been proposed to explain some unusual SNe Ia.

Table 1. Comparing essential features of Ch-mass and subCh-mass WDs.

	unit	Ch-mass WD	subCh-mass WD
mass	$M_\odot$	$1.30 - \geqslant 1.38$	0.9 – 1.2
central density	g cm^{-3}	$10^9 - 10^{10}$	10^7 – 10^8
composition		^{12}C+^{16}O+^{22}Ne	core: ^{12}C+^{16}O+^{22}Ne envelope (env): ^{4}He
reaction		subsonic deflagration	supersonic detonation
first site		(near-)center	off-center (He-env)

The study of SNe Ia as explosions of (sub)Ch-mass WDs is often linked to the open question about the progenitors of SNe Ia: the single degenerate (SD) vs. the double degenerate (DD) scenario. The SD scenario means that the primary WD develops its nuclear runaway by mass accretion from its companion star, which can be a slightly evolved main-sequence, a red-giant, or a He-star.[49,52] The DD scenario means that the primary WD triggers the runaway by dynamical interaction with its companion WD.

We remind that the question on whether SNe Ia develop from Ch-mass WDs is not equivalent to arguing SNe Ia mainly develop in the SD scenario. For example, in the SD scenario, when the WD explodes as an SN Ia depends on the mass accretion rate from its companion star and the WD initial mass (see the left panel of Figure 1). A WD having (1) a high mass accretion rate above $\sim 10^{-9}$ $M_\odot$ yr^{-1} or (2) having a low mass accretion rate and a high initial mass > 1.1 $M_\odot$ is likely to develop nuclear runaway in the Ch-mass limit. Otherwise, the WD is more likely to explode as a subCh-mass WD.[53] Similar features have been seen also for WDs in the DD scenario.

To understand why the C-deflagration is associated with the Chandrasekhar mass WD, we show in the right panel of Figure 1 the relative pressure change of the CO-rich matter as a function of the matter density. During the thermonuclear runaway, ^{12}C and ^{16}O burn to form iron-peak elements peaked at ^{56}Ni, releasing an amount of $\sim 10^{18}$ erg g^{-1}. When the density is high ($\sim 10^9$ g cm^{-3}), the electron degeneracy pressure dominates the matter pressure, and the overall pressure becomes insensitive to its temperature. As a result, the relative pressure jump decreases as the matter becomes more degenerate. Without an abrupt pressure jump, the nuclear runaway in the Ch-mass WD may not spontaneously trigger a shock wave and hence no detonation may form. The hot matter may ignite ^{12}C in the nearby cold matter only by thermal conduction.

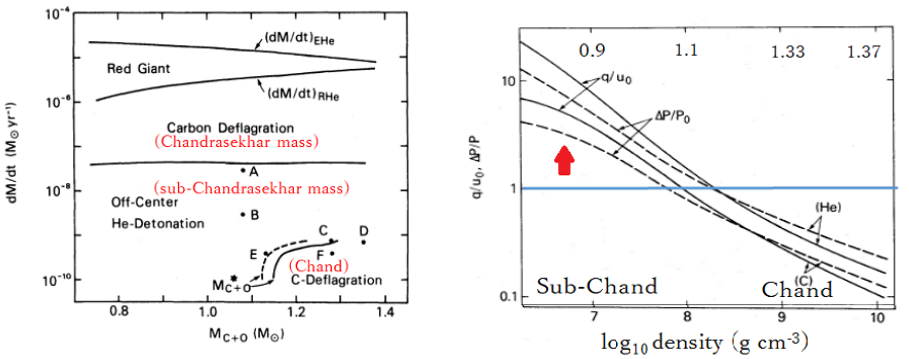

Fig. 1. (left panel) The final fate of the WD in the SD scenario with the mass accretion rate and the initial CO WD mass as parameters (derived and edited from Ref. 53). (right panel) The relative pressure change $\Delta P/P_0$ and relative internal energy change q/u_0 before and after nuclear runaway as a function of the matter density for the He-rich (solid line) and CO-rich (dashed line) matter (Ref. 30). The numbers on the top corresponds to the mass of the WD when the density corresponds to the central density of the WD. The red arrow indicates the relative pressure change of the CO-rich matter.

Unlike the detonation, the subsonic deflagration is subject to hydrodynamical instabilities such as the Rayleigh-Taylor (RT), Kelvin-Helmholtz (KH) and Landau-Derrieus[54–56] instabilities. The analytic model suggests that the buoyancy force can drive the early flame away from the center.[57] In Figure 2 we plot the electron fraction Y_e profile of a canonical PTD model where the deflagration has quenched after the expansion of the WD. The Y_e profile is a useful scalar for tracking how the fluid elements move inside the star. We observe the elongated "mushroom" shape as features of the RT-instabilities and the spiral along and inside the "mushrooms" as features of the KH-instabilities.

However, a WD may not naturally explode if there is only a slow subsonic nuclear flame because the WD expands and quenches the flame before the whole WD is burnt.[8,12] To alleviate this issue, a deflagration-detonation transition[16] and a flame-acceleration scheme[9,58,59] have been proposed for assisting nuclear burning to spread around the entire WD before the WD expands.

2. Typical Type Ia Supernova Explosion

Both the Ch-mass and subCh-mass WD models have their individual strengths and concerns, despite both of them can reproduce the observed features of normal SNe Ia,[60–62] including the Philip's relation.[37,63] For example, the Ch-mass model can produce Mn with an amount consistent with the solar abundance,[64] while the subCh-mass models do not produce a significant amount of Mn. But the DDT mechanism remains a matter of debate whether or not the turbulence is sufficient to pre-condition the CO rich matter.[57,65–69]

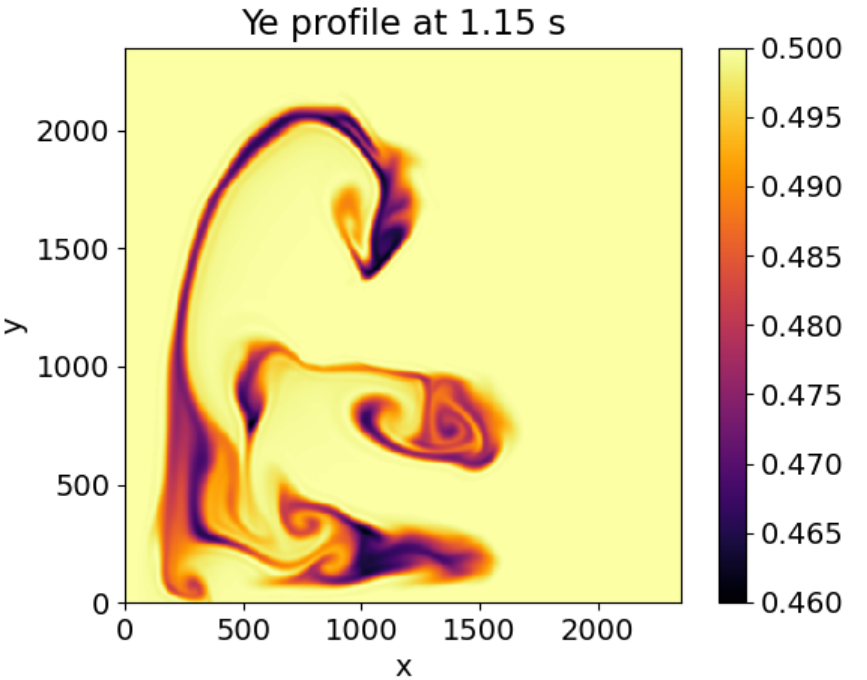

Fig. 2. A snapshot of the electron fraction Y_e profile in a typical PTD model demonstrating simultaneously the Rayleigh-Taylor and Kelvin-Helmholtz instabilities due to interaction of turbulent fluid motion with the deflagration front.

2.1. *Typical Explosion Mechanism of Ch-mass and subCh-mass Models*

We now examine the typical explosion mechanism in both the Ch-mass and subCh-mass WDs. Even though we have described a number of explosion mechanisms in the previous section, in general they are only different by the progenitor or the initial explosion kernel. The underlying mechanism, namely the deflagration and detonation, remains unchanged. Here we examine how the WD explodes accordingly.

In Figures 3 and 4 we plot the temperature profiles of the representative Ch-mass WD explosion using the PTD model with DDT for a WD of 1.37 $M_\odot$, metallicity $Z = 0.02$ and a $c3$ deflagration kernel[22] based on two-dimensional simulations.[70] The WD is burnt by subsonic flame for around 1 s, consuming about $\sim 30\%$ of the CO-rich matter in mass. After that, DDT is assumed to take place and the remaining matter is burnt within ~ 0.1 s. Eventually, the WD undergoes homologous expansion which quenches both deflagration and detonation.

In Figures 5 and 6 we plot similar profiles to Figure 3-4 but for the subCh-mass model with the initial mass 1.10 $M_\odot$, $Z = 0.02$ and a single He-detonation bubble.[35] In the first 1 s, the detonation burns the He-rich matter along the envelope.

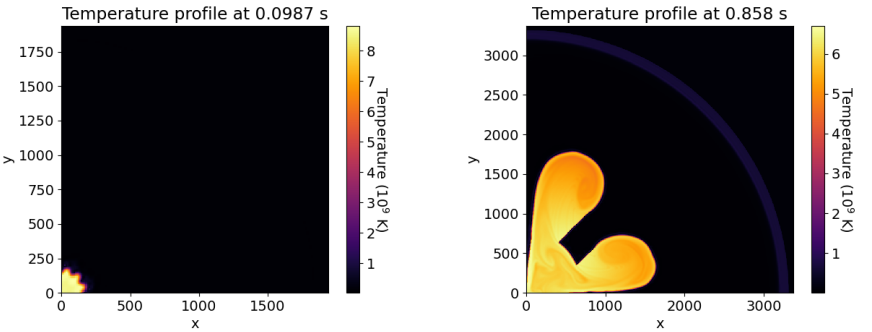

Fig. 3. (left panel) The initial temperature profile of the quadrant cross-section in a typical Ch-mass model using the PTD model with DDT for an initial mass $M = 1.37\ M_{\odot}$, metallicity $Z = 0.02$, and a "three-finger" initial flame kernel.[22] (top right panel) Same as the top left panel when the DDT is assumed to be triggered.

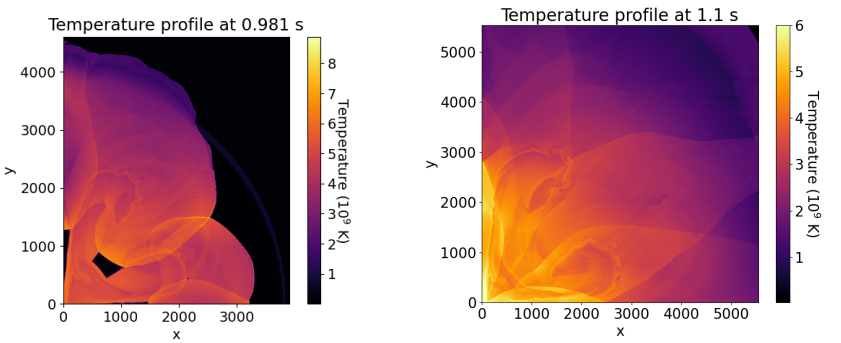

Fig. 4. (left panel) Same as Figure 3 but during the detonation phase. (right panel) Near complete disruption of the WD.

The detonation strength increases during the collision, which creates a shock that penetrates into the CO-core. This creates the C-detonation which later disrupts the entire WD.

2.2. *General Thermodynamical Features*

Typical multi-dimensional SN Ia simulations solve the Eulerian hydrodynamics equations with a simplified nuclear reaction network. To obtain the detailed chemical

Table 2. Major isotopes of iron-peak elements and their corresponding electron fraction.

Isotope	^{54}Fe	^{55}Mn	^{55}Fe	^{55}Fe	^{56}Fe	^{56}Co	^{56}Ni	^{57}Fe	^{58}Ni	^{60}Ni
Ye	0.481	0.454	0.472	0.490	0.464	0.482	0.500	0.456	0.483	0.467

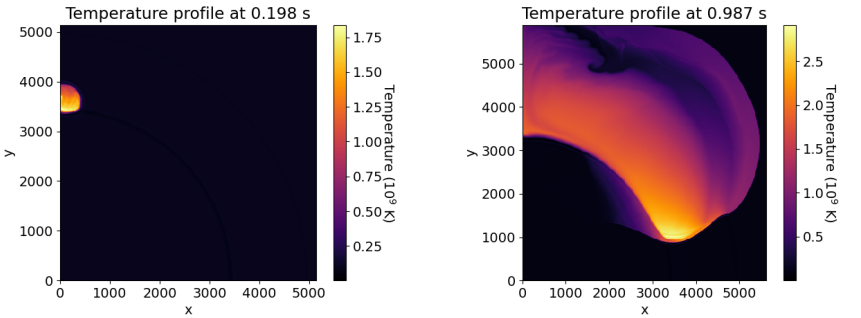

Fig. 5. (left panel) The initial temperature profile of a typical subCh-mass model using the double detonation model with the initial mass $M = 1.10\ M_\odot$, $Z = 0.02$, and a "single bubble" initial detonation kernel.[35] (right panel) Same as the top left panel but during the amplification of the He detonation.

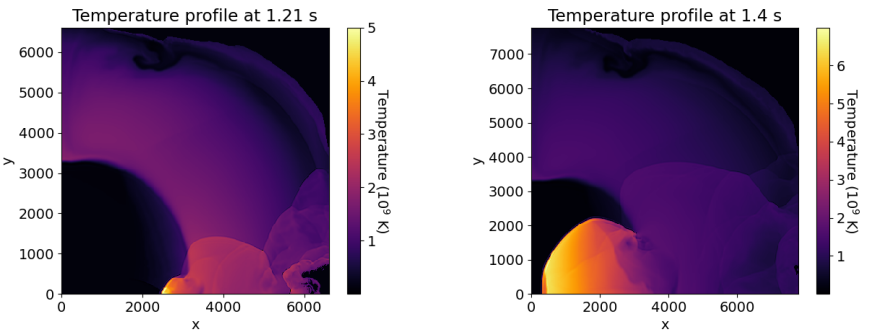

Fig. 6. (left panel) Same as Figure 5 but during the onset of the C-detonation. (right panel) Same as the left panel but during the C-detonation phase.

features of the explosion, a passive tracer particle scheme[71–74] is necessary. This scheme allocates a number of Lagrangian tracers to follow the fluid motion. The notation "passive" means that the tracers do not affect the fluid motion; they only record the thermodynamical condition along their trajectories.

The tracer particles record $(\rho(t), T(t))$ as a Lagrangian fluid packet along its path for reconstructing the exact chemical abundances. For SNe Ia, the trajectory is less convoluted that its peak density and temperature $(\rho_{\rm peak}, T_{\rm peak})$ can characterize the typical nucleosynthesis features inside the tracer. We make numerical experiments to show how various nucleosynthesis quantities depend on the parameters $(\rho_{\rm peak}, T_{\rm peak})$ parameter space.

We assume that the tracers start from given $(\rho_{\rm peak}, T_{\rm peak})$ and then adiabatically expand. The expansion timescale is chosen according to the typical explosion energy 10^{51} erg. The nuclear reactions are computed using the 495-isotope network.[75]

In Figures 7 and 8 we plot the final mean atomic number $\bar{A}$, $Y_{\rm e}$, asymptotic mass fraction of ^{55}Mn and ^{56}Fe for tracers under different initial conditions. The region is

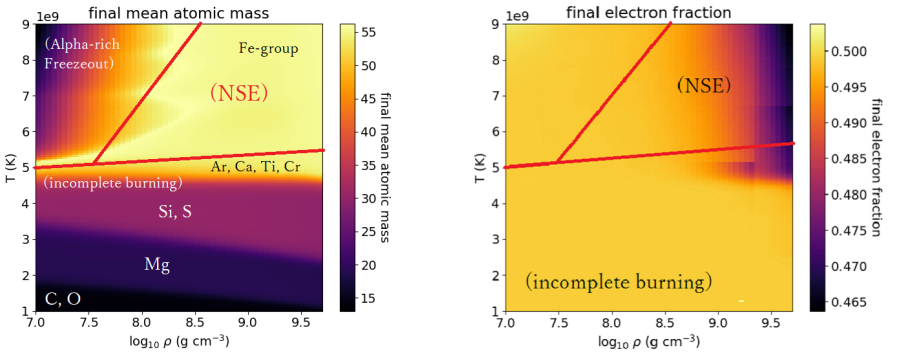

Fig. 7. (left panel) The final mean atomic mass number $\bar{A}$ of the tracer particles starting from different $\rho_{\rm peak}$ and $T_{\rm peak}$ (in units of 10^9 K). (right panel) Same as the left panel, but for the final electron fraction $Y_{\rm e}$ of the tracer.

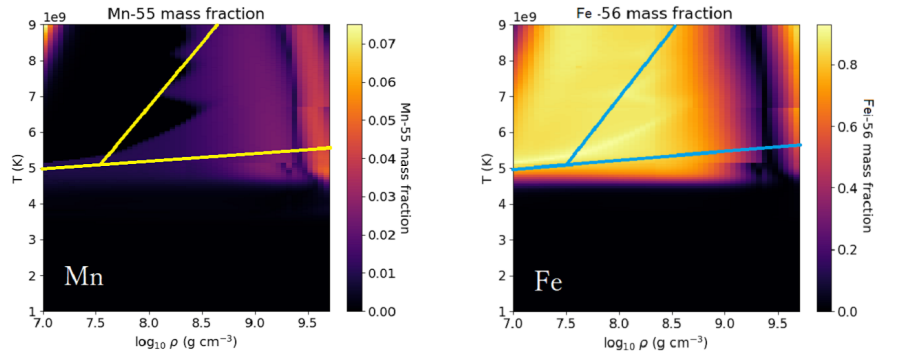

Fig. 8. (left panel) Same as Figure 7, but for the final mass fraction of stable ^{55}Mn. (right panel) Same as the left panel but for the final mass fraction of stable ^{56}Fe.

divided into three regions.[76,77] The low-$\rho_{\rm peak}$ region corresponds to the incomplete Si-burning regime, where the nuclear reaction terminates before reaching Fe-group elements, such as Si, S, Ar and so on. The high-$T_{\rm peak}$ (in units of 10^9 K) and low-$\rho_{\rm peak}$ region corresponds to the α-rich freezeout regime. As the name suggests, the nuclear reaction is confined to be along the α-chain from ^{12}C to ^{56}Ni. The high-$T_{\rm peak}$ and high-$\rho_{\rm peak}$ region corresponds to the nuclear statistical equilibrium (NSE) regime. This regime plays an important role in the Ch-mass WD as it allows isotopes away from the α-chain to form through weak interaction (electron capture).

As the $Y_{\rm e}$-profile indicates, the NSE zone is also the region where matter with $Y_{\rm e} < 0.5$ can be formed. The low $Y_{\rm e}$ environment is vital for forming the parents of ^{55}Mn (see Table 2 for the representative $Y_{\rm e}$ for the major neutron-rich isotopes of iron-peak elements). The ^{55}Mn profile also shows that the NSE zone is the primary site for generating a significant amount of stable ^{55}Mn after decay. On the other hand, ^{56}Fe is mostly formed in the α-rich freezeout and NSE ($Y_{\rm e} \approx 0.5$) regions.

2.3. *Thermodynamical Trajectories of SN Ia Models*

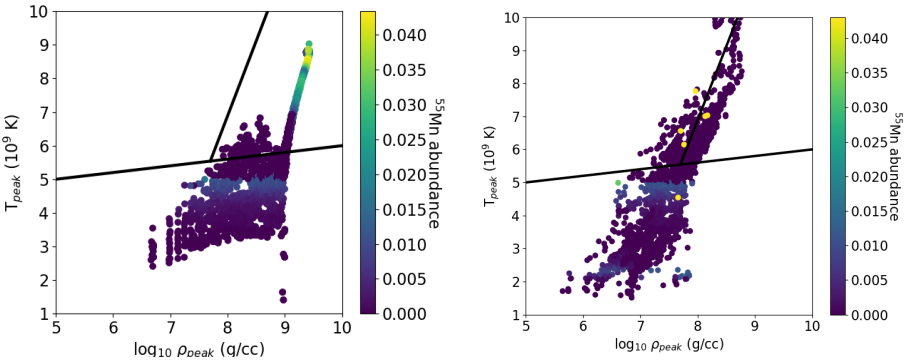

Fig. 9. (left panel) The thermodynamical trajectories of tracer particles of the Ch-mass model with the colour being the asymptotic ^{55}Mn abundance. Same as the left panel but for the subCh-mass model.

Having explored which thermodynamical parameter space is responsible for iron-peak elements, we show in Figure 9 the thermodynamics trajectories of tracers obtained from the typical Ch-mass and subCh-mass models. The chemical abundance of each tracer is directly computed according to its individual (ρ, T) time evolution.

The Ch-mass model (left panel) has two distinctive parts: the high density thin tail and the thick body at low density. At high density ($\rho_{\rm peak} > 10^9$ g cm^{-3}), the tracers are in the NSE regime and have a significantly higher ^{55}Mn and low fluctuations in $T_{\rm peak}$ for the same $\rho_{\rm peak}$. These are the tracers burnt by the subsonic deflagration. The absence of shock ensures that nuclear burning does not generate strong acoustic waves. On the other hand, the majority of tracers burnt by the detonation undergo incomplete Si-burning. The aspherical explosion allows tracers with the same initial mass coordinate to be burnt at a range of time. This leads to a wide temperature range for the same $\rho_{\rm peak}$. There is also a narrow band of tracers for $7 < \log_{10} \rho_{\rm peak} < 9$ and $T_{\rm peak} \approx 5 \times 10^9$ K also responsible for synthesizing a small fraction of ^{55}Mn.

The subCh-mass model (right panel) has a uniform structure where the $T_{\rm peak}$ scales with $\rho_{\rm peak}$ with some fluctuations. Only a small part of tracers reaches the NSE regime but their density is not high enough for the ^{55}Mn synthesis. There is also a narrow band of tracers containing ^{55}Mn by the synthesis of ^{55}Co. In general the global ^{55}Mn in the subCh-mass model is lower than that of the Ch-mass model.

2.4. *Typical Nucleosynthesis in Ch-mass and subCh-mass Models*

Now we have examined the thermodynamical differences between the Ch-mass and subCh-mass WDs. In Figure 10 we compare the qualitative differences in the nucleosynthesis pattern.

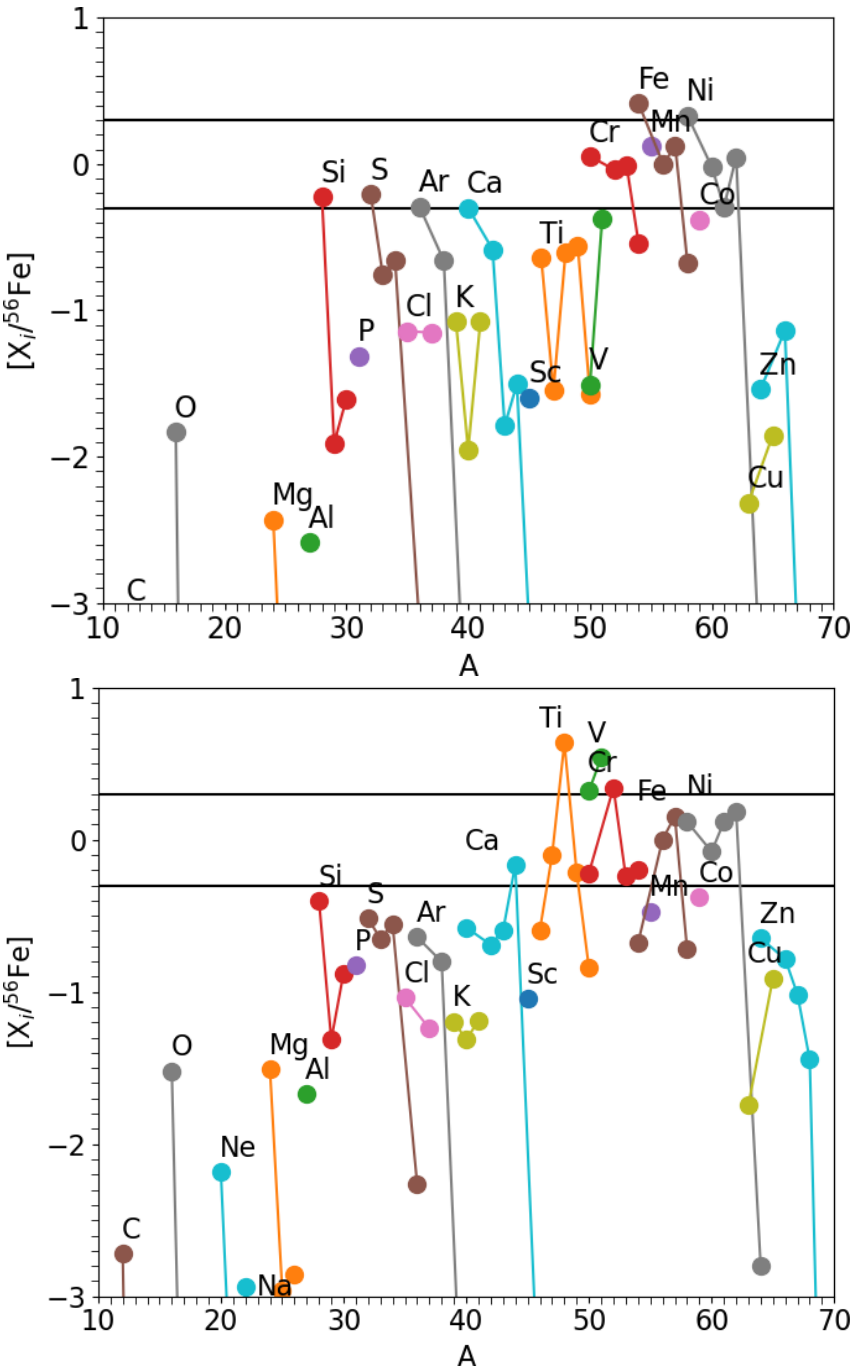

Fig. 10. (top panel) The final chemical abundance pattern of the typical Ch-mass WD[22] assuming the aspherical explosion. (bottom panel) Same as the top panel but for the typical subCh-mass WD.[35] $[X_i/^{56}\mathrm{Fe}] = \log_{10}[(X_i/^{56}\mathrm{Fe})\ /\ (X_i/^{56}\mathrm{Fe})_{\odot}]$. The two horizontal lines correspond to 50% and 200% of the solar value.

Both Ch-mass and subCh-mass WDs share some common features. They are responsible for the production of intermediate mass elements (IMEs) from Si to Ca, and the iron-peak elements from Ti to Ni. Odd number elements of IMEs are underproduced in SNe Ia. Some individual features allow us to distinguish the two models. (1) The aspherical explosion of the subCh-mass model can lead to signatures of strong Ti, V and Cr. (2) Mn is well-produced in the Ch-mass model but not in the subCh-mass model.

3. Applications of Nucleosynthesis

We have surveyed the major differences of the nucleosynthetic signature between the Ch-mass and subCh-mass WDs. Comparisons with observational data allow us to understand the progenitors of observed SNe Ia, which directly constrains the modeling. We can compare the optical signatures directly (i.e., light curves and spectra) by matching the radiative transfer model with SN Ia data.[41,60] One can also extract the chemical abundances from the spectra, and compare with nucleosynthetic results.[62,78] We shall focus on the latter method here.

3.1. *Supernova Remnant Sagittarius A East*

Within thousand years after the SN explosion, the shock-heated gas remains observable in the X-ray band, where the spectra reveal the metal composition inside the ejecta. Such a technique has been applied to the study of galactic supernova remnants (SNRs) including Tycho,[80] Kepler[81] and N103B.[82]

In Ref. 79 the SNR in Sagittarius A (Sgr A) East (G0.0+0.0) is observed based on the X-ray data taken by the *Chandra* telescope. The observed abundance ratios relative to Fe (with respect to the solar ratios) [Xi/Fe] are shown in Figure 11. The SNR features sub-solar intermediate mass elements (IMEs) and slightly super-solar iron-peak elements (Cr, Mn, and Ni).

The sub-solar IMEs exclude the possibility of associating a core-collapse SN as the origin of this remnant. On the left panel, the abundances of two distinctive classes of models, the subCh-mass and Ch-mass DDT models are plotted. The model uncertainties are shown by the shaded area. The subCh-mass models clearly overproduce the IME. Among the Ch-mass DDT models, the model that produces enough Mn and Ni overproduces Cr and the IME. There is a model whose Cr and Ni are consistent with the data points and IMEs are marginal, but its Mn is too small.

The Ch-mass PTD model (i.e., no DDT) with the initial central density of $\sim 5 \times 10^9$ g cm^{-3} is shown to be compatible with the data (right panel of Figure 11). [Such a high central density is realized in the rotating WD model.[83]] Note that this Ch-mass PTD model can well-explain the observed features of SNe Iax. Thus this object is the first identified SN Iax in the Milky Way Galaxy observed as SNR. This example also shows how the abundance guides us to identify the explosion mechanism.

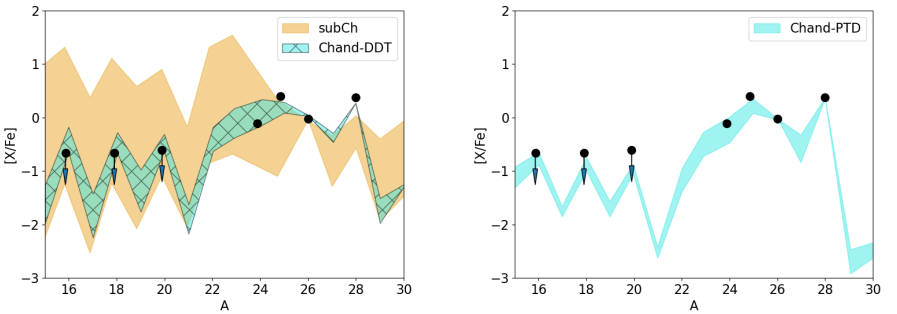

Fig. 11. (left panel) The chemical abundance pattern of the supernova remnant (SNR) Sagittarius A (from Ref. 79) for the data points compared with those of the subCh-mass[35] and Ch-mass DDT[22] models shown by the shaded regions. (right panel) Same as the left panel but for the Ch-mass PTD[15] models.

3.2. *Supernova Remnant 3C 397*

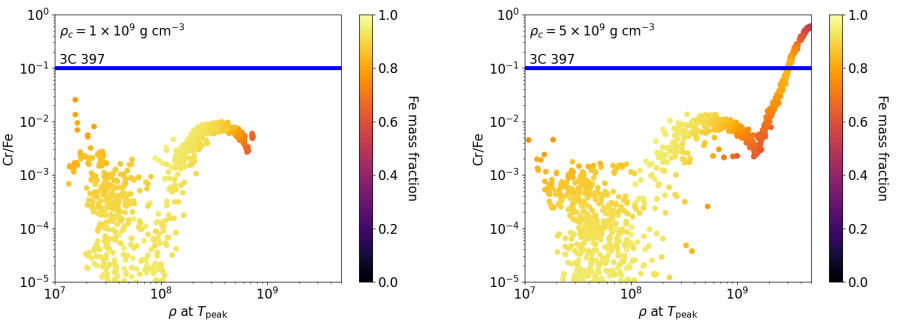

Fig. 12. (left panel) The Cr/Fe distribution of the tracers taken from the Ch-mass model with the initial central density 1×10^9 g cm^{-3}.[22] The color represents the tracer Fe mass fraction. The horizontal line is the measured value in SNR 3C 397 from Ref. 84. (right panel) Same as the left panel but for the model with the initial central density 5×10^9 g cm^{-3}.

The SNR 3C 397 is a nearby object (8 kpc) on the galactic plane. Its close distance allows astronomers to extract the spectra from individual parts similar to Sgr A. This object features a high Mn/Ni ratio, which is a key evidence of the Ch-mass explosion.[85]

In a recent observation using the *XMM-Newton* telescope, the spectra from the South and West hot blobs are measured, which give the constraint on the Cr/Fe mass ratio $\sim 0.106 \pm^{0.011}_{0.009}$.[84] The high value is used to distinguish the explosion progenitor shown in Figure 12. By comparing the tracer in different Ch-mass models, it becomes clear that the low-mass model ($\rho_c = 1 \times 10^9$ g cm^{-3}) does not have tracers reaching the observed high value. Meanwhile the high density tail in the high-mass model

($\rho_c = 5 \times 10^9$ g cm^{-3}) has tracers crossing the expected value. This provides a strong indication that this object is the explosion of the high-mass Ch-mass WD. This also demonstrates how a precise measurement of element abundance ratios can guide us to select the potential progenitor.

3.3. *Milky Way Galaxy*

In the last two sections we have shown how the SNR abundance determines its progenitor and the explosion mechanism. While there is no distinctive SNR showing chemical abundances exclusively for subCh-mass WD models, it is possible that a large sample size is needed to understand the distribution of each model. To understand the SN Ia explosion globally, we need the chemical abundances from a larger system, for example, the Milky Way Galaxy. The elements ejected by supernovae become the building block of the next-generation stars.[6] The surface abundance of stars in the solar neighbourhood may thus indicate how much each element is ejected by generations of SNe Ia.

In Ref. 86 the galactic chemical evolution model is computed with supernova abundance patterns taken from literatures. The Mn/Fe evolution is plotted in Figure 13. Two contrasting classes of models are shown, one assuming the pure Ch-mass WD explosion, and the other two assuming pure subCh-mass WD. To reproduce the trend as well as the magnitude of the data, a non-negligible fraction of the Ch-mass WD is necessary.

We remark that the supernova history can be strongly dependent on the galaxy evolution history. Some galaxies (e.g., Sculptor dwarf spheroidal galaxy) have a low Mn/Fe ratio that indicates the dominance of the subCh-mass WD explosion in their evolution histories.[90,91] Meanwhile, some early rise of [Mn/Fe] in this subclass of galaxies can be a result of the Ch-mass SN Iax explosion.[92]

3.4. *Perseus Galactic Cluster*

The Milky Way Galaxy can provide a detailed reference in how generations of stars contributes to the cosmic metal enrichment. However, large N-body simulations suggest that each galaxy is unique in their evolution history. To understand how each supernova model contributes in the cosmic scale, data from an even larger system is important to average out the statistical fluctuations of individual galaxies.

In Ref. 93 the X-ray spectra of the Perseus Cluster is studied by the *Hitomi* telescope. The highly resolved spectral lines provide the abundance measurement with uncertainties down to $\sim 10\%$. The high precision can distinguish supernova models and mechanisms explicitly. The fitting using SN Ia and CCSN models from literature is shown in Table 3. The best-fit model is found to be the scenario assuming pure Ch-mass WD explosion. If the fraction of the Ch-mass WD is relaxed as a model parameter, the expected Ch-mass WD still contributes about $10 - 40\%$ of the SN Ia population, depending on the exact CCSN models.

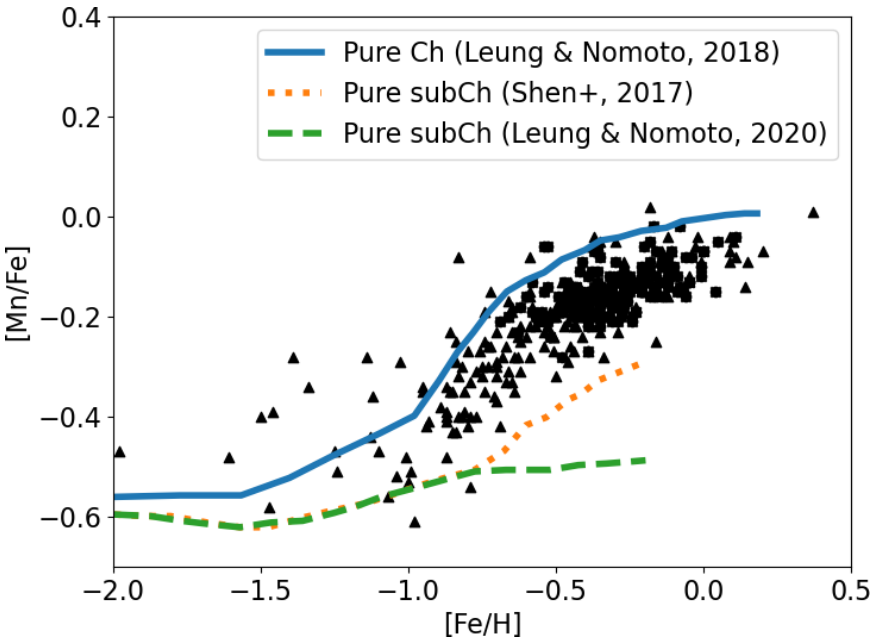

Fig. 13. The [Mn/Fe] against metallicity [Fe/H] for the galactic chemical evolution models taken from Ref. 86. Solid lines come from theoretical models assuming pure Ch-mass and subCh-mass explosion history. Data points are the stellar abundances from the solar neighbourhood.[87–89]

Table 3. Models assuming different stellar and supernova models and their corresponding (Ch-mass) SN Ia rates (data taken from [Ref. 93]).

Model	$f_{\rm Ia}$	$f_{\rm Chand}$	χ^2
pure Ch-mass[Ref. 22]+ CCSN[Ref. 94]	0.21 ± 0.02	N/A	11.78
Ch-mass[Ref. 95] + subCh-mass[Ref. 32] + CCSN[94]	0.25 ± 0.06	0.36 ± 0.14	23.96
Ch-mass[Ref. 95] + subCh-mass[Ref. 32] + CCSN[96]	0.38 ± 0.06	0.09 ± 0.09	15.73

4. Conclusion

In this review article we have presented the physical background about the Ch-mass and subCh-mass WD models as the SN Ia explosion progenitors. We discussed the differences in their explosion mechanisms and their associated nucleosynthetic signatures. We have also demonstrated how the chemical abundances of SNRs, Milky Way Galaxy, and galactic clusters can help us distinguish (1) the individual SN explosion scenario and (2) the relative importance of each explosion model.

Nucleosynthesis will remain an important subject in the future supernova study thanks to observational projects such as XRISM (X-Ray Imaging and Spectroscopy Mission). Given the power of resolving spectral lines as its predecessor *Hitomi*, we can anticipate that the high quality spectral data, and hence the precise chemical

abundance measurements, will shed light on supernova models to an unprecedented accuracy.

We investigate the structure of polarized charged white dwarfs with finite temperature as a possible type Ia supernovae source. The white dwarf is modeled considering an isothermal core with central temperature 10^8 [K] and an envelope where the temperature distribution depends on the mass density. Regarding the fluid, we assume that it is composed of nucleons and electrons. The structure of the polarized charged white dwarfs is obtained by solving the Einstein-Maxwell equations with charge densities represented by two Gaussians, forming an electric dipole layer at the stellar surface. We obtain larger and more massive white dwarfs when polarized charge and the Gaussians width are increased. We find that to appreciate effects in the white dwarf's structure, the electric polarized charge must be in the order of 5.0×10^{20}[C]. We obtain a maximum white dwarf mass of around $2.4M_{\odot}$ for a polarized charge of 1.5×10^{21}[C]. This mass result can indicate that polarized charged white dwarfs are possible progenitors of superluminous type Ia supernovae. Furthermore, the mass-central density curves we obtain are very similar to the ones reached recently for ultra-magnetized white dwarfs.

Keywords: White dwarfs; charged white dwarfs; type Ia supernovae explosions

Introduction

The mechanisms that increase the mass of a white dwarf (WD) have been extensively studied since supermassive WDs were associated with superluminous Type Ia supernovae (2003fg,[1] 2009dc,[2] 2006gz[3] and 2007if[4]). In what concerns the structure of WDs, in literature, there are works consider magnetic field, rotation, and electric field to explain the increase of such mass. To present considerable effects in the WD structure, recent works[5,6] present magnetic fields are the order of 9×10^{13}[G] and electric field of around 10^{16} [V/cm] .

We investigate charged white dwarfs made up by a non-degenerate fluid with isothermal core with central temperature $T_c = 10^8$[K] and envelope with temperature distribution.[7] Moreover, we assume a charge polarization[8] in the surface of WDs. We obtain very massive white dwarfs which can be the progenitors of Type Ia Supernovae. We note that the polarization generate notable effect in the structure of WDs and it decreases the electric field outside the star.

1. Structure equilibrium equations and boundary conditions

The line element considered to describe a charged WD, in Schwarzschild-like coordinates, is given by

$$ds^2 = -e^{\nu}dt^2 + e^{\lambda}dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\phi^2, \tag{1}$$

where ν and λ depend on the radial coordinate only. The inclusion of the electromagnetic tensor in the energy-momentum tensor leads to the nonzero Maxwell-Einstein equations:

$$\frac{dq}{dr} = 4\pi\rho_e r^2 e^{\lambda/2}, \tag{2}$$

$$\frac{dm}{dr} = 4\pi\varepsilon^2 + \frac{q}{r}\frac{dq}{dr}, \tag{3}$$

$$\frac{dP}{dr} = -(P+\varepsilon)\left[4\pi r p + \frac{m}{r^2} - \frac{q^2}{r^3}\right]e^{\lambda} + \frac{q}{4\pi r^4}\frac{dq}{dr}, \tag{4}$$

$$\frac{d\nu}{dr} = -\frac{2}{(p+\varepsilon)}\left[\frac{dP}{dr} - \frac{q}{4\pi r^4}\frac{dq}{dr}\right], \tag{5}$$

with q and m representing respectively the electric charge and the mass within the radius r. The potential metric e^{λ} is described as

$$e^{\lambda} = \left[1 - \frac{2m}{r} + \frac{q^2}{r^2}\right]^{-1}. \tag{6}$$

Due to temperature, the white dwarfs are considered to have a partial degeneracy, thus the contribution of electrons in the EoS is related to Fermi-Dirac integrals. Once the temperature distribution is defined,[7] these integrals are solved by using an adaptive quadrature method.[9] Next, we proceed to integrate Eqs. (2)-(5) by using the fourth-order Runge-Kutta method for the uncharged star, i.e., $Q = 0$. For this aim, in the center $r = 0$, it is considered the boundary conditions:

$$m(0) = 0, \;\; \varepsilon(0) = \varepsilon_0, \text{ and } \nu(0) = \nu_0, \tag{7}$$

and the star's surface is determined at $P(r = R^+) = 0$. This first integration enables us to find the values of the total star mass M and total radius R^+. The location of the second and negative Gaussian at R^- is determined through the relation $R^- = R^+ + \Delta R$, where $\Delta R = 4b$ and $b = 5$[km]. The value of b employed is the

smallest necessary to obtain considerable effects on the structure of the white dwarf. Once found the polarized charge, by using the charge density, we integrate again Eqs. (2)-(5) to obtain the charged white dwarf structure. The boundary conditions in Eq. (7) are used together with $q(0) = 0$ and $\rho_e(0) = \rho_{e0}$.

2. Equation of state and charge density profile

Regarding the stellar fluid, we consider that the equation of state is made of by nucleons, electrons, and photons.[10,11] Due to our consideration of very high central temperatures ($T_c = 10^8$ [K]), we neglect the lattice interactions. Thus, the pressure P and energy density ε is depicted by

$$P = P_e + P_N + P_\gamma, \tag{8}$$

$$\varepsilon = \varepsilon_e + \varepsilon_N + \varepsilon_\gamma, \tag{9}$$

where the subindexes e, N and γ represent the electrons, nucleons, and photons contributions, respectively.

We assume that electrons and protons are susceptible to a centrifugal force responsible for accelerating heavy particles away from light ones. Consequently, polarization forms in the stellar envelope. Inspired in Negreiros work,[8] we consider the polarization to be defined with the inclusion of two Gaussians in the charge density:

$$\rho_e = e^{-\lambda/2}\left[k^+ \exp\left(-\frac{(r-R^+)^2}{b^2}\right) + k^- \exp\left(-\frac{(r-R^-)^2}{b^2}\right)\right], \tag{10}$$

where r represents the radial coordinate, $b = 5$ [km] is the Gaussian width, and with k^+ and k_- being constants that depend on the global charge neutrality. The R^+ is the radius for the uncharged configuration. Moreover, $R^- = R^+ + \Delta R$, being $\Delta R = 4b$ a fixed value for all the central energy densities.

To obtain k, we solve the integration by considering a total zero charge

$$Q_t = \int_0^\infty e^{\lambda/2} 4\pi r^2 \rho_e dr = 0. \tag{11}$$

By using Eq. (10) in this last relation, we find

$$k^+ = \frac{Q}{8\pi}\left(\frac{\sqrt{\pi}b\left(R^+\right)^2}{2} + \frac{\sqrt{\pi}b^3}{4}\right)^{-1}, \tag{12}$$

$$k^- = \frac{-Q}{8\pi}\left(\frac{\sqrt{\pi}b\left(R^-\right)^2}{2} + \frac{\sqrt{\pi}b^3}{4}\right)^{-1}. \tag{13}$$

With the intent to better illustrate the stellar charge profile, we present the charge density as a function of radial coordinate in Fig. 1.

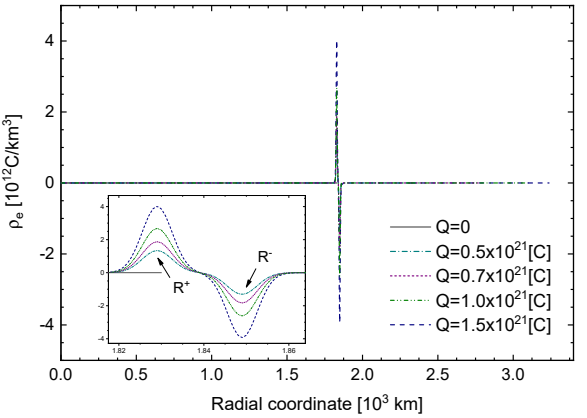

Fig. 1. The charge density as a function of the radial coordinate for a star with central energy density $\varepsilon_c = 10^{10}[\mathrm{g\ cm}^{-3}]$ and several polarized charge values.

3. White dwarf configurations

Consequently to the polarized charge, we find a very high electric field in the stellar envelope and no electric field outside the star (in contrast to previous charge white dwarfs studies[6]). In our calculations, considering a star with central density $\varepsilon_c = 5 \times 10^{10}$ [g/cm^3], we find maximum internal electric fields of around 10^{16} [V/cm]. Under these conditions, the radius is increased in 77% and the mass 63% for $Q = 1.5 \times 10^{21}$[C]. This electric field induces an increase in the internal star pressure.

The pressure in the stellar interior enhancing due to the charge density was already noticed in previous charge white dwarfs studies.[6] The pressure profile found by Carvalho and collaborators increases with charge and decreases due to self-gravitation. In our work, the neutralization of charge is the main responsible to decrease the stellar charge pressure. Thus, compared to Carvalho's work,[6] the charge density we propose affects more the mass than the radius.

In Fig. 2 we show the mass as a function of central energy density. This figure is important to analyze the relation between polarized charge white dwarfs and Type Ia Supernovae. We can note that for the uncharged sequence, the mass increases with central energy density until it reaches a maximum mass (pink dot) and decreases. This behavior is different for sequences of charged stars. These curves increase mass with central energy density (the same pattern observed for ultra-magnetized white dwarfs[5]). Another important observation in this figure is related to the maximum mass obtained.

For the maximum polarized charge we find maximum masses around $\approx 2.4 M_\odot$ for 1.5×10^{21}[C]. This increase in mass is obtained for the first time for charged white dwarfs with no electric field outside the star, which is the main novelty of this work.

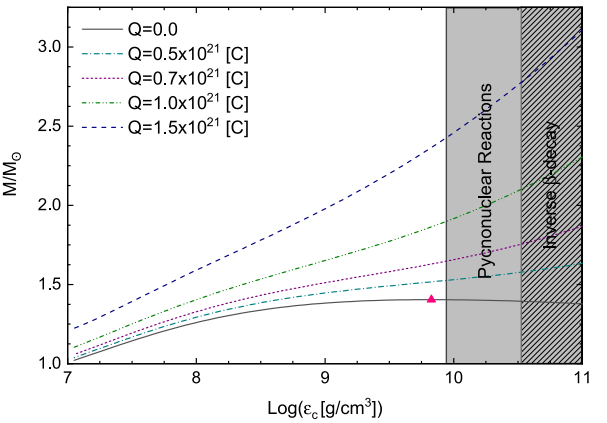

Fig. 2. The mass as a function of the energy density for several sequences of constant polarized charge and $T_c = 10^8$[K].

4. Conclusion

In this work, we investigated the structure of charged hot white dwarfs to associate them with superluminous type Ia supernovae. In what concerns to the stellar fluid, we consider a central temperature of $T_c = 10^8$[K] and a temperature distribution in the envelope.[11] Besides, due to the high central temperature considered, we neglected the particles' interactions. We used Maxwell-Einstein equations to find the structure of these charged polarized white dwarfs. We found that more massive and bigger white dwarfs are found with our predictions.

Our calculations enable the finding of maximum masses around $2.4M_{\odot}$ for stable charge white dwarfs configurations. Albeit we reach very high electric fields to obtain these results ($\approx 10^{16}$ [V/cm]), the electric field outside the star is zero. For the first time, isolated charged white dwarfs are obtained with a zero electric field outside.

This contribution summarises our recent determination of the spin period of the magnetic white dwarf in CTCV J2056-3014, a cataclysmic variable binary system. Its X-ray and optical emission comes from its magnetic accretion column and is modulated with a 29.6 s period, due to the WD rotation. We briefly discuss this object in the context of other fast-spinning white dwarfs.

Keywords: White dwarfs; Cataclysmic variable stars; X-rays: stars.

1. Introduction

White dwarfs (WDs) are the evolutionary fate of most stars. WDs are composed of degenerated matter and, together with neutrons stars and stellar black holes, constitute the group of compact stellar objects with strong gravitational fields in

their neighborhood. The maximum mass that a WD can reach is around 1.4 $M_\odot$, the Chandrasekhar limit. The exact limit depends on many assumptions as the rotation, the magnetic field strength, and the adopted equation of state, which is related to the physical conditions and processes taking place in the stellar interior. Due to the compactness of their degenerated interior, WDs can rotate very rapidly, reaching spin periods as small as a few tens of seconds. WDs also show the largest values of magnetic moments among stellar objects. As stars in general, they are found isolated or in binary systems.

In isolated WDs, high values of mass, spin, and magnetic field seem to appear together. WD 0316-849 is one example of such an extreme WD. It has a magnetic field (B) of around 500 MG, a spin (P_{spin}) of 725 s, and a mass (M_{WD}) equal to 0.86 $M_\odot$(see Ref. 1 and references therein). ZTF J190132.9+145808.7 has been recently associated with a very massive WD, $M_{WD} > 1.3$ $M_\odot$. Its P_{spin} is 416.4 s and its surface magnetic field is estimated to be in the range 600 – 900 MG.[2] Those WDs are probably originated by mergers - see, for instance, the discussion in Ref. 3. In particular, mergers can produce remnants with high angular momenta.

CVs are binary systems in which a WD accretes matter from the secondary star, a low-mass on the main sequence or slightly evolved that loses material by Roche lobe overflow. The magnetic CVs are those systems in which the WD magnetic field is strong enough to play a role in the dynamics of the accretion flow. If the WD magnetic field is not strong enough to synchronize the WD spin with the orbital period, the system is classified as an intermediate polar.

The optical and X-ray emission of intermediate polars is caused by mass accretion onto the magnetic WD and modulates with the WD spin. It is caused by accretion onto a magnetic WD. This process produces a stand-off shock near the WD surface where gravitational energy is converted to thermal energy. This enhances the gas density and heats it to keV temperatures producing the X-ray emission and the high excitation optical spectrum. The footprint of the accretion structure covers a small area of the WD surface. Therefore, the WD rotation causes a modulation of the emission as seen by the observer.

In this contribution, we outline our recent finding that CTCV J2056-3014, an intermediate polar, harbors a very fast-spinning WD. We also discuss this result in the context of similar objects.

2. CTCV J2056-3014

The optical spectrum of CTCV J2056-3014[4,5] is characterized by a very blue continuum and strong emission lines, including the Bowen complex, indicative of high excitation temperatures. The radial velocity variation of the emission lines indicates an orbital period of 1.76 h.[4] The first indications that CTCV J2056-3014 could be an intermediate polar were the possible association with the X-ray source 1RXS J205652.1−301433 and a photometric modulation of around 15 min.[4] However, this periodic variability was not confirmed by further observations.[6]

Recently, XMM-Newton X-ray observations of CTCV J2056-3014 have revealed a coherent modulation at 29.6098 ± 0.0014 s, also present in the optical emission.[7] This modulation and the X-ray spectrum of CTCV J2056-3014 confirm that the object is an intermediate polar, i.e., an accreting magnetic WD in an asynchronous CV. The fit of its X-ray spectrum provides an accretion mass rate, $\dot{M}$, of about 6×10^{-12} $M_{\odot}yr^{-1}$ (Ref. 7).

Most intermediate polars have X-ray luminosities, L_X, of $\sim 10^{33}$ erg s^{-1}. The luminosity of CTCV J2056-3014 is around 100 times smaller (10^{31} erg s^{-1}); a property shared with a very small group of CVs named low-luminosity intermediate polars (LLIPs).[8] It is not clear if the number of LLIPs is small because they are rare objects or because their X-ray faintness hampers their discovery in X-ray surveys. If the true number of LLIPs is high and we are missing them because of observational biases, this class of objects is probably a relevant contributor to the Galactic X-ray background.[8]

3. The fastest spinning WDs

In this section, we enumerate the bona fide fastest spinning WDs, which are all located in compact binary systems. However, for completeness, we also mention some objects that could be WDs with a rapid spin. A summary of selected characteristics of individual objects is shown in Table 1.

There is a debate in the literature if some soft gamma-ray repeaters (SGR) and anomalous X-ray pulsars (AXP), the so-called magnetars, could contain a WD instead of a neutron star.[9,10] For example, the spectral energy distribution from the infrared to the gamma-rays of 4U 0142+61 (P_{spin}= 8.62 s) can be fitted in a scenario of a fast, massive, and magnetic WD.[3] If some magnetars were indeed WDs, they would put strong constraints on the physics of the WD interiors, to cite only one consequence of this hypothesis. In spite of the importance of this subject, those objects are not considered here.

WZ Sge is a short orbital period cataclysmic variable that shows dwarf-nova outbursts with a very long recurrence time (a few decades). The system has intermittent periodical signals at 28.87 s and 28.96 s. One of these periods could be the WD spin period, but it is not a settled question (see Ref. 11 and references therein). We do not consider this system as a confirmed fast-spinning WD, but we list its properties in Table 1.

Another fast-spinning compact object is RX J0648.0-4418, with a P_{spin} of 13.2 s. This object is in a relatively wide binary system, with an orbital period of 1.55 d. However, it is debated if the compact object is a WD or a neutron star.[7,12] In some sense, this object is a link between fast-spinning WDs and magnetars. As for WZ Sge, we do not include it in the list of bona fide fast-spinning WDs, but its properties can be found in Table 1.

AE Aqr was the first discovered fast and magnetic WD, and its peculiar properties prompted many studies.[13] Its WD spins at a 33 s rate. The system is the

prototype of a propeller: a system in which the centrifugal force of a magnetic fast-rotating object prevents the accretion from a mass reservoir to reach the object's surface. This is one of the possible accretion-flow configurations in cataclysmic variables. It depends on the WD magnetic field, WD spin, and accretion rate.[14] However, even if part of the material is propelled out of the WD magnetosphere, some material can reach the WD surface. This is probably the case for AE Aqr,[15,16] since its X-ray luminosity is small but not null: $\dot{M} \approx 10^{31}$ erg s^{-1}.[15] The radius of the companion star is twice as large as is expected for its mass, indicating a very inflated object.

V1460 Her is an intermediate polar with a WD that spins at 38.9 s.[17] The companion star is less massive than that of AE Aqr, but it is also significantly inflated. Contrary to AE Aqr, there is an accretion disk in V1460 Her, clearly seen in optical spectra.

At the time of this conference, CTCV J2056-3014 was known as the fastest-spinning WD. However, a faster WD has been recently discovered: LAMOST J024048.51+195226.9, with a spin period of 24.9328 $\pm$ 0.0038 s.[18] The system shows strong evidence of an outflow with properties consistent with those expected for a propeller.[19]

4. Discussion and conclusions

Two possible mechanisms for spinning up WDs are mergers and accretion.

The isolated WDs with large values of M_{WD}, B, and P_{spin} are probably produced by mergers. The majority of the most massive WDs have high values of magnetic fields,[1,2,24–26] which indicates that these two properties may have a common origin. Simulations show that double-degenerated mergers can produce WDs with high and stable magnetic fields.[27] From an observational perspective, there is also evidence for mergers. The color-magnitude distribution of a *Gaia* sample of nearby WDs ($d \lesssim 100$ pc) indicates the presence of two populations of WDs, which can be explained if some objects are formed by a merger.[28] Considering objects within 20 pc, the fraction of WDs in binary systems is considerably smaller than the fraction of binary systems composed of two main-sequence objects. This can be explained if a portion of the isolated WDs is formed via mergers.[29] Although mergers can play an important role in producing extreme WDs, the bona fide fastest-rotating WDs are all located in binary systems, specifically cataclysmic variables.

In cataclysmic variables, the rapid WD spin may be the result of the mass transfer. Specifically, the accretion transforms the orbital angular momentum into the rotational angular momentum of the WD. To reach the observed high P_{spin}, high values of $\dot{M}$ are necessary. However, a high mass-transfer rate should produce a high X-ray luminosity, which is not observed in the fast-spinning WDs (see Table 1). Therefore, the current high spin is explained by a previous phase of high mass transfer rate from a secondary star in a thermal time-scale phase. In fact, the

Table 1. Selected properties of the confirmed fastest spinning WDs and related objects.

secondary stars in AE Aqr[13] and V1460 Her[17] are twice as large as is expected for their masses, which reinforces the idea of a star slightly out of equilibrium. If the same is true for CTCV J2056-3014 and LAMOST J024048.51+195226.9 cannot be said, because their secondary stars have not yet been directed observed. Along its evolution, a CV evolves to shorter orbital periods. Consequently, the component separation as well as the radius of the secondary star shrink. In particular, the mass of the secondary, M_{sec}, is expected to decrease together with the orbital period. Moreover, above the observed period gap in the orbital period distribution of CVs, the angular-momentum transfer occurs by magnetic braking and produces larger $\dot{M}$ in comparison with objects below the period gap, which should have the angular momentum transfer sustained by gravitational radiation. Interestingly, CTCV J2056-3014 is the only object among the fast-spinning WD below the period gap.

The WDs in CTCV J2056-3014 and AE Aqr are certainly magnetic.[7] The understanding of the origin of the modulation in V1460 Her and LAMOST J024048.51+195226.9 would benefit from X-ray observations, which could reveal the presence of a magnetic WD.

Until recently, AE Aqr occupied an isolated position as the fastest-spinning confirmed WD. In the last years, other fast-spinning WDs have been discovered, all of them in CVs. Although most of them are similar to AE Aqr in the context of CV evolution, CTCV J2056-3014 - the only system with an orbital period below the CV period gap - seems to be a more evolved object. Those new results can help us understanding the physics behind the rapid spin of WDs in CVs and how the WD spin evolves along the CV evolution.

We discuss some aspects of Sousa et al. [1, 2] concerning two mechanisms of gravitational wave (GW) emission in fast-spinning white dwarfs (WDs): accretion of matter and magnetic deformation. In both cases, the GW emission is generated by an asymmetry around the rotation axis of the star. However, in the first case, the asymmetry is due to the amount of accreted matter in the magnetic poles, while in the second case it is due to the intense magnetic field. We have estimated the GW amplitude and luminosity for three binary systems that have a fast-spinning magnetized WD, namely, AE Aquarii, AR Scorpii and RX J0648.0-4418. In addition, we applied the magnetic deformation mechanism for SGRs/AXPs described as WD pulsars. We found that, for the first mechanism, the systems AE Aquarii and RX J0648.0-4418 can be observed by the space detectors BBO and DECIGO if they have an amount of accreted mass of $\delta m \geq 10^{-5} M_{\odot}$. For the second mechanism, the three systems studied require that the WD has a magnetic field above $\sim 10^9$ G to emit GWs that can be detected by BBO. Furthermore, we found that some SGRs/AXPs as WD pulsars can be detected by BBO and DECIGO, whereas SGRs/AXPs as highly magnetized neutron stars are far below the sensitivity curves of these detectors.

1. Introduction

Over the last years, the astrophysical community's interest in highly magnetized white dwarfs (HMWDs) has increased. Recent results of the Sloan Digital Sky Survey (SDSS) have confirmed these white dwarfs (WDs) with surface magnetic fields ranging from 10^6 G up to 10^9 G [see e.g. Refs. 3–5]. Besides their high magnetic fields, most of them have been shown to be massive, and responsible for the high-mass peak at 1 $M_{\odot}$ of the WD mass distribution.[3,6,7]

Typically, WDs have rotation periods of days or even years. However, recently, a WD pulsar was discovered, called AR Scorpii. This star emits from X-ray to radio wavelengths, pulsing in brightness with a period of 1.97 min.[8] Moreover, other sources have been proposed as candidates of WD pulsars. Specific examples are AE Aquarii with a short rotation period of $P = 33.08$ s[9] and RX J0648.0-4418

(RX J0648, hereafter) that is a massive WD with $M = 1.28 M_{\odot}$ and with a very fast spin period of $P = 13.2$ s, that belongs to the binary system HD 49798/RX J0648.0-4418.[10] Nevertheless, it is worth mentioning that the nature of RX J0648 is unclear, meaning it is not yet clearly known whether this star is a WD or a neutron star.[11,12]

Recently, from XMM-Newton observations, the authors in Ref. 13 reported that CTCV J2056-3014 is a X-ray-faint intermediate polar harboring an extremely fast-spinning WD with a coherent pulsation of 29.6 s, thus being the fastest confirmed spin in a WD [see also Ref. 14]. Other fast-spinning WDs have been observed more recently. As examples we can cite: V1460 Her, which is an eclipsing cataclysmic variable, with a overluminous K5-type donor star and a WD that rotates with a period of 38.9 s[15] and ZTF J190132.9+145808.7, which is a highly magnetized and rapidly rotating white dwarf, featuring a magnetic field with strengths between 600 MG and 900 MG on its surface, and a stellar radius that is only slightly larger than the radius of the Moon.[16] This WD has a rotation period of 6.94 min which is considered short as this star is an isolated WD.

Notwithstanding, several studies of magnetized and fast-rotating WDs have been done. In particular, we can highlight one involving WD pulsars in an alternative description for Soft Gamma Repeaters (SGRs) and Anomalous X-Ray Pulsars (AXPs) [see e.g. Refs. 17–20]. From this perspective, the process of energy emission released by dipole radiation in a WD can be explained by a canonical spin-powered pulsar model, since they share quite similar aspects.[18,21]

On the other hand, LIGO and Virgo detectors have recently made direct observations of gravitational waves (GWs).[22,23] All these GW detections are within a frequency band ranging from 10 Hz to 1000 Hz, which is the operating band of LIGO and Virgo. Nevertheless, as is well known, there are proposed missions for lower frequencies, such as LISA,[24,25] whose frequency band is of $(10^{-4} - 0.01)$ Hz, BBO[26,27] and DECIGO[28,29] in the frequency band ranging from 0.01 Hz to 10 Hz.

The generation of continuous GWs in different possibilities has already been proposed.[30–34] More recently, in Refs. 1, 2, 35, it has been suggested that rotating magnetized WDs can emit continuous GWs with amplitudes possibly detected by upcoming GW detectors such as LISA, DECIGO and BBO. Here we revisit our two works [Refs. 1, 2], where we investigate two mechanisms of gravitational radiation emission in fast-rotating magnetized WD: matter accretion and magnetic deformation. In both cases, the emission in GW is produced by the asymmetry around the star's rotation axis.

2. Gravitational emission mechanisms

WDs might generate gravitational radiation whether they are not perfectly symmetric around their rotation axis. The huge dipole magnetic field that can make the star become oblate[36] and accretion of matter are two examples where this asymmetry can occur.

2.1. *Accretion of matter*

The GW emission is shown here for the case of a WD accreting matter via the magnetic poles which do not coincide with the rotation axis of the star. In this scenario, the system's secondary star transfers matter to the WD through an accretion column and accumulates an amount of mass on the magnetic poles.

Thus, we consider a rigid object rotating about a non-major axis (x_1, x_2, x_3) and which has a deformity about one of the major axes (x_1, x_2, x_3), where are positioned the main moments of inertia I_1, I_2 e I_3, respectively.

With this configuration and doing $I_1 = I_2$, the gravitational amplitude and luminosity are given respectively by[37,38]

$$h_{0_{ac}} = \frac{4G}{c^4}\frac{(I_1 - I_3)\omega^2}{r}\sin^2\theta, \tag{1}$$

$$L_{GW_{ac}} = -\frac{2}{5}\frac{G}{c^5}(I_1 - I_3)^2\omega^6\sin^2\theta(16\sin^2\theta + \cos^2\theta), \tag{2}$$

where, ω is the angular velocity, θ is the angle between the rotation and magnetic dipole axes and r is the distance to the emitting source.

Now, to determine the moments of inertia I_1 and I_3, we consider that the object has an amount of mass accumulated on the x_3' axis. We reduce this system to a large sphere with two smaller spheres of matter on the x_3' axis: one at each of the poles of the larger sphere. This would be equivalent to a WD accreting matter by the two magnetic poles. Therefore, it follows immediately that

$$\begin{aligned} I_1 &= \frac{2}{5}MR^2 + 2\delta m\ R^2, \\ I_3 &= \frac{2}{5}MR^2 + 2\frac{2}{5}\delta m\ a^2, \end{aligned} \tag{3}$$

where M is the mass of the star, R is the radius of the star, δm is the amount of mass accumulated on one magnetic pole and a its radius.

Considering that $R \gg a$ and by substituting these last expressions into Eqs. (1) and (2), one obtains

$$h_{0_{ac}} = \frac{8G}{c^4}\frac{\delta m\ R^2\omega^2}{r}\sin^2\theta, \tag{4}$$

and

$$L_{GW_{ac}} = -\frac{8}{5}\frac{G}{c^5}\delta m^2R^4\omega^6\sin^2\theta(16\sin^2\theta + \cos^2\theta). \tag{5}$$

Thereby, we find expressions for the gravitational luminosity and the GW amplitude for the case of a WD accumulating mass, which depends on the accreted mass, the distance to the source, the radius of the star and how fast it is rotating.

2.2. *Magnetic deformation*

This section deals with the deformation of the WD induced by its own huge magnetic field. Due to the combination of magnetic field and rotation, a WD can become triaxial, presenting therefore a triaxial moment of inertia. In order to investigate the effect arising from the magnetic stress on the equilibrium of stars, let us introduce the equatorial ellipticity, defined as[37,38]

$$\epsilon = \frac{I_1 - I_2}{I_3}. \tag{6}$$

where I_1, I_2 and I_3 are main moments of inertia with respect to the (x, y, z) axes, respectively.

If the star rotates around the $z-$axis, then it will emit monochromatic GWs with a frequency twice the rotation frequency, f_{rot}, with amplitude given by[37,38]

$$h_{0_{df}} = \frac{16\pi^2 G}{c^4}\frac{I_3 f_{rot}^2}{r}\,\epsilon, \tag{7}$$

and luminosity as follows:

$$L_{GW_{df}} = -\frac{32}{5}\frac{G}{c^5} I_3^2 \epsilon^2 \omega_{rot}^6. \tag{8}$$

On the other hand, recall that the ellipticity of magnetic origin can be written as[39,40]

$$\epsilon = \kappa \frac{B_s^2 R^4}{GM^2}, \tag{9}$$

where, B_s is the magnetic field strength on the star's surface and κ is the distortion parameter, which depends on the magnetic field configuration and equation of state (EoS) of the star.

Now, substituting this last equation into Eqs. (7) and (8) and considering $I_3 = 2MR^2/5$, one immediately obtains that

$$h_{df} = \frac{32\pi^2}{5c^4}\frac{R^6 f_{rot}^2}{rM}\kappa B_s^2, \tag{10}$$

$$L_{GW_{df}} = -\frac{2^{13}\pi^6}{5^3 c^5}\frac{R^{12} f_{rot}^6}{GM^2}\kappa^2 B_s^4. \tag{11}$$

Note that the two equations just above depend on the rotation frequency and the magnetic field strength.

In contrast, the GW amplitude can also be written as a function of the variation of the star's rotation frequency $\dot{f}_{rot}$. In this case, we must consider that a part of the spindown luminosity is converted into GWs. Thus, we can infer an efficiency, η_{df}, for the variation of the rotation frequency as $\dot{\bar{f}}_{rot} = \eta_{df}\dot{f}_{rot}$, such that $\dot{\bar{f}}_{rot}$ can be

interpreted as the part of $\dot{f}_{rot}$ related to the GW brake. Hence, the GW amplitude can be written as follows

$$h_0^{sd} = \left(\eta_{df} \, \frac{5}{2} \frac{G}{c^3} \frac{I_3 \dot{f}_{rot}}{r^2 f_{rot}} \right)^{1/2} . \tag{12}$$

3. Gravitational waves from rapid rotation white dwarfs

3.1. *Accretion of matter*

Considering the scenario of an amount of mass accumulated on the magnetic poles, we apply Eq. (4) for the three binary systems that have fast-spinning WDs: AE Aqr, AR Sco and RX J0648. The parameters for the systems are listed in Table 1.

From Eq. (4), one notes that the amplitude depends on the amount of mass accumulated; however, it is not easy to predict how much matter may have been accreted to WD and how much has been dispersed on its surface. Thus, for this analysis, we assign four values for the mountain of matter for the analyzed systems: $\delta m = (10^{-3} M_\odot,\ 10^{-4} M_\odot,\ 10^{-5} M_\odot,\ 10^{-6} M_\odot)$ [see Refs. 41–43 for details about accretion in WDs]. Besides that, we consider that the angle between the magnetic and rotation axes is $\theta = 30°$.

Table 1. Parameters of 3 binary systems: Period (P), spindown ($\dot{P}$), WD radius (R) and distance to Earth (r).

Systems	P (s)	$\dot{P}$ (10^{-15} s/s)	R (10^8 cm)	r (pc)
AE Aqr[a]	33.08	56.4	7.0	100
AR Sco[b]	118.2	392	7.1	116
RX J0648[c]	13.18	6.0	3.0	650

Note: [a]see 44; [b]see 34; [c]see 45.

Assuming these values for δm and the parameters listed in Table 1, we obtain $h_{0_{ac}}$ for the three systems, which are shown in Figure 1.

With the amplitude estimations, we compare them with the sensitivity curves of the gravitational wave space detectors. This outcome is shown in Figure 2 where we have the sensitivity curve for LISA, BBO and DECIGO with a signal-to-noise ratio (SNR) of 8 and an integration time of $T = 1$ yr. We notice from this figure that AE Aqr and RX J0648 are good candidates to be detected by BBO and DECIGO if they have an accumulated mass of $\delta m \geq 10^{-5} M_\odot$. For the AR Sco system, the gravitational radiation emitted by this process would hardly be able to be detected by the three space instruments. This system would need to have a very high mass mountain of $\sim 10^{-3} M_\odot$ to be above, for example, the sensitivity curve of the BBO detector.

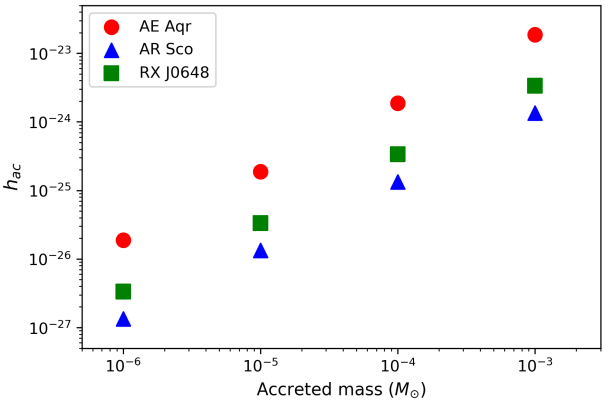

Fig. 1. GW amplitude as a function of accreted mass to AE Aqr, AR Sco and RX J0648.

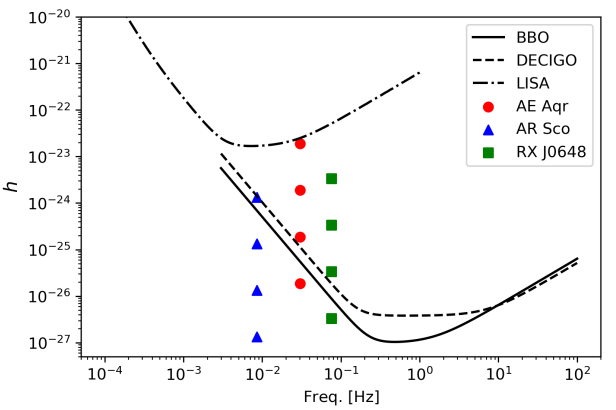

Fig. 2. GW amplitude for AE Aqr, AR Sco and RX J0648 for different values of mass ($10^{-3}M_\odot$, $10^{-4}M_\odot$, $10^{-5}M_\odot$, $10^{-6}M_\odot$, from top to bottom) and the sensitivity curves for LISA, BBO and DECIGO for $SNR = 8$ and integration time of $T = 1$ yr.

Now, we consider the efficiency of this mechanism with respect to the rotational energy rate lost by the systems. To do this, we consider the efficiency of the process ($\eta_{acr} = L_{GW_{acr}}/L_{sd}$) for the four δm's considered above, i.e., how much of the spin-down luminosity is converted to gravitational luminosity for every δm (see Table 2). We find that the contribution of gravitational luminosity to the spindown luminosity is irrelevant, since, for the four values of δm adopted, the efficiency $\eta_{acr} \ll 1$. Thereby, the contribution of gravitational luminosity to the spindown luminosity is negligible when we consider this mechanism.

Table 2. The efficiency of the mechanism of GWs due to the amount of mass accumulated at the WD magnetic poles for different values of δm.

AE Aquarii		**AR Scorpii**		**RX J0648**	
δm	η_{acr}	δm	η_{acr}	δm	η_{acr}
$(M_\odot)$	$(L_{GW_{acr}}/L_{sd})$	$(M_\odot)$	$(L_{GW_{acr}}/L_{sd})$	$(M_\odot)$	$(L_{GW_{acr}}/L_{sd})$
10^{-3}	1.02×10^{-2}	10^{-3}	3.41×10^{-5}	10^{-3}	0.175
10^{-4}	1.02×10^{-4}	10^{-4}	3.41×10^{-7}	10^{-4}	1.75×10^{-3}
10^{-5}	1.02×10^{-6}	10^{-5}	3.41×10^{-9}	10^{-5}	1.75×10^{-5}
10^{-6}	1.02×10^{-8}	10^{-6}	3.41×10^{-11}	10^{-6}	1.75×10^{-7}

3.2. *Magnetic deformation*

Here, we consider the generation of GWs due to the deformation of the WD structure of the same binary systems (AE Aqr, AR Sco and RX J0648) caused by their own intense magnetic field. For this, we use Eq. (12) to calculate the GW amplitude as a function of the efficiency $\eta_{df} = L_{GW_{def}}/L_{sd}$. The GW amplitudes are shown in Figure 3 as a function of η_{df}, where we use the parameters of Table 1 for all 3 systems.

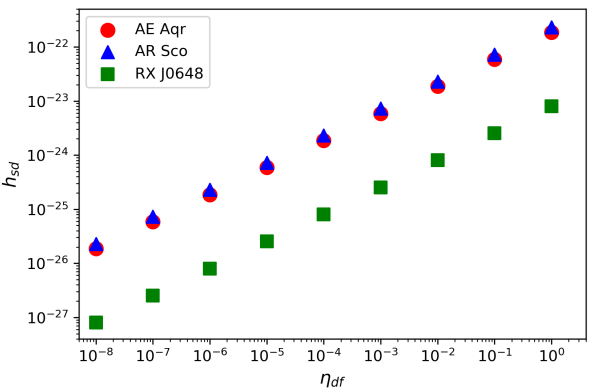

Fig. 3. GW amplitude for different values of efficiency ($\eta_{df} = L_{GW_{def}}/L_{sd}$) to AE Aqr, AR Sco and RX J0648.

From Figure 4, we plot the GW amplitudes inferred in Figure 3, together with sensitivity curves for LISA, BBO and DECIGO for one year of integration time and $SNR = 8$. It is worth noting that all three systems are detectable by BBO and DECIGO as long as AE Aqr has an efficiency $\eta_{df} \geq 10^{-6}$, AR Sco an efficiency $\eta_{df} \geq 10^{-4}$ and RX J0648 an efficiency $\eta_{df} \geq 10^{-5}$. Thus, even if the GWs have a small contribution to the spindown of these systems, they can emit GWs with amplitudes that can be detected by the space antennas.

Nevertheless, it is interesting to know what the value of the magnetic field needed to produce these detectable amplitudes. Thus, we calculate the magnetic

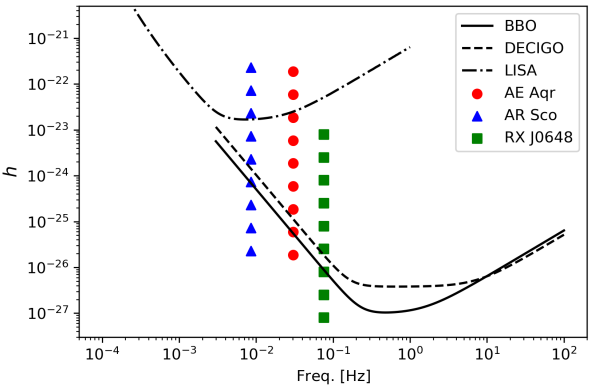

Fig. 4. GW amplitudes as presented in Figure 3 compared to the sensitivity curves of LISA, BBO and DECIGO for $SNR = 8$ and integration time of $T = 1$ year. Here, the efficiency values (1, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7} and 10^{-8}) are displayed from top to bottom.

field strength so that these sources can be detected by BBO, which is the most sensitive instrument of the three considered in the present work. To do so, we use Eq. (10) together with the minimum efficiency for which each system is detectable by this instrument and we adopted $\kappa \simeq 10$ [see Ref. 46]. Table 3 shows theses results. Notice that the systems must have WDs with high magnetic fields, around $(10^9 - 10^{10})$ G, which are about two orders of magnitude larger than the canonical model of WD pulsars.

In addition, we can further calculate the GW amplitude by considering the upper limit values of the magnetic field strength, B_{dip}, inferred from the canonical model of WD pulsars. Table 4 presents the results of this study. Notice that the amplitudes of the GW shown in this Table is very small to be observed by the space detectors, since they are well below the sensitivities of these detectors. In other words, the space detectors will not be able to detect these sources when considering the upper limit of the magnetic field strength.

Table 3. Minimum efficiency for the sources to be detected by the BBO detector along with the required magnetic field strength.

Minimum efficiency detected by BBO			
Systems	η_{df}	h_{def}	B (G)
AE Aqr	10^{-6}	1.9×10^{-25}	2.8×10^{9}
AR Sco	10^{-4}	2.3×10^{-24}	3.6×10^{10}
RX J0648	10^{-5}	2.5×10^{-26}	1.6×10^{10}

3.3. *GWs from SGRs/AXPs as fast-spinning WDs*

An alternative model has been proposed for SGRs/AXPs considering they are fast-rotating and magnetized WDs [see e.g. Refs. 17–20 for further details]. From this

Table 4. Elipticity (ϵ), GW amplitude (h_{def}), GW luminosity ($L_{GW_{def}}$) and efficiency of the mechanism (η_{df}) for the upper limit of magnetic field (B_{dip}) of each system.

SYSTEMS	B_{dip} (G)	ϵ	h_{def}	$L_{GW_{def}}$ (erg/s)	η_{df}
AE Aqr	5.0×10^{7}	5.1×10^{-9}	6.2×10^{-29}	2.13×10^{21}	1.1×10^{-13}
AR Sco	5.0×10^{8}	5.3×10^{-7}	4.6×10^{-28}	1.25×10^{22}	4.02×10^{-12}
RX J0648	1.0×10^{8}	2.8×10^{-10}	9.5×10^{-31}	1.33×10^{20}	1.4×10^{-14}

perspective, a canonical spin-powered pulsar model can explain the process of energy emission released by dipole radiation in a WD, since they share quite similar aspects.[21] In addition, these sources could also be candidates for GW emission, since the high magnetic field can deform the star in a non-symmetrical way, thus generating a variation in the quadrupolar moment of the star.

Therefore, we consider in this section that SGRs/AXPs are fast-spinning and magnetized WDs which emit GWs due to the deformation caused by their own intense magnetic field. Thus, using Eq. 10 and adopting $\kappa \simeq 10$, we calculate the GW amplitude for the 23 confirmed SGRs/AXPs[47] [a], considering these objects as a very massive WD. To do so, we assume three values of mass and their corresponding radius, namely, $M_{WD} = 1.4 M_{\odot}$ ($R_{WD} = 1.0 \times 10^{8}$ cm), 1.2 $M_{\odot}$ ($R_{WD} = 6.0 \times 10^{8}$ cm) and 1.0 $M_{\odot}$ ($R_{WD} = 7.5 \times 10^{8}$ cm) [see Ref. 48 for further details about the mass-radius relation].

After estimating the amplitude, we placed them on the sensitivity curves of the BBO and DECIGO detectors. Figure 5 shows theses results, such that the GW amplitude is presented as a function of frequency for some SGRs/AXPs. In this Figure, the bullets stands for $M_{WD} = 1.2 M_{\odot}$ and the vertical bars, that crosses the bullets, stands for $1.0 M_{\odot} \leq M_{WD} \leq 1.4 M_{\odot}$, from top to bottom.

Notice that some SGRs/AXPs produce GWs with amplitudes that can be detected by BBO and DECIGO. Some of them, for example 1E 1547.0-5408 and SGR 1806-20, could well be detected for the entire mass range considered, while others would be detected depending on how massive they are.

SGRs/AXPs described as WDs generate GW amplitudes much larger than SGRs/AXPs described in the magnetar model where they are neutron stars [see e.g. Refs. 49, 50 for details about magnetar model]. This is because WDs have moments of inertia four orders of magnitude greater than a neutron star. Consequently, the GW amplitudes generated by these sources as neutron stars are far below the sensitivity curves of BBO and DECIGO [see Fig. 6]. Therefore, if these space based instruments detect continuous GWs from these sources, this would corroborate the model of fast spinning and magnetic WDs.

[a]For information about the SGRs/AXPs, we refer the reader to the McGill University's online catalog available at: `http://www.physics.mcgill.ca/~pulsar/magnetar/main.html`

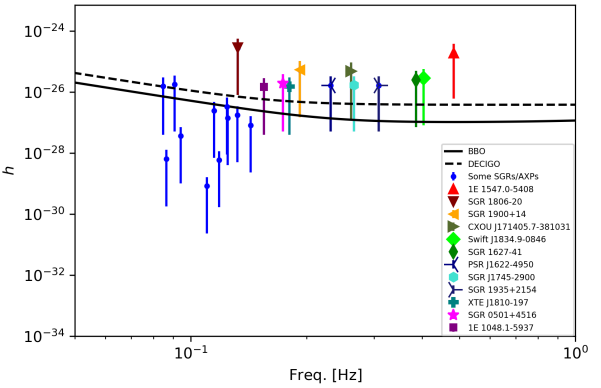

Fig. 5. GW amplitude as a function of frequency for SGRs/AXPs as fast-spinning and magnetized WDs for masses in the interval $1.0M_{\odot} \leq M_{WD} \leq 1.4M_{\odot}$, represented by the vertical bars, from top to bottom. The bullets stand for $M_{WD} = 1.2M_{\odot}$. Also plotted the sensitivity curves for BBO and DECIGO for $SNR = 8$ and integration time $T = 1$ year.

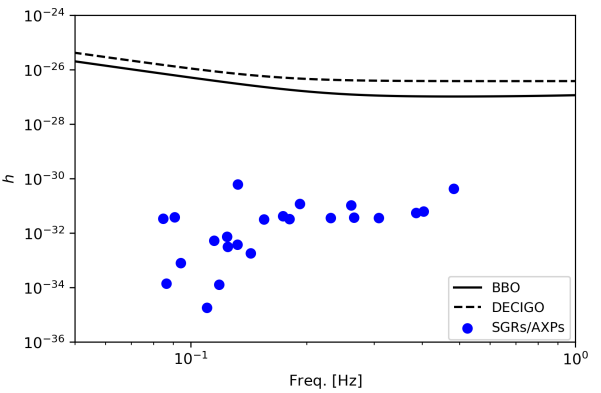

Fig. 6. GW amplitude as a function of frequency for SGRs/AXPs as NSs. Also plotted the sensitivity curves for BBO and DECIGO for $SNR = 8$ and integration time of $T = 1$ year. We consider a NS of $M = 1.4M_{\odot}$, radius $R = 10$ km.

4. Final remarks

We investigate two mechanisms - accretion of matter and magnetic deformation - for the production of gravitational waves in fast-spinning WDs. These uncommon WDs have high rotation and huge magnetic fields. Also, these stars are considered in an alternative model to describe SGRs and AXPs, where they are characterized as rotation-powered WD pulsars.

Then, we firstly study the following three binary systems: AE Aqr, AR Sco and RX J0648. For the accretion of matter mechanism, our results show that the AE Aqr and RX J0648 are good candidates for BBO and DECIGO if they have an

amount of mass accumulated of $\delta m \geq 10^{-5} M_{\odot}$, considering 1 year of integration time and $SNR = 8$. In contrast, AR Sco is unlikely to be detected because it is needed a large amount of mass accumulated in the magnetic pole of this WD.

Now, regarding the magnetic deformation mechanism, to emit gravitational radiation with amplitudes that are detectable by BBO, for example, the three binary systems studied require that the WD has a magnetic field above $\sim 10^9$ G. Nevertheless, these WDs are inferred to have magnetic fields with intensity around two orders of magnitude smaller. Moreover, we also conclude that gravitational radiation has an irrelevant contribution to the spindown luminosity of these systems for both mechanism.

Still, taking into account the magnetic deformation mechanism, we investigate the SGRs/AXPs as rotation-powered WD pulsars assigning a mass range $1.0 M_{\odot} \leq M_{WD} \leq 1.4 M_{\odot}$ for these objects. We conclude that a possible detection of continuous GWs coming from SGRs/AXPs would be a good indication that could corroborate the WD pulsar model, as for the neutron stars description, they are far below the BBO and DECIGO sensitivity curves.

Over the last decade or so, we have been developing the possible existence of highly magnetized white dwarfs with analytical stellar structure models. While the primary aim was to explain the nature of the peculiar overluminous type Ia supernovae, later on, these magnetized stars were found to have even wider ranging implications including those for white dwarf pulsars, soft gamma-ray repeaters and anomalous X-ray pulsars, as well as gravitational radiation. In particular, we have explored in detail the mass-radius relations for these magnetized stars and showed that they can be significantly different from the Chandrasekhar predictions which essentially leads to a new super-Chandrasekhar mass-limit. Recently, using the stellar evolution code STARS, we have successfully modelled their formation and cooling evolution directly from the magnetized main sequence progenitor stars. Here we briefly discuss all these findings and conclude with their current status in the scientific community.

Keywords: Conduction; equation of state; magnetic fields; magnetohydrodynamics; opacity; radiative transfer; white dwarfs.

1. Introduction

More than a dozen overluminous Type Ia supernovae (SNe Ia) have already been observed[1,2] which strongly suggest the existence of massive progenitors with masses $M > 2M_{\odot}$. Although the evolutions of accreting or rapidly differentially rotating white dwarf (WD) binaries have been used to explain such progenitors,[3,4] these models are unable to explain masses up to $2.8M_{\odot}$ that are inferred from the observations. Highly magnetised super-Chandrasekhar WDs (B-WDs) have been recently proposed as the possible progenitors of these peculiar overluminous SNe Ia. In addition to SNe Ia, B-WDs are also considered as promising candidates for soft gamma-ray repeaters (SGRs) and anomalous X-ray pulsars (AXPs) at lower magnetic fields than neutron star (NS) based magnetar, satisfying their ultraviolet luminosity cut-off.[13]

It has been shown that strong magnetic fields can modify the equation of state (EoS) of electron degenerate matter and yield super-Chandrasekhar WDs,[6–8] irrespective of the rotation rate. Indeed, the observational data from the Sloan Digital Sky Survey (SDSS) suggest that magnetized WDs tend to have larger masses than

their non-magnetic counterparts, even though they span the same effective temperature range.[9,10] Inspired by above findings, the effect of strong magnetic fields on the stellar structure, for various field configurations, has been explored for both Newtonian[6] and general relativistic formalisms.[8,11,12]

Magnetized WDs have many important implications apart from their link to peculiar SNe Ia and hence their other properties are worth exploring.[13–15] Recent works[16–19] have shown that B-WDs can be too dim to detect directly, and have also explored[20,21] the ability of rotating B-WDs to generate gravitational radiation which can be detected by the space-based gravitational wave detectors. Furthermore, other additional physics such as modified gravity,[22,23] ungravity effect,[24] effects of net charge,[25,26] lepton number violation[27] and anisotropic pressure[28] have also been explored to show the possible existence of super-Chandrasekhar WDs. Here we discuss the broad implications of these magnetized stars as well as their current status.

2. Origin and evolution of strong magnetic fields

It has been well known that purely poloidally or toroidally dominated fields are both structurally unstable.[29,30] However, it also has been shown that magnetized WDs with toroidally dominated mixed field configuration (along with small poloidal component) are one of the most plausible cases[31] and have approximately spherical shape.[8] Although the surface fields can be observationally inferred, the interior field cannot be directly constrained. Nevertheless, there is a sufficient evidence that the stars exhibit dipolar fields in their outer regions and hence are expected to have stronger interior (toroidally dominated) fields than at the surface. Numerical simulations have indeed shown that central fields of B-WDs can be several orders of magnitude higher than the surface field.[8,14,32]

The evolution of the poloidal and toroidal magnetic field components along with the angular momentum has been modelled recently with the Cambridge stellar evolution code STARS,[32] using advection-diffusion equations coupled to the structural and compositional equations of stars. They have shown that the magnetic field is likely to be dipolar, decaying as an inverse square law for most of the star. Their results also suggest that at the end of main sequence, the star may have toroidally dominated magnetic fields. The left panel of Figure 1 shows the evolution of toroidal field in the stellar interior as a function of radius at the end of main sequence, while the right panel shows the field as a function of the mass coordinate at various times after the helium exhaustion in the core, during the asymptotic giant phase.

Large-scale magnetic fields can be governed in the degenerate core of B-WDs even during the late stages of stellar evolution,[32] and very high fields can develop in these stars based on the conservation of magnetic flux, besides from the dynamo mechanism. Hence, strong fields inside magnetized WDs can also be of fossil origin.[33] This can be understood as follows. While the mass of the WD increases due to accretion, magnetic field is advected into its interior. Consequently, the gravitational

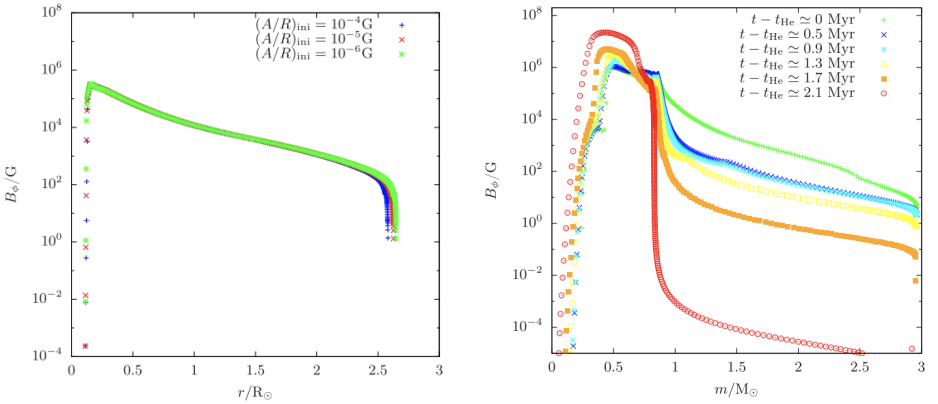

Fig. 1. *Left panel:* Toroidal field in the interior of the star as a function of the radius at the end of the main sequence. *Right panel:* Toroidal field inside the star as a function of the mass coordinate at various times after the helium exhaustion in the core, during the asymptotic giant phase.

power dominates over the degeneracy pressure leading to the contraction of the star. The initial seed magnetic field is then amplified as the total magnetic flux remains conserved. For magnetic field $B \sim 10^8$ G in a star of size $R \sim 10^6$ km, the resultant flux will be $\sim 10^{20}$ G km^2. From flux freezing, for a 1000 km size B-WD, the magnetic field can then grow up to $\sim 10^{14}$ G. Once the field increases, the total outward force further builds up to balance the inward gravitational force and the whole cycle is repeated multiple times. Therefore, the magnetic fields of highly magnetized WDs are likely to be fossil remnants from their main-sequence progenitor stars.

Repeated episodes of accretion and spin-down have also been suggested as a plausible mechanism that can lead to a highly magnetized WD.[14] Here, the entire evolution of the B-WD can be classified in two phases: accretion-powered and rotation-powered. The accretion-powered phase is governed by three conservation laws: linear and angular momenta conservation and conservation of magnetic flux, around the stellar surface, given by

$$\begin{aligned} l\Omega(t)^2 R(t) &= \frac{GM(t)}{R(t)^2}, \\ I(t)\Omega(t) &= \text{constant}, \\ B_s(t)R(t)^2 &= \text{constant}, \end{aligned} \tag{1}$$

where l accounts for the dominance of gravitational force over the centrifugal force, hence $l > 1$, I is the stellar moment of inertia and Ω is the angular velocity of the star that includes contribution acquired due to accretion as well. Solving these equations simultaneously gives the time evolution of radius, magnetic field and angular velocity during the accretion phase. Accretion discontinues when

$$-\frac{GM}{R^2} = \frac{1}{\rho}\frac{d}{dr}\left(\frac{B^2}{8\pi}\right)_{r=R} \sim -\frac{B_s^2}{8\pi R\rho}, \tag{2}$$

where ρ is the density of the inner disk edge. If the magnetic field is dipolar, $\dot{\Omega} \propto \Omega^3$ for a fixed magnetic field. Generalizing it to $\dot{\Omega} = k\Omega^n$ with constant k giving for the spin-powered phase, we obtain

$$\Omega = [\Omega_0^{1-n} - k(1-n)(t-t_0)]^{1/1-n}, \tag{3}$$

$$\text{and } B_s = \sqrt{\frac{5c^3 I k \Omega^{n-m}}{R^6 \sin^2\alpha}}. \tag{4}$$

Here Ω_0 is the initial angular velocity for the spin-powered phase (once accretion stops) at time $t = t_0$. The value of k is fixed such that B_s can be constrained at $t = t_0$, which is known from the field evolution in the preceding accretion-powered phase. Here $n = m = 3$ corresponds to the dipole field configuration, therefore m represents the deviation from dipolar field, especially for $n = 3$. Figure 2 shows the sample evolutions of angular velocity and magnetic field as functions of stellar mass. In both cases, initially larger Ω with accretion drops significantly during the spin-powered phase, followed by a phase of its increasing trend. At the end of the evolution, the star can be left either as a super-Chandrasekhar WD and/or an SGR/AXP candidate with a higher spin frequency.

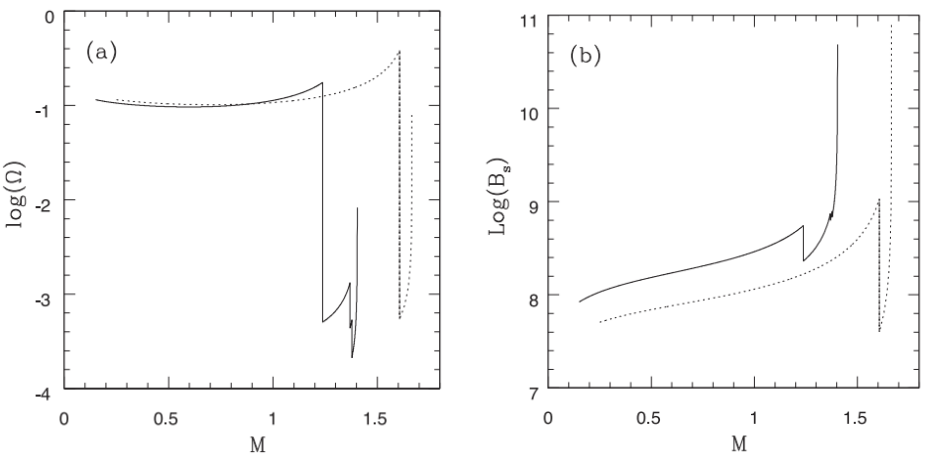

Fig. 2. Time evolution of angular velocity (left) and magnetic field (right) as functions of mass. The solid curves correspond to the case with $n = 3$, $m = 2.7$, $\rho = 0.05\,\mathrm{g\,cm^{-3}}$, $l = 1.5$ and dotted curves correspond to the case with $n = 3$, $m = 2$, $\rho = 0.1\,\mathrm{g\,cm^{-3}}$, $l = 2.5$. The other parameters are fixed with $k = 10^{-14}$, $\dot{M} = 10^{-8}\,M_\odot \mathrm{yr}^{-1}$, $\alpha = 10^\circ$ and $R = 10^4$ km at $t = 0$.

3. Rotating magnetized white dwarfs

Although, in nature, WDs are expected to consist of mixed fixed geometry, here we consider toroidally dominated magnetic field cases as they ensure the stability of these stars. It has been shown that toroidally dominated (and purely toroidal) field not only makes the star (slightly) prolate but also increases its equatorial

radius.[8,34,35] Figure 3 shows specific cases for toroidal field configuration combined with rotation. In the left panel, as the angular frequency is small, it does not affect the star considerably and results in a marginally prolate star. In contrast, the right panel, due to high angular velocity, exhibits that the low density region is affected more due to rotation than the high density region, resulting in an oblate shaped WD. From the magnetic field strength isocontours shown in the center panel, we can see that the surface magnetic field can decrease up to $\sim 10^9$ G even if the central field is $\sim 10^{14}$ G. For both cases, the magnetic to gravitational energies ratio (ME/GE) as well as kinetic to gravitational energies ratio (KE/GE) are chosen to be $\lesssim 0.1$ to maintain stable equilibrium.[36–38]

We have also considered differentially rotating B-WDs.[8] The angular velocity profile in the XNS code is specified as[39,40]

$$F(\Omega) = A^2(\Omega_c - \Omega) = \frac{R^2(\Omega - \omega)}{\alpha^2 - R^2(\Omega - \omega)^2}, \tag{5}$$

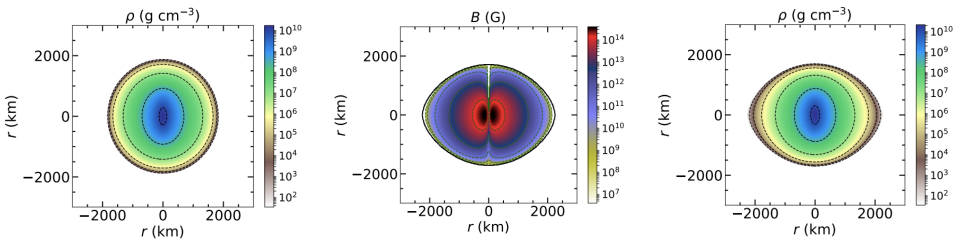

Fig. 3. Density and magnetic field strength isocontours for uniformly rotating B-WDs with toroidal magnetic field are shown in the left and center panels, respectively. The parameters used for both are $\Omega \sim 0.0628$ rad/s, $B_{max} \sim 2.7 \times 10^{14}$ G, ME/GE ~ 0.1, KE/GE $\sim 3.6 \times 10^{-6}$. The density isocontours for the $\Omega \sim 3.6537$ rad/s, $B_{max} \sim 2.7 \times 10^{14}$ G, ME/GE ~ 0.1, KE/GE $\sim 1.3 \times 10^{-2}$ case is shown in the right panel.

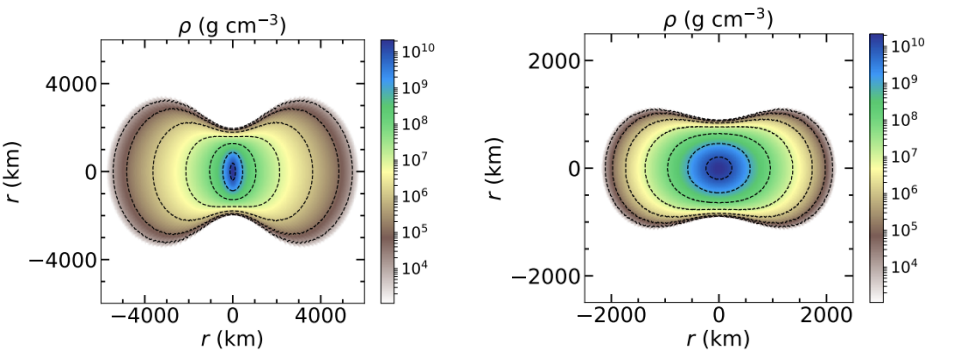

Fig. 4. Density isocontours for differentially rotating magnetized WD is shown. For the left panel, we have toroidal field with $\Omega \sim 0.62$ rad/s, $\Omega_c \sim 10.15$ rad/s, $B_{max} \sim 3.2 \times 10^{14}$ G, ME/GE ~ 0.14, KE/GE ~ 0.1. For the right panel, we use poloidal field with $\Omega \sim 2.74$ rad/s, $\Omega_c \sim 20.30$ rad/s, $B_{max} \sim 3.9 \times 10^{11}$ G, ME/GE $\sim 7.8 \times 10^{-8}$, KE/GE ~ 0.14.

where A is a constant that indicates the extent of differential rotation, $R = \psi^2 r\sin\theta$, $\omega = -\beta^\phi$, Ω_c is the angular velocity at the center and ω is the angular velocity at radius r. Figure 4 shows the density isocontours of differentially rotating B-WDs for toroidal field with surface angular velocity $\Omega \sim 0.62\,\mathrm{rad/s}$, $\Omega_c \sim 10.15\,\mathrm{rad/s}$, $B_{max} \sim 3.2 \times 10^{14}\,\mathrm{G}$, ME/GE ~ 0.14, KE/GE ~ 0.1 (left panel) and poloidal field with $\Omega \sim 2.74\,\mathrm{rad/s}$, $\Omega_c \sim 20.30\,\mathrm{rad/s}$, $B_{max} \sim 3.9 \times 10^{11}\,\mathrm{G}$, ME/GE $\sim 7.8 \times 10^{-8}$, KE/GE ~ 0.14 (right panel). It can be seen that "polar hollow" structure can form with differential rotation regardless of the specific geometry of the magnetic field.

4. Non-rotating magnetized WDs with finite temperature

Apart from increasing the limiting mass of WDs, strong magnetic fields can also influence the thermal properties such as luminosity, temperature gradient and cooling rate of the star.[16,18,19] In order to model such a WD, the total pressure inside the star is modelled by including the contributions from the degenerate electron gas, ideal gas and magnetic pressures. The interface is defined to be the radius where the contributions from electron degenerate core and outer ideal gas pressures are equal. The presence of strong fields gives rise to additional pressure $P_B = B^2/8\pi$ and density $\rho_B = B^2/8\pi c^2$ inside the magnetized WDs.[41]

Assuming the B-WD to be approximately spherical, the model equations for magnetostatic equilibrium, photon diffusion and mass conservation can be written within a Newtonian framework as

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}r}(P_{\mathrm{deg}} + P_{\mathrm{ig}} + P_B) &= -\frac{Gm(r)}{r^2}(\rho + \rho_B),\\
\frac{\mathrm{d}T}{\mathrm{d}r} &= -\max\left[\frac{3}{4ac}\frac{\kappa\rho}{T^3}\frac{L_r}{4\pi r^2}, \left(1 - \frac{1}{\gamma}\right)\frac{T}{P}\frac{\mathrm{d}P}{\mathrm{d}r}\right],\\
\frac{\mathrm{d}m}{\mathrm{d}r} &= 4\pi r^2(\rho + \rho_B).
\end{aligned} \tag{6}$$

Here we have ignored the magnetic tension terms for radially varying B. In these equations, P_{deg} and $P_{\mathrm{ig}} = \rho kT/\mu m_p$ are the electron degeneracy pressure and hence the ideal gas pressure respectively, ρ is the matter density, T is the temperature, $m(r)$ is the mass enclosed within radius r, κ is the radiative opacity, L_r is the luminosity at radius r, and γ is the adiabatic index of the gas.

The opacity in the surface layers of non-magnetised WD is approximated with the Kramers' formula, $\kappa = \kappa_0 \rho T^{-3.5}$, where $\kappa_0 = 4.34 \times 10^{24} Z(1 + X)\ \mathrm{cm^2\ g^{-1}}$, and X and Z are the mass fractions of hydrogen and heavy elements (other than hydrogen and helium) in the stellar interior respectively. To capture the radial variation of the field magnitude within the B-WD, we adopt a profile used extensively to model magnetized NSs and B-WDs,[11,42] given by

$$B\left(\frac{\rho}{\rho_0}\right) = B_{\mathrm{s}} + B_0\left[1 - \exp\left(-\eta\left(\frac{\rho}{\rho_0}\right)^{\gamma}\right)\right], \tag{7}$$

where B_s is the surface magnetic field, B_0 is a fiducial magnetic field, $\eta = 0.8$ and $\gamma = 0.9$ are dimensionless parameters along with $\rho_0 = 10^9\,\mathrm{g/cm^3}$ determining how the field decays from the core to the surface. The radial luminosity can be assumed to be constant so that $L_r = L$ as there is no hydrogen burning or other nuclear fusion reactions taking place within the WD core. We solve the differential equations by providing the surface density, mass and surface temperature as the boundary conditions.

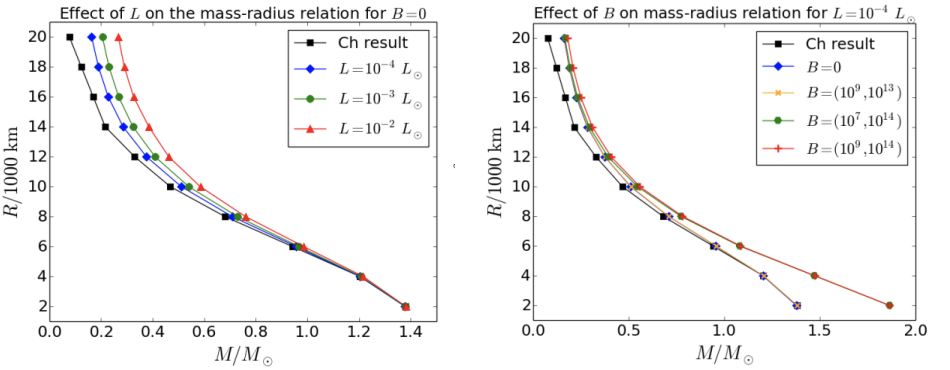

Fig. 5. *Left panel:* The effect of L on the mass–radius relation of non-magnetised WDs is shown for $L = 10^{-4}\ L_\odot$ (blue diamonds), $L = 10^{-3}\ L_\odot$ (green circles) and $L = 10^{-2}\ L_\odot$ (red triangles), along with the Chandrasekhar result (black squares). *Right panel:* The effect of field strength on the mass–radius relation of B-WDs is shown for $B = (B_s, B_0) = (0, 0)$ (blue diamonds), $B = (10^9, 10^{13})$ G (orange crosses), $B = (10^7, 10^{14})$ G (green circles) and $B = (10^9, 10^{14})$ G (red pluses), along with the Chandrasekhar result (black squares) for $L = 10^{-4}\ L_\odot$.

For strong magnetic fields, variation of radiative opacity with B can be modelled as $\kappa = \kappa_B \approx 5.5 \times 10^{31} \rho T^{-1.5} B^{-2} \mathrm{cm^2\ g^{-1}}$.[43,44] The field dependent Potekhin's opacity is used instead of Kramers' opacity if $B/10^{12}\ \mathrm{G} \geq T/10^6\ \mathrm{K}$, which is valid for the strong B cases that we consider here. The left panel of Figure 5 shows the effect of luminosity on the mass-radius relation for non-magnetized WDs compared to Chandrasekhar's results.[45] Although the increase in L leads to progressively higher masses for larger WDs, Chandrasekhar mass limit is retained irrespective of the luminosity. The right panel of Figure 5 shows the effect of magnetic field on the mass-radius relation for B-WDs with $L = 10^{-4}\,L_\odot$ and compares them with the non-magnetic Chandrasekhar results. It can be seen that the magnetic field affects the mass-radius relation in a manner analogous to increasing L, by shifting the curve towards higher masses for WDs with larger radii. The mass-radius curves for $B_0 \lesssim 10^{13}\,\mathrm{G}$ practically overlap with each other and retain the Chandrasekhar mass limit. However, for strong central fields with $B_0 \sim 10^{14}\,\mathrm{G}$, super-Chandrasekhar WDs are obtained with masses as high as $\sim 1.9\,M_\odot$.

In order to ensure structural stability of a B-WD, an increase in magnetic energy density has to be compensated by a corresponding decrease in the thermal energy

and hence the luminosity. This effect is especially prominent for B-WDs with larger radii where the magnetic, thermal and gravitational energies are comparable with each other. We find that a slight decrease in the luminosity for $R \gtrsim 12000\,\mathrm{km}$ WDs leads to masses that are similar to their non-magnetic counterparts. However, the smaller radii B-WDs require a substantial drop in their luminosity (well outside the observable range) and still do not really achieve masses that are similar to the non-magnetized WDs.

5. Effect of cooling evolution and field dissipation

Magnetic fields inside a WD undergo decay by Ohmic dissipation and Hall drift processes with timescales given by[46, 47]

$$t_{\rm Ohm} = (7 \times 10^{10}\ \mathrm{yr})\, \rho_{c,6}^{1/3} R_4^{1/2} (\rho_{\rm avg}/\rho_c), \tag{8}$$

$$t_{\rm Hall} = (5 \times 10^{10}\,\mathrm{yr})\ l_8^2 B_{0,14}^{-1} T_{c,7}^2 \rho_{\rm c,10}, \tag{9}$$

where $\rho_{\rm c,n} = \rho_c/10^n\,\mathrm{g\,cm^{-3}}$, $R_4 = R/10^4\,\mathrm{km}$, $T_{c,7} = T_c/10^7\,\mathrm{K}$, $B_{0,14} = B_0/10^{14}\,\mathrm{G}$ and $l = l_8 \times 10^8\,\mathrm{cm}$ is characteristic length scale of the flux loops through WD outer core. Ohmic decay is the dominant field dissipation process for $B \lesssim 10^{12}$ G, while for $10^{12} \leq B/\mathrm{G} \leq 10^{14}$ the decay occurs via Hall drift and for $B \gtrsim 10^{14}$ G, the principal decay mechanism is likely to be ambipolar diffusion.[46] The magnetic field decay in magnetars with surface fields between 10^{14} and 10^{16} G can be solved using

$$\frac{\mathrm{d}B}{\mathrm{d}t} = -B\left(\frac{1}{t_{\rm Ohm}} + \frac{1}{t_{\rm Amb}} + \frac{1}{t_{\rm Hall}}\right), \tag{10}$$

where $t_{\rm Amb}$ denotes the ambipolar diffusion time scale.

On the other hand, the thermal energy of WDs is radiated away gradually over time in the observed luminosity from the surface layers as the star evolves. The rate at which thermal energy of ions is transported to surface and radiated depends on the specific heat, given by

$$L = -\frac{d}{dt}\int c_v dT = (2 \times 10^6\ \mathrm{erg/s})\, \frac{A m_\mu}{M_\odot}\left(\frac{T}{K}\right)^{7/2}, \tag{11}$$

where $c_v \approx 3k_B/2$ is the specific heat at constant volume. Given an initial L and temperature T_0 at time t_0, final temperature after cooling is given by $(T/\mathrm{K})^{-5/2} - (T_0/\mathrm{K})^{-5/2} = 2.406 \times 10^{-34}\,\tau/\mathrm{s}$, where $\tau = t - t_0$ is the WD age.

The left panel of Figure 6 shows the effect of B-WD evolution on their mass-radius relations including both magnetic field decay and thermal cooling effects. The luminosities are varied with field strength such that the masses can match those obtained for the non-magnetized WDs. For $B = (B_s, B_0) = (10^9, 10^{14})\,\mathrm{G}$, although the maximum mass $\sim 1.9\,M_\odot$ shown in the track at small radius turns out to be much larger than the Chandrasekhar limit, we find that it is lowered considerably

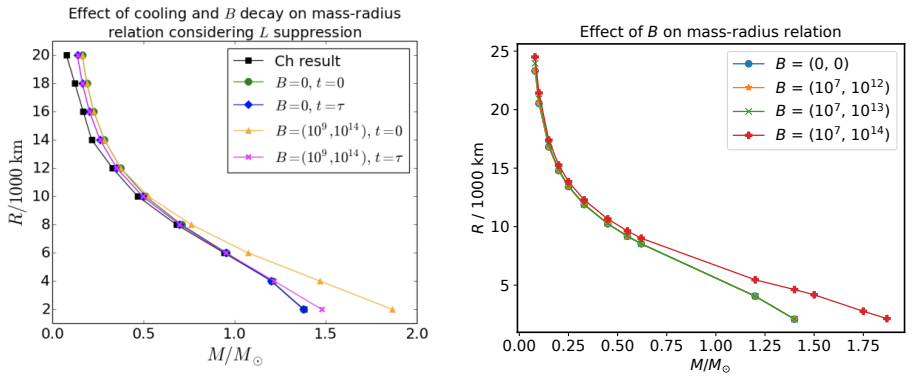

Fig. 6. *Left panel:* The effect of magnetic field on the WD luminosity set to match with the non-magnetised mass–radius relation for the analytical model. The results are shown for $B = (0, 0)$ at initial time $t = 0$ (green circles), $B = (0, 0)$ at $t = 10$ Gyr (blue diamonds), $B = (10^9, 10^{14})$ G at $t = 0$ (orange triangles) and $B = (10^9, 10^{14})$ G at $t = 10$ Gyr (magenta crosses). *Right panel:* STARS results to show the effect of magnetic field on the mass–radius relation of highly magnetized WDs for $B = (0, 0)$ (blue circles), $B = (10^7, 10^{12})$ G (orange stars), $B = (10^7, 10^{13})$ G (green crosses) and $B = (10^7, 10^{14})$ G (red pluses).

to $\sim 1.5\,M_\odot$ primarily as a result of magnetic field decay and also thermal cooling over $t = 10$ Gyr.

Further, we use the STARS stellar evolution code to qualitatively investigate the B-WD mass-radius relationship at different field strengths, with the objective of numerically validating our semi-analytical models. In the right panel of Figure 6, we show the mass-radius relations obtained from STARS. We obtain results that are in good agreement with our analytical formalism and the magnitude of B_0 dictates the shape of the mass-radius curve. In validation of our analytical approach, we have found that the limiting mass $\sim 1.8703\,M_\odot$ obtained with the STARS numerical models is in very good agreement with $M \approx 1.87\,M_\odot$ that is inferred from the semi-analytical calculations for WDs with strong fields $B = (10^{6-9}, 10^{14})$ G. We argue that the young super-Chandrasekhar B-WDs only sustain their large masses up to $\sim 10^5 - 10^6$ yr, and this essentially explains their apparent scarcity even without the difficulty of detection owing to their suppressed luminosities.

6. Continuous gravitational waves from magnetized white dwarfs

The question then remains, how to detect B-WDs directly. Continuous gravitational waves can be among the alternate ways to detect super-Chandrasekhar WD candidates directly. If these B-WDs are rotating with certain angular frequency, then they can efficiently emit gravitational radiation, provided that their magnetic field and rotation axes are not aligned,[48] and these gravitational waves can be detected by upcoming instruments such as LISA, BBO, DECIGO, Einstein Telescope, etc. The dimensionless amplitudes of the two polarizations of the gravitational wave

(GW) at a time t are given by[48,49]

$$h_+ = h_0 \sin\chi \left[\frac{1}{2}\cos i \sin i \cos\chi \cos\Omega t - \frac{1+\cos^2 i}{2}\sin\chi\cos 2\Omega t\right],$$
$$h_\times = h_0 \sin\chi \left[\frac{1}{2}\sin i \cos\chi \sin\Omega t - \cos i \sin\chi \sin 2\Omega t\right], \quad (12)$$

with $h_0 = (-6G/c^4)Q_{z'z'}(\Omega^2/d)$, where $Q_{z'z'}$ is the quadrupole moment of the distorted star, χ is the angle between the rotation axis z' and the body's third principal axis z, i is the angle between the rotation axis of the object and our line of sight. The left panel of Figure 7 shows a schematic diagram of a pulsar with z' being the rotational axis and z the magnetic field axis, where the angle between these two axes is χ. The GW amplitude is

$$h_0 = \frac{4G}{c^4}\frac{\Omega^2 \epsilon I_{xx}}{d}, \quad (13)$$

where $\epsilon = (I_{zz} - I_{xx})/I_{xx}$ is the ellipticity of the body and I_{xx}, I_{yy}, I_{zz} are the principal moments of inertia. Note, we have used the XNS code[50] to simulate the underlying axisymmetric equilibrium configuration of B-WDs in general relativity. Moreover, we assume the distance between the WD and the detector to be 100 pc.

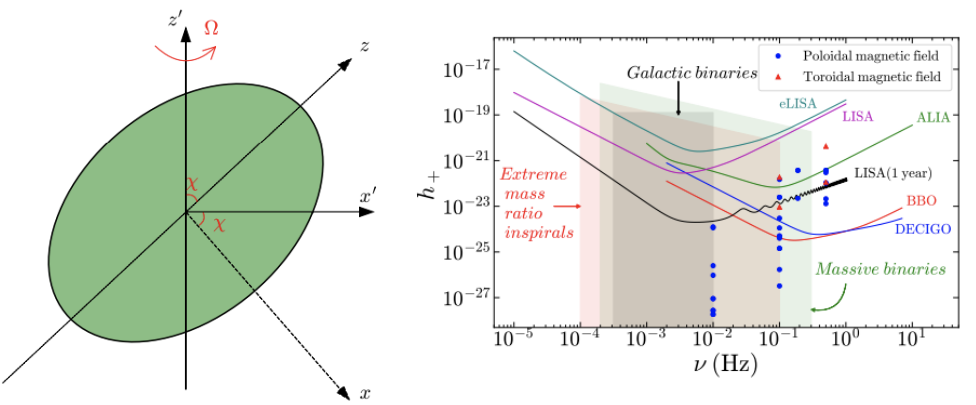

Fig. 7. *Left panel:* Schematic diagram of a B-WD with z' being the rotational axis and z the magnetic axis. *Right panel:* The dimensionless GW amplitudes for WDs are shown as functions of frequency, along with the sensitivity curves of various detectors. Optimum i is chosen for χ at $t = 0$.

Since a pulsating WD can emit both dipole and gravitational radiations simultaneously, it is associated with both dipole and quadrupolar luminosities. The dipole luminosity for an axisymmetric WD is given by[51]

$$L_D = \frac{B_p^2 R_p^6 \Omega^4}{2c^3}\sin^2\chi\, F(x_0), \quad (14)$$

where $x_0 = R_0\Omega/c$, B_p is the magnetic field strength at the pole, R_p is radius of the pole and R_0 is the average WD radius. The function $F(x_0)$ is defined as

$$F(x_0) = \frac{x_0^4}{5(x_0^6 - 3x_0^4 + 36)} + \frac{1}{3(x_0^2 + 1)}. \tag{15}$$

Similarly, the quadrupolar GW luminosity is given by[49]

$$L_{GW} = \frac{2G}{5c^5}(I_{zz} - I_{xx})^2\Omega^6 \sin^2\chi\,(1 + 15\sin^2\chi). \tag{16}$$

It should be noted that this formula is valid if χ is very small. The total luminosity is due to both dipole and gravitational radiations. Therefore, the changes in Ω and χ with time are dependent on both L_D and L_{GW}. The variations of Ω and χ with respect to time are given by[51]

$$\frac{d(\Omega I_{z'z'})}{dt} = -\frac{2G}{5c^5}(I_{zz} - I_{xx})^2\Omega^5 \sin^2\chi\,(1 + 15\sin^2\chi) - \frac{B_p^2 R_p^6 \Omega^3}{2c^3}\sin^2\chi\,F(x_0), \tag{17}$$

$$I_{z'z'}\frac{d\chi}{dt} = -\frac{12G}{5c^5}(I_{zz} - I_{xx})^2\Omega^4 \sin^3\chi\cos\chi - \frac{B_p^2 R_p^6 \Omega^2}{2c^3}\sin\chi\cos\chi\,F(x_0), \tag{18}$$

where $I_{z'z'}$ is the moment of inertia about z'-axis. Equations (17) and (18) need to be solved simultaneously to obtain the timescale over which a WD can radiate.

The right panel of Figure 7 shows the dimensionless GW amplitudes for the WDs as functions of their frequencies, along with the sensitivity curves of various detectors. It can be seen that the isolated WDs may not be detected directly by LISA, but can be detected after integrating the signal to noise ratio S/N for 1 year. As WDs are larger in size compared to NS, they cannot rotate as fast as NS and hence ground-based GW detectors such as LIGO, Virgo and KAGRA are not expected to detect the isolated WDs. These isolated WDs are also free from the noise due to the galactic binaries as well as from the extreme mass ratio inspirals (EMRIs).

7. Summary and conclusions

We have shown that highly magnetized, stable WDs, namely B-WDs, have a variety of implications, including enigmatic peculiar over-luminous SNe Ia. Numerical simulations utilizing the stellar evolution code STARS indicate that the central field in strongly magnetized B-WDs can be toroidally dominated whereas the surface fields are more of dipole nature. The mass $\sim 1.87\,M_\odot$ obtained for these B-WDs from the STARS numerical models, as of now, is totally consistent with the estimates from the analytical stellar structure models for strong fields $B = (10^{6-9}, 10^{14})$ G. These young super-Chandrasekhar B-WDs have suppressed luminosities and are difficult to observe or rare, due to their decaying magnetic fields. We have found that these WDs may not remain super-Chandrasekhar for long i.e. beyond $\sim 10^{5-6}$ year due to

decaying field primarily, and indicate rapidly losing pulsar nature and/or low luminosity. However, these stars can be very promising candidates for GW detectors such as LISA (with 1 year integrated S/N) and also for Einstein Telescope and future DECIGO/BBO missions. Therefore, appropriate missions in GW astronomy and otherwise, e.g. radio astronomy, should be planned in order to probe them in the future.

Electron captures by atomic nuclei in dense matter are among the most important processes governing the late evolution of stars, limiting in particular the stability of white dwarfs. Despite considerable progress in the determination of the equation of state of dense Coulomb plasmas, the threshold electron Fermi energies are still generally estimated from the corresponding Q values in vacuum. Moreover, most studies have focused on nonmagnetized matter. However, some white dwarfs are endowed with magnetic fields reaching 10^9 G. Even more extreme magnetic fields might exist in super Chandrasekhar white dwarfs, the progenitors of overluminous type Ia supernovae like SN 2006gz and SN 2009dc. The roles of the dense stellar medium and magnetic fields on the onset of electron captures and on the structure of white dwarfs are briefly reviewed. New analytical formulas are derived to evaluate the threshold density for the onset of electron captures for arbitrary magnetic fields. Their influence on the structure of white dwarfs is illustrated by simple analytical formulas and numerical calculations.

Keywords: White dwarf; Chandrasekhar limit; Electron capture; Magnetic field.

1. Introduction

In 1926, the British physicist Ralph Fowler showed that the energy and the pressure of matter in the dense core of a white dwarf remain finite at zero temperature due to quantum mechanics. Considering that electrons are no longer bound to nuclei under such extreme conditions, he derived the equation of state of a degenerate electron Fermi gas.[1] Another British physicist, Edmund Clifton Stoner, calculated the

structure of white dwarfs with uniform density in 1929.[2] The same year, Wilhelm Anderson, a physicist at the University of Tartu in Estonia, first stressed the importance of taking into account the relativistic motion of electrons.[3] He showed that the mass of a white dwarf tends to some finite value as the electron concentration increases, namely $M_{\rm And} \sim 0.69 M_\odot$ assuming an electron fraction $y_e = 0.4$ (with $M_\odot$ the mass of the Sun). Improving Anderson's approximate treatment, Stoner[4] found $M_{\rm St} \simeq 1.10 M_\odot$. Soon afterwards, the young Indian physicist Subrahmanyan Chandrasekhar solved the hydrostatic equilibrium equations for an ultrarelativistic electron Fermi gas using the theory of polytropes.[5] His numerical result, $M_{\rm Ch} \simeq 0.91 M_\odot$ (for $y_e = 0.4$), thus differed by less than 20% from that obtained earlier by Stoner, a remarkably close agreement as pointed out by Chandrasekhar himself. A year later, the Russian physicist Lev Landau showed that any degenerate star has a maximum mass, which can be expressed in terms of the fundamental constants as

$$M_{\rm L} = 3.1 \frac{m_{\rm P}^3}{m^2} y_e^2 \,, \tag{1}$$

where we have introduced the Planck mass

$$m_{\rm P} = \sqrt{\frac{\hbar c}{G}} \,, \tag{2}$$

($\hbar$ is the Planck-Dirac constant, c is the speed of light, G is the constant of gravitation) and m is the average mass per nucleon. Incidentally, such a scaling was already apparent in Stoner's analysis of a uniform density star. Combining his equations (17) and (19b) leads to

$$M_{\rm St} = \frac{15\sqrt{5\pi}}{16} \frac{m_{\rm P}^3}{m^2} y_e^2 \,. \tag{3}$$

Landau however did not believe in the physical reality of this limit and even invoked some violation of the laws of quantum mechanics inside massive stars to prevent them from collapsing (see Ref. 6 for a historical perspective on Landau's contribution). As early as 1928, the process by which atoms are crushed at high densities was actually discussed by the Russian physicist Yakov Frenkel.[7] More importantly, he calculated the equation of state of an electron Fermi gas for an arbitrary degree of relativistic motion as well as the correction due to electrostatic interactions between electrons and atomic nuclei. He also studied the conditions for which incompressible "superdense stars" can exist and derived indirectly the mass limit. Correcting for an error in his expression for the gravitational energy[a] and neglecting the electrostatic correction lead to the same result as the one published by Stoner in 1930. Frenkel's pioneer work remained unnoticed during several decades, and is still not very well-known today.[8]

[a] The factor 5/3 in his key equation (19a) should read 3/5; this error goes back to his incorrect expression (18) for the gravitational energy.

The analyses of Anderson and Stoner showed that the maximum mass of white dwarfs is only reached asymptotically when the electron concentration tends to infinity and the stellar radius goes to zero. This conclusion was later confirmed by the numerical calculations of Chandrasekhar for more realistic density profiles.[9] However, soon after the discovery of the neutron by James Chadwick in 1932, it was realized that matter becomes predominantly composed of neutrons at high densities.[10,11] In December 1933, during a meeting of the American Physical Society at Stanford, Wilhelm Baade and Fritz Zwicky predicted the existence of *neutron stars* formed from the catastrophic gravitational collapse of stars during supernova explosions.[12] Baade and Zwicky were apparently unaware of the studies about white dwarfs. The connection was first made by Landau[13] and Gamow.[14] At a conference in Paris in 1939, Chandrasekhar also pointed out[15]:

> If the degenerate core attains sufficiently high densities, the protons and electrons will combine to form neutrons. This would cause a sudden diminution of pressure resulting in the collapse of the star to a neutron core.

In 1956, the French physicist Evry Schatzman[16] showed that the central density of white dwarfs is limited by the onset of electron captures by nuclei, implying that the radius of the most massive white dwarfs remains *finite*. Detailed calculations of the structure of white dwarfs taking into account matter neutronization were performed at the end of the 1950s and at the beginning of the 1960s.[17–19] Electron captures are now known to play a key role in the late stages of stellar evolution (see Ref. 20 for a recent review).

Although the electrostatic correction to the equation of state of an electron Fermi gas was calculated long ago[7] (see Ref. 21 and references therein for the latest developments on the equation of state of dense Coulomb plasmas), the threshold electron Fermi energy μ_e for the onset of electron captures by nuclei is still generally estimated from the corresponding Q value in *vacuum*. Moreover, the presence of magnetic fields is usually ignored. However, a significant fraction of white dwarfs have been found[22] to have magnetic fields up to 10^9 G, and potentially much stronger fields may exist in their core.[23] Moreover, it has been recently proposed that very massive so-called super-Chandrasekhar white dwarfs (with a mass $M \gtrsim 2M_\odot$) endowed with extremely strong magnetic fields could be the progenitors of overluminous type Ia supernovae like SN 2006gz and SN 2009dc[24–26] (see also Refs. 27–30). The existence of such stars was actually first studied much earlier by Shul'man,[31] who found that the maximum mass of degenerate stars could be increased by two orders of magnitude if the magnetic field is strongly quantizing.[32,33] However, the stability of such super Chandrasekhar white dwarfs will still be limited by electron captures.[34,35] Detailed calculations of the global structure of these stars taking these processes into account have been carried out in Refs. 36, 37.

In this paper, we review our recent studies of the role of electron-ion interactions and magnetic fields in the onset of electron captures in cold white-dwarf cores.[36,38]

We also present more accurate and more general formulas for the threshold density and pressure, applicable not only to nonmagnetic and strongly magnetized white dwarfs but also to stars with intermediate magnetic field strengths. The impact of electron captures on the global structure of white dwarfs is discussed and new numerical results are presented.

2. Core of white dwarfs with magnetic fields

The core of a white dwarf consists of a dense Coulomb plasma of nuclei in a charge compensating background of relativistic electrons. Apart from carbon and oxygen (the primary ashes of helium burning), the core may contain other nuclei like helium,[39–41] neon and magnesium,[42] or even iron.[43,44] Iron white dwarfs could be formed from the explosive ignition of electron degenerate oxygen-neon-magnesium cores,[45] or from failed detonation supernovae.[46] For simplicity, we assume that the stellar core is made of only one type of nuclei with charge number Z and mass number A (see, e.g. Ref. 38 for the treatment of mixtures). We further suppose that the star has sufficiently cooled down such that thermal effects can be neglected.

Whereas nuclei with number density n_N exert a negligible pressure $P_N = 0$, they contribute to the mass density

$$\rho = n_N M'(A, Z)\,, \tag{4}$$

where $M'(A, Z)$ denotes the ion mass including the rest mass of Z electrons and can be obtained from the experimental *atomic* mass $M(A, Z)$ by subtracting out the binding energy of the atomic electrons (see Eq. (A4) of Ref. 47). In principle, the presence of a magnetic field can have some effect on nuclei.[48,49] However, the change of nuclear masses is negligible even for the strongest magnetic fields of order 10^{15} G expected in super Chandrasekhar white dwarfs.[29,36,50]

To a very good approximation, electrons can be treated as an ideal Fermi gas. In the presence of a magnetic field, the electron motion perpendicular to the field is quantized into Landau-Rabi levels.[51,52] Quantization effects on the equation of state are significant when B exceeds $B_{\rm rel}$, where

$$B_{\rm rel} \equiv \frac{m_e^2 c^3}{e\hbar} \approx 4.4 \times 10^{13}\ {\rm G}\,, \tag{5}$$

where m_e is the electron mass and e is the elementary electric charge. The expressions for the energy density $\mathcal{E}_e$ and pressure P_e for arbitrary magnetic field strength can be found in Ref. 53.

The main correction to the ideal electron Fermi gas arises from the electron-ion interactions, as first shown by Frenkel[7] (see e.g. Ref. 53 for a discussion of higher-order corrections). For pointlike ions embedded in a uniform electron gas with number density $n_e = Z n_N$ (from electric charge neutrality), the corresponding energy density is given by (see e.g. Chap. 2 of Ref. 53)

$$\mathcal{E}_L = C_M \left(\frac{4\pi}{3}\right)^{1/3} e^2 n_e^{4/3} Z^{2/3}\,, \tag{6}$$

where C_M is the Madelung constant. The contribution to the pressure is thus given by

$$P_L = n_e^2 \frac{d(\mathcal{E}_L/n_e)}{dn_e} = \frac{\mathcal{E}_L}{3}\,. \tag{7}$$

The pressure of the Coulomb plasma finally reads $P = P_e + P_L$.

In the following, we shall consider that ions are arranged in a body-centered cubic lattice since this configuration leads to the lowest energy.[53] In this case, the Madelung constant is given by[54] $C_M = -0.895929255682$. According to the Bohr-van Leeuwen theorem,[55] the electrostatic corrections (6) and (7) are independent of the magnetic field apart from a negligibly small contribution due to quantum zero-point motion of ions about their equilibrium position.[56]

3. Onset of electron captures by nuclei in dense environments

The onset of electron captures by nuclei (A, Z) is formally determined by the same condition irrespective of the magnetic field strength by requiring the constancy of the Gibbs free energy per nucleon at fixed temperature and pressure.[38] The threshold electron Fermi energy is found to first order in the fine-structure constant $\alpha = e^2/(\hbar c)$ from the condition:

$$\gamma_e + C_M \left(\frac{4\pi n_e}{3}\right)^{1/3} \alpha \lambda_e F(Z) = \gamma_e^\beta(A, Z)\,, \tag{8}$$

$$F(Z) \equiv Z^{5/3} - (Z-1)^{5/3} + \frac{1}{3} Z^{2/3}\,, \tag{9}$$

$$\gamma_e^\beta(A, Z) \equiv -\frac{Q_{\rm EC}(A, Z)}{m_e c^2} + 1\,, \tag{10}$$

where $\gamma_e \equiv \mu_e/(m_e c^2)$, $\lambda_e = \hbar/(m_e c)$ is the electron Compton wavelength, and we have introduced the Q-value (in vacuum) associated with electron capture by nuclei (A, Z):

$$Q_{\rm EC}(A, Z) = M'(A, Z)c^2 - M'(A, Z-1)c^2\,. \tag{11}$$

These Q-values can be obtained from the tabulated Q-values of β decay by the following relation:

$$Q_{\rm EC}(A, Z) = -Q_\beta(A, Z-1)\,. \tag{12}$$

In principle, the daughter nucleus may be in an excited state. However, such a transition would occur at a higher density.

In the absence of magnetic fields, the threshold condition (8) can be solved analytically.[57] Recalling that the electron Fermi energy is given by

$$\mu_e = m_e c^2 \sqrt{1 + x_r^2}\,, \tag{13}$$

where $x_r = \lambda_e k_e$ and $k_e = (3\pi^2 n_e)^{1/3}$ is the electron Fermi wave number, the solution reads

$$x_r^\beta = \gamma_e^\beta \left\{ \sqrt{1 - \left[1 - \tilde{F}(Z)^2\right]/(\gamma_e^\beta)^2} - \tilde{F}(Z) \right\} \left[1 - \tilde{F}(Z)^2\right]^{-1}, \tag{14}$$

with

$$\tilde{F}(Z) \equiv C_M \left(\frac{4}{9\pi}\right)^{1/3} \alpha F(Z)\,. \tag{15}$$

The pressure $P_\beta(A, Z)$ at the onset of electron captures is given by

$$P_\beta(A,Z) = \frac{m_e c^2}{8\pi^2 \lambda_e^3} \left[x_r^\beta \left(\frac{2}{3}(x_r^\beta)^2 - 1 \right) \sqrt{1 + (x_r^\beta)^2} + \ln(x_r^\beta + \sqrt{1 + (x_r^\beta)^2}) \right] + \frac{C_M \alpha}{3} \left(\frac{4}{243\pi^7}\right)^{1/3} (x_r^\beta)^4 \frac{m_e c^2}{\lambda_e^3} Z^{2/3}\,. \tag{16}$$

The corresponding average mass density is found from Eq. (4) and is given by

$$\rho_\beta(A,Z) = \frac{M'(A,Z)}{Z} \frac{(x_r^\beta)^3}{3\pi^2 \lambda_e^3}\,. \tag{17}$$

Numerical results are summarized in Table 1 for nuclei expected to be found in the core of white dwarfs, using data from the 2020 Atomic Mass Evaluation.[58] Fundamental constants were taken from NIST CODATA 2018[b]. We have not considered helium since this element is expected to undergo pycnonuclear fusion in white-dwarf cores before capturing electrons.

Table 1. Dimensionless threshold electron Fermi energy $\gamma_e = \mu_e/(m_e c^2)$, mass density ρ_β and pressure P_β for the onset of electron captures by the given nuclei in unmagnetized white dwarfs.

	^{16}O	^{12}C	^{20}Ne	^{24}Mg	^{56}Fe
γ_e	22.0	27.8	15.2	12.2	8.74
ρ_β [g cm^{-3}]	2.06×10^{10}	4.16×10^{10}	6.81×10^{9}	3.51×10^{9}	1.37×10^{9}
P_β [dyn cm^{-2}]	2.73×10^{28}	6.99×10^{28}	6.21×10^{27}	2.56×10^{27}	6.46×10^{26}

In the presence of a magnetic field, the threshold condition (8) must be solved using the following relation between n_e and γ_e:

$$n_e = \frac{2B_\star}{(2\pi)^2 \lambda_e^3} \sum_{\nu=0}^{\nu_{\max}} g_\nu x_e(\nu)\,, \tag{18}$$

$$x_e(\nu) = \sqrt{\gamma_e^2 - 1 - 2\nu B_\star}\,, \tag{19}$$

[b] https://physics.nist.gov/cuu/Constants/index.html

where we have introduced $B_\star \equiv B/B_{\rm rel}$, and the degeneracy $g_\nu = 1$ for $\nu = 0$ and $g_\nu = 2$ for $\nu \geq 1$. The index $\nu_{\rm max}$ is the highest integer for which $\gamma_e^2 - 1 - 2\nu_{\rm max} B_\star \geq 0$, i.e.

$$\nu_{\rm max} = \left[\frac{\gamma_e^2 - 1}{2B_\star} \right], \tag{20}$$

where [.] denotes the integer part.

In the weakly quantizing regime meaning that many Landau-Rabi levels are populated ($\nu_{\rm max} \gg 1$), analytical solutions can be found. Remarking that the magnetic field enters explicitly in (8) only through the small electrostatic correction, the threshold electron Fermi energy is still approximately given by the solution in the absence of magnetic fields, namely $\gamma_e \approx \sqrt{1 + (x_r^\beta)^2}$ with x_r^β given by (14). Substituting in Eqs. (18) and (19), using the expansions (41) obtained in Ref. 59 leads to the following estimate for the density marking the onset of electron captures:

$$\rho_\beta(A,Z) \approx \frac{M'(A,Z)}{2\pi^2 Z \lambda_e^3} \left[\frac{2}{3} \left(\gamma_e^2 - 1 \right)^{3/2} + (2B_\star)^{3/2} \zeta \left(\frac{-1}{2}, \left\{ \frac{\gamma_e^2 - 1}{2B_\star} \right\} \right) + \frac{B_\star^2}{6\sqrt{\gamma_e^2 - 1}} \right], \tag{21}$$

where $\zeta(z,q)$ is the Hurwitz zeta function defined by

$$\zeta(z,q) = \sum_{\nu=0}^{+\infty} \frac{1}{(\nu+q)^z} \tag{22}$$

for $\Re(z) > 1$ and by analytic continuation to other $z \neq 1$ (excluding poles $\nu + q = 0$), and $\{.\}$ in the argument denotes the fractional part. The first term in Eq. (21) represents the threshold density in the absence of magnetic field. The second term accounts for magnetic oscillations while the last term is a higher-order correction. The expression for the associated pressure is more involved. Using Eqs. (41), (43) and (44) of Ref. 59 yields[c]

$$\begin{aligned} P_\beta(A,Z) \approx \frac{m_e c^2}{4\pi^2 \lambda_e^3} \Bigg\{ & \frac{1}{2} \left(1 - 2B_\star + \frac{2B_\star^2}{3} \right) \log \left(\frac{\gamma_e + \sqrt{2B_\star + \gamma_e^2 - 1}}{1 + \sqrt{2B_\star}} \right) \\ & - \frac{1}{2} \left(\gamma_e \sqrt{2B_\star + \gamma_e^2 - 1} - \sqrt{2B_\star} \right) + \frac{1}{3} \left(\gamma_e \sqrt{2B_\star + \gamma_e^2 - 1}^3 - \sqrt{2B_\star}^3 \right) \\ & + B_\star \left(\operatorname{arccosh} \gamma_e - \gamma_e \sqrt{\gamma_e^2 - 1} \right) - (2B_\star)^{5/2} \int_0^{+\infty} \frac{\tilde{\zeta}_3(-1/2, q+1)}{\sqrt{1 + 2B_\star q}} dq \end{aligned}$$

[c]In the notations of Ref. 59, the electron contribution to the pressure can be directly obtained from the grand potential density by $P_e = -\omega_0^{(\rm mon)} - \omega_0^{(\rm osc)}$. The total pressure is found by adding the electrostatic correction (7) using the expansion for the electron density.

$$+\frac{2}{3}\frac{(2B_\star)^{5/2}}{\gamma_e}\zeta\left(\frac{-3}{2},\left\{\frac{\gamma_e^2-1}{2B_\star}\right\}\right)+\frac{2}{15}\frac{(2B_\star)^{7/2}}{\gamma_e^3}\zeta\left(\frac{-5}{2},\left\{\frac{\gamma_e^2-1}{2B_\star}\right\}\right)$$
$$+\frac{1}{240}\left(\frac{B_\star}{\gamma_e}\right)^4+4B_\star^2\int_0^1\zeta\left(\frac{-1}{2},q\right)\zeta\left(\frac{1}{2},q+\frac{1}{2B_\star}\right)dq$$
$$+\frac{2}{3}\left(\frac{2}{3\pi}\right)^{1/3}C_M\alpha Z^{2/3}\left[\frac{2}{3}\left(\gamma_e^2-1\right)^{3/2}\right.$$
$$\left.+(2B_\star)^{3/2}\zeta\left(\frac{-1}{2},\left\{\frac{\gamma_e^2-1}{2B_\star}\right\}\right)+\frac{B_\star^2}{6\sqrt{\gamma_e^2-1}}\right]^{4/3}\Bigg\}, \tag{23}$$

with

$$\tilde{\zeta}_3(z,q)=\zeta(z,q)-\frac{1}{z-1}q^{-z+1}-\frac{1}{2}q^{-z}-\frac{z}{12}q^{-z-1}\,. \tag{24}$$

An analytical solution also exists in the strongly quantizing regime whereby electrons are all confined to the lowest Landau-Rabi level ($\nu_{\max}=0$). Introducing

$$\bar{F}(Z,B_\star)\equiv\frac{1}{3}C_M\alpha F(Z)\left(\frac{2B_\star}{3\pi}\right)^{1/3}<0\,, \tag{25}$$

$$\upsilon\equiv\frac{\gamma_e^\beta}{2|\bar{F}(Z,B_\star)|^{3/2}}\,, \tag{26}$$

the solutions are given by the following formulas[60]:

$$\gamma_e=\begin{cases}8|\bar{F}(Z,B_\star)|^{3/2}\cosh^3\left(\frac{1}{3}\operatorname{arccosh}\upsilon\right) & \text{if } \upsilon\geq 1\,,\\ 8|\bar{F}(Z,B_\star)|^{3/2}\cos^3\left(\frac{1}{3}\arccos\upsilon\right) & \text{if } 0\leq\upsilon<1\,.\end{cases} \tag{27}$$

The threshold pressure and density are respectively given by:

$$P_\beta(A,Z,B_\star)=\frac{B_\star m_e c^2}{4\pi^2\lambda_e^3}\left[\gamma_e\sqrt{\gamma_e^2-1}-\ln\left(\sqrt{\gamma_e^2-1}+\gamma_e\right)\right.$$
$$\left.+\frac{C_M\alpha}{3}\left(\frac{16B_\star Z^2}{3\pi}\right)^{1/3}\left(\gamma_e^2-1\right)^{2/3}\right], \tag{28}$$

$$\rho_\beta(A,Z,B_\star)=\frac{B_\star}{2\pi^2\lambda_e^3}\frac{M'(A,Z)}{Z}\sqrt{\gamma_e^2-1}\,. \tag{29}$$

Let us recall that Eq. (27) is only valid if all electrons lie in the lowest Landau-Rabi level, i.e. if their Fermi energy does not exceed $\gamma_e=\sqrt{1+2B_\star}\approx\sqrt{2B_\star}$ or equivalently if their density does not exceed $n_e=B_\star^{3/2}/(\sqrt{2}\pi^2\lambda_e^3)$ using Eqs. (18) and (19).

This condition translates into a lower bound for the magnetic field $B_\star \geq B_{\star 1}$. To find $B_{\star 1}$, we substitute the above expressions for γ_e and n_e in Eq. (8). This leads to

$$B_{\star 1} = \frac{(\gamma_e^\beta)^2}{2}\left[1 + \frac{C_M \alpha}{(3\pi)^{1/3}} F(Z)\right]^{-2}. \tag{30}$$

Values for some nuclei are summarized in Table 2. For magnetic field strength $B_\star \lesssim B_{\star 1}$, the threshold condition (8) must be solved numerically.

Table 2. Magnetic field strength in units of $B_{\rm rel}$ above which electrons are confined to the lowest Rabi level when captured by the given nuclei.

Full results for different nuclei expected to be found in white-dwarf cores are shown in Figs. 1 and 2. Changes in the occupation of Rabi levels as the magnetic field is increased lead to typical oscillations of the threshold density ρ_β: the onset of electron captures can thus be shifted to either lower or higher density as compared to unmagnetized matter. The lowest value is reached for $B_\star = B_{\star 1}$ and lies about 25% below the threshold density in the absence of magnetic fields irrespective of the composition (this can be easily shown by taking the ratio of Eqs. (29) and (17) using (30) and ignoring all terms in α). In the strongly quantizing regime, ρ_β is unbound from above and increases almost linearly with $B_\star$.

4. Global structure of white dwarfs

The core of a white dwarf is expected to be surrounded by a helium mantle and an hydrogen envelope. Their contribution to the mass of the star cannot exceed $\sim 1\%$ to avoid a thermonuclear runaway. For simplicity, we will ignore these layers here.

In the model originally considered by Chandrasekhar,[5] the interior of a white dwarf was described using the equation of state of an ideal electron Fermi gas. The composition, assumed to be uniform, was only included throughout the charge neutrality condition. In the ultrarelativistic limit, the resulting equation of state reduces to the polytropic form $P \approx K_0 \rho^{4/3}$ with

$$K_0 = \frac{\hbar c (3\pi^2)^{1/3}}{4} \left(\frac{Z}{M'(A,Z)} \right)^{4/3} . \tag{31}$$

The mass and radius of a white dwarf with central density ρ_c can be deduced from the theory of polytropes[61]

$$M_{\rm Ch} = 4\pi \left(\frac{K_0}{\pi G} \right)^{3/2} \xi_1^2 |\theta'(\xi_1)| \, , \tag{32}$$

$$R_{\rm Ch} = \sqrt{\frac{K_0}{\pi G}} \frac{\xi_1}{\rho_c^{1/3}} \tag{33}$$

respectively, where $\xi_1 \simeq 6.89685$ and $\xi_1^2 |\theta'(\xi_1)| \simeq 2.01824$. Substituting the expression for K_0 thus yields

$$M_{\rm Ch} = \frac{\sqrt{3\pi}}{2} \xi_1^2 |\theta'(\xi_1)| \frac{m_{\rm P}^3}{m^2} y_e^2 \simeq 3.09798 \frac{m_{\rm P}^3}{m^2} y_e^2 \, , \tag{34}$$

$$R_{\rm Ch} = \frac{\sqrt{3\pi}}{2} \xi_1 \lambda_e \frac{m_{\rm P}}{m} \frac{y_e}{x_{r,c}} \simeq 10.5866 \lambda_e \frac{m_{\rm P}}{m} \frac{y_e}{x_{r,c}} \, , \tag{35}$$

where

$$m \equiv \frac{M'(A,Z)}{A}\,, \tag{36}$$

and $x_{r,c}$ denotes the relativity parameter at the density ρ_c. Equation (34) coincides with the maximum mass because the ultrarelativistic regime is only valid at high densities such that the relativity parameter in the central core of the star satisfies $x_{r,c} \gg 1$. In the limit $x_{r,c} \to +\infty$, the radius $R_{\rm Ch}$ vanishes.

The electrostatic corrections (6) and (7) can be easily taken into account by simply renormalizing the constant K_0 as

$$K = K_0\left[1 + \alpha\frac{8C_M}{6}\left(\frac{4}{9\pi}\right)^{1/3} Z^{2/3}\right]. \tag{37}$$

The mass and radius thus become[d]

$$M = \left[1 + \alpha\frac{8C_M}{6}\left(\frac{4}{9\pi}\right)^{1/3} Z^{2/3}\right]^{3/2} M_{\rm Ch} < M_{\rm Ch}\,, \tag{38}$$

$$R = R_{\rm Ch}\left[1 + \alpha\frac{8C_M}{6}\left(\frac{4}{9\pi}\right)^{1/3} Z^{2/3}\right]^{1/2} < R_{\rm Ch}\,. \tag{39}$$

This shows how the electron-ion interactions lower both the mass and the radius. It can be seen that the radius of the most massive white dwarfs still vanishes in the limit $x_{r,c} \to +\infty$. However, as discussed earlier, nuclei in the white dwarf core will capture electrons as soon as the central density ρ_c exceeds the threshold density ρ_β. The daughter nuclei are generally unstable against a second electron capture. The transition is accompanied by a discontinuous increase of density given by

$$\frac{\Delta\rho}{\rho_\beta} = \frac{Z}{Z-2}\frac{M'(A,Z-2)}{M'(A,Z)}\left[1 + \alpha C_M\left(\frac{4}{9\pi}\right)^{1/3}\left(Z^{2/3} - (Z-2)^{2/3}\right)\frac{\sqrt{1+x_r^2}}{x_r}\right] - 1\,, \tag{40}$$

where x_r is given by Eq. (14). The density jump is about 50% for carbon, 33% for oxygen, 25% for neon, 20% for magnesium, and 8.2% for iron.

Because these reactions occur at the same pressure, the adiabatic index defined by

$$\Gamma = \frac{d\log P}{d\log\rho} \tag{41}$$

therefore vanishes thus making the star unstable. In the limit of ultrarelativistic electrons, the average threshold density and pressure reduce to

$$\rho_\beta(A,Z) \approx \frac{M'(A,Z)}{Z}\frac{\mu_e^\beta(A,Z)^3}{3\pi^2(\hbar c)^3}\left[1 + \alpha C_M\left(\frac{4}{9\pi}\right)^{1/3} F(Z)\right]^{-3}, \tag{42}$$

[d]Such kind of scaling was briefly mentioned in Ref. 19 through an effective mean molecular weight per electron.

$$P_\beta(A,Z) \approx \frac{\mu_e^\beta(A,Z)^4}{12\pi^2(\hbar c)^3}\left[1+4C_M\alpha Z^{2/3}\left(\frac{4}{243\pi}\right)^{1/3}\right]\left[1+\alpha C_M\left(\frac{4}{9\pi}\right)^{1/3}F(Z)\right]^{-4}. \tag{43}$$

Substituting Eq. (42) in (39) using (35) leads to the following lower bound for the radius of a white dwarf:

$$R_{\min} = \frac{\sqrt{3\pi}}{2}\xi_1\lambda_e\frac{m_{\rm P}}{m}\frac{y_e}{\gamma_e^\beta(A,Z)}\left[1+\alpha C_M\left(\frac{4}{9\pi}\right)^{1/3}F(Z)\right] \times\left[1+\alpha\frac{8C_M}{6}\left(\frac{4}{9\pi}\right)^{1/3}Z^{2/3}\right]^{1/2}. \tag{44}$$

The factors in square brackets account for the electron-ion interactions: the first arises from the shift in the threshold density for the onset of electron captures whereas the second is due to the correction to the equation of state. Both factors lead to a reduction of the radius. Results of Eq. (44) are summarized in Table 3.

Table 3. Minimum radius (in km) of nonmagnetic stable white dwarfs.

^{12}C	^{16}O	^{20}Ne	^{24}Mg	^{56}Fe
958	1209	1743	2168	2791

The mass remains unchanged since it does not depend on the density and is still given by Eq. (38). However, departure from the polytropic equation of state $P = K\rho^{4/3}$ and the fact that the central density ρ_c is finite induce a slight reduction of the maximum mass. Following the perturbative approach described in Chapter 6 of Ref. 62 and based on the minimization of some approximation for the total energy of the star, we find

$$\frac{\delta M}{M} \approx -\frac{k_3}{k_2}\frac{3\pi}{(\gamma_e^\beta)^2}\left(\frac{3}{2\xi_1^4|\theta'(\xi_1)|^2}\right)^{1/3}\left[1+\alpha\frac{8C_M}{6}\left(\frac{4}{9\pi}\right)^{1/3}Z^{2/3}\right]^{-1} \times\left[1+\alpha C_M\left(\frac{4}{9\pi}\right)^{1/3}F(Z)\right]^2 \tag{45}$$

where $k_2 = 0.639001$ and $k_3 = 0.519723$. Results are summarized in Table 4. The influence of electron captures and electron-ion interactions are all the more important that matter contains heavier elements: whereas the overall reduction of the Chandrasekhar mass $M_{\rm Ch}$ amounts to 3% for carbon, it reaches 13% for iron.

The stability of a white dwarf can be further limited by general relativity, as first shown by Kaplan.[63] The critical density above which the stellar core becomes unstable can be estimated from the minimization of the total energy. Including the electrostatic correction in Eq.(6.10.28) of Ref. 62 we find

$$\rho_{\rm GR} = \frac{16k_3(k_2)^2}{(3\pi^2)^{2/3}k_4(k_1)^2}\frac{M'(A,Z)^2}{Z^2\lambda_e^3 m_e}\left[1+\alpha\frac{8C_M}{6}\left(\frac{4}{9\pi}\right)^{1/3}Z^{2/3}\right]^{-2}\ {\rm g\ cm^{-3}}, \tag{46}$$

Table 4. Maximum mass (in solar units) of nonmagnetic white dwarfs for an ultra-relativistic electron Fermi gas (first line), with electrostatic correction (second line) and electron captures (third line).

1.413	1.401	1.377	1.353	1.095

where $k_1 = 1.75579$ and $k_4 = 0.918294$. Because $C_M < 0$, electron-ion interactions thus make the star more stable. We have also solved the Tolman-Oppenheimer-Volkoff[64,65] equations for calculating the whole sequence of white dwarfs in full general relativity. In this way, we have determined more accurately the central (mass-energy) density $\rho_{\rm GR}$ at which $dM/d\rho_{\rm GR} = 0$ marking the onset of instability. The hydrostatic equilibrium equations were integrated from the center of the star up to the point where electrons start to bind to nuclei at the density $\rho_{\rm eip} = ZM'(A,Z)/a_0^3$ with a_0 the Bohr radius. Results are collected in Table 5. The values are systematically lower than those estimated from Eq. (46). Comparing Tables 1 and 5 shows that the central density is limited by general relativity rather than electron captures in carbon white dwarfs. Their mass-density relation is plotted in Fig. 3. The minimum radii and maximum masses of white dwarfs with different composition are indicated in Tables 6 and 7 respectively (note that the mass and radius of carbon white dwarfs at the onset of electron captures are respectively $1.484 M_\odot$ and 855 km). For comparison, results obtained by solving numerically the Newtonian hydrostatic equilibrium equations are also given. Examining Tables 3 and 6 reveals that the polytropic approximation is more reliable for estimating the maximum mass than the minimum radius.

Table 5. Highest density $\rho_{\rm GR}$ (in g cm^{-3}) in nonmagnetic stable white dwarfs in general relativity, as calculated by minimization of the approximate total energy (first line) and by solving the hydrostatic equilibrium equations (second line).

The influence of a very strong magnetic field on the structure of white dwarfs was studied in Ref. 24 within the theory of polytropes making use of the fact that $P \propto \rho^2$ in the strongly quantizing regime. However, it was soon realized that this assumption is unrealistic and that the influence of the magnetic field itself on the stellar structure cannot be ignored.[27,34,66–68] Moreover, the magnetic-field configuration inside the

star should be calculated from Maxwell's equations consistently with the stellar equilibrium equations. For all these reasons, the structure of magnetic white dwarfs is not easily amenable to a simple analytical treatment.

To study the influence of strong magnetic fields and the role of electron captures in white dwarfs, we have thus computed fully self-consistently numerical solutions of the Einstein-Maxwell equations using the LORENE library,[69] suitably extended to allow for magnetic-field dependent equations of state and magnetization effects.[70] We have found that purely poloidal magnetic fields of order 10^{14} G lead to super Chandrasekhar white dwarfs with a mass $\sim 2M_\odot$. Although such magnetic fields

have been found to have a rather small influence on the equation of state, they induce extreme stellar deformations with the most massive white dwarfs adopting a donut-like shape.[36] Similarly to nonmagnetic white dwarfs, electron captures limit the maximum mass and the minimum radius of magnetic white dwarfs, as summarized in Table 8. However, the distortion of the star induced by magnetic fields tends to lower their density. For the most extreme configurations, the maximum density thus lies below the threshold density for the onset of electron captures. The mass-radius relations for magnesium and neon white dwarfs are plotted in Fig. 4.

Table 8. Maximum mass (in solar units) of magnetic white dwarfs, as determined by extreme deformations or electron captures (values in parentheses) for different magnetic moments $\mathcal{M}$ in A m^2.

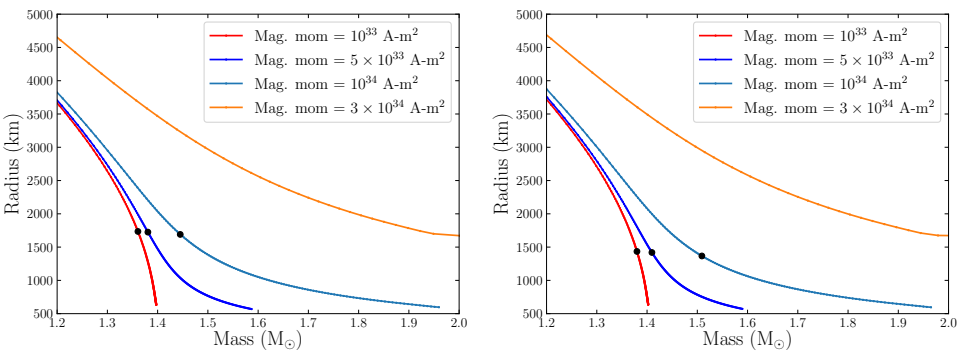

Fig. 4. Radius (in km) versus gravitational mass (in solar units) of white dwarfs for different magnetic moments: (a) for ^{24}Mg, (b) for ^{20}Ne. The onset of electron captures is marked by a filled circle.

The global stability criterion $\partial M/\partial \rho > 0$ still remains valid for magnetic white dwarfs provided the derivatives are evaluated for a fixed magnetic moment $\mathcal{M}$. As shown in Fig. 5, this instability is entirely removed by the presence of strong magnetic fields. In other words, the magnetic field makes the star more stable. In particular, the maximum mass of magnetic white dwarfs made of carbon is not limited by general relativity as their nonmagnetic relatives but by electron captures.

For magnetic white dwarfs to be the progenitors of overluminous type Ia supernova, i.e. to have masses $\sim 2M_\odot$, their magnetic field must be strong enough. Their minimum observable polar magnetic fields are indicated in Table 9 for different compositions. In all cases, the magnetic dipole moment is 3×10^{34} A m^2.

5. Conclusions

The stability of white dwarfs is limited by the onset of electron captures by nuclei in their core. We have presented very accurate analytical formulas for calculating the threshold electron Fermi energy, mass density and pressure in cold dense Coulomb plasmas with magnetic fields, taking into account Landau-Rabi quantization of electron motion. In particular, the density exhibits typical quantum oscillations associated with the filling of energy levels. As a consequence, electron captures in magnetic white dwarfs may occur at a lower or higher density than in their non-magnetic relatives depending on the magnetic field strength. The lowest possible density is found to lie about 25% below its value in the absence of magnetic field essentially independently of the composition. On the contrary, the density is not

limited from above and increases almost linearly with the magnetic field strength in the strongly quantizing regime.

Taking into account electron-ion interactions using the polytropic approximation $P \approx K\rho^{4/3}$ with K given by Eq. (37), we have explicitly shown how electron captures alter the maximum mass of nonmagnetic white dwarfs and set a lower limit to their radius. We have also solved numerically the hydrostatic equilibrium equations using the full equation of state, both in Newtonian theory and in general relativity. We have found that electron captures reduce the maximum mass of white dwarfs by 3-13% compared to the Chandrasekhar model.

Solving the Einstein-Maxwell equations taking into account the magnetization of dense matter, we have found that white dwarfs with purely poloidal magnetic fields can be significantly more massive than their nonmagnetic relatives. We have also shown that the presence of strong magnetic fields makes the star more stable. The maximum mass of magnetic white dwarfs (including those made of carbon) is thus solely limited by electron captures. In turn, the large stellar deformations induced by the strongest magnetic fields lower the stellar density below the electron capture threshold. White dwarfs with polar magnetic fields exceeding 10^{13} G could thus be massive enough to explain overluminuous type Ia supernova independently of the composition of their core. On the other hand, a purely poloidal magnetic-field configuration is unstable. The magnetic field in super Chandrasekhar white dwarfs is expected to have both poloidal and toroidal components. The question as to whether such stars can exist still remains open.

Although the present study was focused on white dwarfs, it may be also of interest for neutron stars as electron captures by nuclei constituting the outer crust of magnetars may explain their persistent luminosity and outbursts.[71] The general analytical formulas for the threshold density and pressure could thus be applied to determine the precise locations of these reactions.

In this work, we investigate the observable white dwarfs with high-surface gravity in the framework of general relativity. We consider the stellar fluid composed of nucleons and electrons confined in a Wigner-Seitz cell surrounded by free photons. Besides, we implement a temperature depending on the mass density with the presence of an isothermal core. The impact of temperature on the equilibrium and stability of white dwarfs is observed. We compare our results with massive white dwarfs estimated from the Extreme Ultraviolet Explorer Survey and Sloan Digital Sky Survey. We find that the high-surface gravity white dwarfs are well described by our curves with higher central temperatures. Our results suggest that these hot massive stars detected are within the range of white dwarfs with more radial stability. Moreover, we note the radial instability is attained before the pycnonuclear reaction for $T_c \geq 1.0 \times 10^8$[K].

Keywords: White dwarfs; charged white dwarfs; type Ia supernovae explosions

Introduction

Observable white dwarfs' structure has been reported in works using the Extreme Ultraviolet Explorer Survey (EUVE) and Sloan Digital Sky Survey (SDSS).[1–4] Some of these stars have a great surface gravity ($\log(g/g_\odot) \geq 4.4$) and a high effective temperature ($T_{\rm eff} \gtrsim 10^4$[K]).[1,2] Due to their high surface gravity, it is important to investigate their instabilities against small radial perturbation and pycnonuclear reactions in general relativity scope considering temperature.

The studies concerning instabilities in white dwarfs[5,6] consider a completely degenerate star. To compare results with observable white dwarfs, we include temperature in the model. Thus, following recent white dwarfs models with finite temperature,[7,8] we analyze the structure and stability of hot white dwarf' and compare

the results with some observable data. In this article, we detail some conclusions of the previous work.[9]

We study the structure and stability of hot massive white dwarfs and we compare our results with those ones reported by EUVE and SDSS. In addition, we made an instability analysis against the pycnonuclear reactions and radial perturbations. We analyze the stellar fluid by considering nucleons and electrons confined in a Wigner-Seitz cell with surrounding free photons. For this case, the pressure and energy density are respectively considered as following

$$P = P_{\rm e} + P_{\rm N} + P_{\gamma} + P_{L}, \tag{1}$$

$$\varepsilon = \varepsilon_{\rm e} + \varepsilon_{\rm N} + \varepsilon_{\gamma} + \varepsilon_{L}, \tag{2}$$

with the subscripts e, N, and γ representing the respective contributions of electrons, nucleons, and photons. Due to the partially degeneracy, the electron contributions are obtained with an adaptive quadrature method.[8]

1. The stellar structure equations and boundary conditions

We consider the unperturbed white dwarf is made of by a perfect fluid, whose energy-momentum tensor is expressed of the form

$$T_{\mu\beta} = (P + \varepsilon)u_{\mu}u_{\beta} + Pg_{\mu\beta}. \tag{3}$$

The background metric employed to describe the spherically symmetric white dwarf, in Schwarzschild-like coordinates, is given by

$$ds^2 = -e^{\nu}dt^2 + e^{\lambda}dr^2 + r^2d\theta^2 + r^2\sin^2\theta d\phi^2, \tag{4}$$

where the functions ν and λ dependent on the radial coordinate only. The nonzero Einstein field equation components, for the line element assumed, lead to obtain the stellar structure equations:

$$\frac{dm}{dr} = 4\pi\varepsilon^2, \tag{5}$$

$$\frac{dP}{dr} = -(P + \varepsilon)\left[4\pi rp + \frac{m}{r^2}\right]e^{\lambda}, \tag{6}$$

$$\frac{d\nu}{dr} = -\frac{2}{(p + \varepsilon)}\frac{dP}{dr}, \tag{7}$$

being m the mass inside the radius r. The potential metric e^{λ} is described as

$$e^{\lambda} = \left[1 - \frac{2m}{r}\right]^{-1}. \tag{8}$$

Since we are considering a temperature distribution T dependent on mass density ρ with the presence of an isothermal core, we assume that the parameters T and ρ are related by the equality

$$T/\rho^{2/3} = \text{constant}. \tag{9}$$

The process starts integrating the stellar structure equations from the center ($r = 0$) until the surface of the star ($r = R$). At the center of the star are considered the initial conditions:

$$m(0) = 0, \;\; \varepsilon(0) = \varepsilon_0, \text{ and } \nu(0) = \nu_0. \tag{10}$$

The surface of the star is determined at $P(r = R) = 0$.

2. Results

Due to our analysis be restricted to very massive WD, we can use a simple equation for the temperature distribution as Eq. (9). To ensure this affirmation, we compare the mass and radius obtained with the temperature distribution in Eq. (9) and the one found by Kritcher and collaborators[10] which considers a more complete processes as radiation and convection. To analyze massive WDs, we use the temperature distribution stated Eq. (9). By using this relation, we obtain similar masses to those reported by Kritcher's and collaborators[10] for stars near the maximum-mass limit. This is due to the more contribution of the WD mass coming from the degenerate core, which has a constant temperature. The envelope with a different temperature distribution should only modify the stellar radius. In this case, the percentage between the difference obtained by Eq. (9) and Kritcher's envelope, for $g \geq 10^9 [\text{cm s}^{-2}]$, is around 2%.

The surface gravity as a function of radial coordinate is plotted in Fig. 1 for several central temperatures and $M = 1.37 M_\odot$. From the panel, we note that the surface gravity increases with the radial coordinate until it reaches the maximum gravity point, hereafter, gravity decays monotonically with the increment of the radial coordinate.

The change of surface's gravity and total radius of the star with the increment of the central temperature is also observed in Fig. 1. For larger temperature, greater total stellar radius and lower surface's gravity are found. In this sense, WDs with smaller surface gravity -than those ones predicted with the cold catalyzed matter- are expected to have high central temperatures.

The mass against the total radius is shown in Fig. 2 for different values of central temperature. The full triangles in pink over the curves indicate the maximum mass points. The blue dots represent the threshold instability due to pycnonuclear reactions. In addition, in figure, some observational results obtained from the catalogs Nalezyty[2] in green diamond, and in Vennes[1] in brown squares. In all curves of the panel, we note that the mass grows with the surface's gravity until reaches the maximum mass point, thereafter, the mass decreases with the grows of gravity.

In Fig. 2, we observe that the analysis of the pycnonuclear reaction has to be considered for central temperatures below $T_c < 10^8 [\text{K}]$. For central temperatures above $10^8 [\text{K}]$, the secular stability point is reached before the pycnonuclear reaction. It is important to mention that the secular stability point is marked by the maximum mass point.

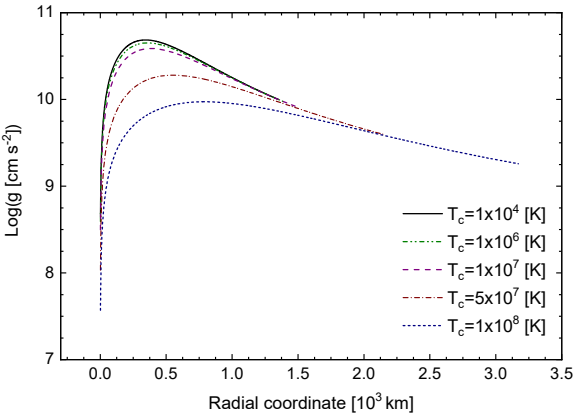

Fig. 1. Surface gravity as a function of radial coordinate for several central temperatures with a fixed $M = 1.37 M_{\odot}$.

Vennes,[1] and Nalezyty[2] have reported some very massive white dwarfs with very high surface gravity. In Fig. 2, these white dwarfs are matching with the curves of very high central temperatures and are very close to the instabilities thresholds. Indeed, one of them, with a mass of $M = 1.41 M_{\odot}$ can have a central temperature higher than 10^8[K]. From this, we could understand that these massive white dwarfs could be treated differently. Using the surface gravity and effective temperature reported by Vennes, we could investigate these stars by employing the values of effective temperature and surface gravity. Moreover, considering the general relativity effects, we found that the masses of these stars decrease, thus highlighting the importance of general relativity in the study of massive white dwarfs.

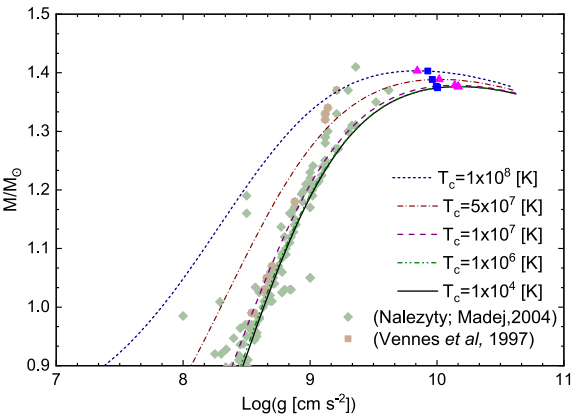

Fig. 2. Mass as a function of surface gravity for several central temperatures. The green diamonds[2] and the brown squares[1] represents observational data.

3. Conclusion

In this work, we investigate the structure and stability of hot white dwarfs. We regard the stellar fluid as composed of nucleons and electrons confined in a Wigner-Seitz cell, with free photons. We consider the temperature profile depending on the mass density with the presence of an isothermal core. We use the stellar structure equations to analyze the equilibrium configurations of white dwarfs and the stability against the pycnonuclear reactions and small radial perturbations.

Comparing our results with observational data, we found that the high masses white dwarfs provided by Vennes[1] could be described by our model. Morevoer, we dicussed about the importance of considering central temperature and general relativity in the study of massive white dwarfs.

A study of the infrared emission of SGR/AXPs in a disk scenario and its implications for their origin

Sarah Villanova Borges

Department of Physics, University of Wisconsin-Milwaukee,

E-mail: svborges@uwm.edu

Soft Gamma-Ray Repeaters and Anomalous X-ray Pulsars (SGR/AXPs) are widely accepted to be magnetars, isolated neutron star (NS) with a huge decaying magnetic field. They can emit from radio up to hard X-rays, being infrared (IR) one of the most interesting and poorly studied energy ranges. The origin of this IR emission is still controversial, since some authors argue in favor of a magnetospheric emission, whereas others point out to a disk. In this work, we revisit the IR emission of SGR/AXPs in a disk perspective. We find that all SGR/AXPs with IR emission in the K-band are consistent with the presence of an irradiated disk. Even though this finding does not rule out any of the proposed natures, it is a piece of new evidence to confirm the presence of disk around this class. If the disk origin where unambiguously confirmed, this would have important impacts on understanding the origin of SGR/AXPs.

Keywords: Soft Gamma-Ray Repeaters; Anomalous X-ray Pulsars; infrared emission.

1. Introduction

The soft gamma-repeaters/anomalous X-ray pulsars (SGR/AXPs) are observationally characterized by a quiescent soft X-ray with luminosity in the range 10^{29} – 10^{35} erg.s^{-1}, period of 2 – 12 s, and spin-down of 10^{-15} to 10^{-10} s.s^{-1} see, e.g.,[24]. Some SGR/AXPs also present emission in other energy ranges, such as radio, optical, infrared (IR), and hard X-rays, as well as soft gamma-ray flares events. SGR/AXPs are widely thought to be magnetars, isolated neutron stars (NSs) emitting by the decay of their ultra-strong magnetic field, in the range of $10^{13} - 10^{15}$ G.[6] There is also alternative models, such as the NS accreting scenario,[36] the white dwarf (WD) pulsar model,[20] and the accreting WD model.[1]

The near-infrared (NIR) emission was confirmed or proposed for a total of 13 SGR/AXPs[15,24,31] and its origin is still debated. For the AXP 4U 0142+61 , the IR emission is well modeled by an irradiated disk, reinforced by an unconfirmed silicate feature around 9.5 μm.[39,40] Nonetheless, the lack of mid-IR emission during the 2007 flare of 1E 1048.1-5937 seems to rule out the presence of a disk in this object.[38] Thus, some authors still argues in favor of an IR magnetospheric emission.[13]

Two classical observational approaches can confirm magnetospheric origin in the IR emission of SGR/AXPs: search for polarization and pulsed emission. High polarization and pulsed fraction are expected for a magnetospheric emission. However, a low pulsed fraction is consistent with both models. Moreover, low polarization

discards magnetospheric synchrotron and curvature emission but cannot distinguish between a cyclotron emission and a disk. In this sense, an extensive study of IR polarization and periodic emission can be inconclusive.

For that reason, we suggest a distinct method to determine the IR origin of SGR/AXPs. We propose the search for a correlation between the luminosity in IR and X-rays that can be confronted with the expected correlation for a disk and magnetospheric models. In this sense, the disk could represent the best path to confirm the origin of SGR/AXPs. For instance, if the leftover of a supernova event formed the disk, it probably contains iron, silicon, oxygen, helium, and traces of hydrogen.[17] In this sense, an IR spectroscopy of 4U 0142+61, the magnetar with the brightest quiescent emission, could give essential clues to the origin of the class.

This proceeding aims to study the IR emission of SGR/AXPs and is organized as follows. In Section 2, we present the disk model we have used to fit the data. In section 3, we present the correlation between IR and X-rays. In Section 4, we discuss the consequences of the results for the origin of SGR/AXPs, slow rotating NSs, and the period of Fast Radio Bursts (FRBs). In Section 5, we summarize our findings.

2. An irradiated disk model for isolated neutrons stars

To study the expected correlation between IR and X-rays for an irradiated disk emission, we are going to consider the same irradiated disk model used to fit 4U 0142+61.[39] The emitted flux of a debris disk in a given frequency ν can be expressed by[8,27]:

$$F_{disk} = \frac{2\cos(i)}{D^2} \times \int_{R_{in}}^{R_{out}} B_\nu(T_{irr}(R)) R dR; \tag{1}$$

where, i is the inclination of the disk in respect to the observer, D is the distance to the observer, R is the distance from each infinitesimal part of the disk to the NS, $T_{irr}(R)$ is the debris disk temperature, and B_ν is the emitted spectrum of each element of the disk. Meanwhile T_{irr} is given by[37]:

$$T_{irr}(R) = 25,280 \text{ K } f^{2/7} \left(\frac{L_X}{L_E}\right)^{2/7} \left(\frac{R_\odot}{R}\right)^{3/7}, \tag{2}$$

where L_E is the Eddington luminosity, $R_\odot$ is the radius of the Sun and the f parameter related with the albedo. Since we expect all SGR/AXPs to have similar temperature and composition, f can be treated as a constant.

With those equations in hand, we can estimate the expected correlation between IR and X-rays luminosity in IR. Calling $x = \frac{h\nu}{kT(R)}$, we have:

$$R \propto x^{7/3} \left(\frac{k}{h\nu}\right)^{7/3} \left(f\frac{L_X}{L_E}\right)^{2/3}; \tag{3}$$

$$dR \propto x^{4/3} \left(\frac{k}{h\nu}\right)^{7/3} \left(f\frac{L_X}{L_E}\right)^{2/3} dx; \tag{4}$$

Considering $T_{out} \sim 500$ K and $T_{in} \sim 1500$ K, which is consistent with the temperature range for 4U 0142+61 and also for disk in isolated WDs,[11,39] the flux equation can be approximated to:

$$F_{Ks} \propto \frac{4\pi h \cos i \nu^3}{c^2 d^2} \left((L_X)^{4/3} \left(\frac{k}{h\nu} \right)^{14/3} \right) \times \int_{T=500K}^{T=1500K} \frac{x^{11/3} dx}{e^x - 1}, \tag{5}$$

where all parameters are constant, except for F_{Ks}, $\cos i$, and L_x. If we define the monochromatic luminosity in the *Ks-band* such as:

$$\begin{aligned} L_{Ks} &= 4\pi D^2 \int_0^\infty F_{Ks} \delta(\nu - \nu_{Ks}) d\nu \\ &= 4\pi D^2 F_{Ks} \nu_{Ks}, \end{aligned} \tag{6}$$

we find the correlation:

$$L_{Ks} \propto (\cos i) L_{XR}^{1.33}.$$

Since $0 < \cos i < 1$, we expect, at most, one order of magnitude change for a given object. Thus, for a correlation ranging in several orders of magnitude the expected correlation between the monochromatic luminosity in the Ks-band and the bolometric X-rays luminosity is can be simplified to:

$$L_{Ks} \propto L_{XR}^{1.33}. \tag{7}$$

It is important to highlight that this correlation considers that the disk properties (albedo, inner and outer temperatures of the dusty region) are similar among all objects. Moreover, this correlation discards the contribution of two different mechanisms in the Ks wavelength (such as a non-thermal component along with the disk).

3. A correlation between infrared and X-rays

The search for correlations is a valuable tool to understand the emission mechanism on different energy ranges. For SGR/AXPs, there are a few preliminary studies of the correlation between IR and X-rays. For some outbursts events, an enhancement of the IR emission was proposed.[10,28,30] In others, no correlation has been seen.[29,32,38] Nonetheless, those previous studies were limited since they have only examined the behavior of a single object per time along with the event and did not take into account the hard X-rays.

In this sense, we decide to revisit the possible correlation between IR and X-rays as a tool to confirm the irradiated disk origin. As discussed in sec. 2, if the disk is the main emission mechanics for IR, it is expected a correlation between the X-rays and IR luminosities. To search for such correlation, we chose the IR k_s-band since it

is the one with most observations in the magnetar class. For the bolometric X-rays luminosity, we have considered the sum of the luminosity of the 0.5-10 keV (L_s) and 15 - 60 keV (L_H) ranges. All IR and X-rays data are simultaneous or from close dates.

We have used observation from K_s, K' and K bands, considering that the luminosity in all bands is the same (justified since their central wavelengths are extremely close). Nonetheless, we have used the corrected zero-point magnitude for each specific filter. Moreover, not all objects have simultaneous Soft and Hard X-rays observation. When only one is available, the following equation was used to estimate the other[7]:

$$\frac{F_{hard}}{F_{soft}} = (0.59 \pm 0.07) \times (\dot{P}/10^{-11})^{0.51\pm0.05} \tag{8}$$

where $\dot{P}$ is the spin-down.

We first check the correlation using both Spearman ($\rho = 0.87$) and Pearson ($p = 0.93$) correlation coefficients, which points out to a strong correlation between the data. To find the best-fit from the data and its goodness, we consider a linear, logarithmic trend and R^2 defined by:

$$R^2 = \frac{\sum_1^n (\hat{y}_i - \bar{y})^2}{\sum_1^n (y_i - \bar{y})^2} \tag{9}$$

where y_i is the data, $\hat{y}_i$ is the fitted result, and $\bar{y}$ is the mean of the data. We use a 1σ error for all fits. Figure 1 shows the best correlation between the luminosity in the K_s-band (L_{Ks}) and X-rays (L_{XR}). The best fit is ($R^2 = 0.87$): $L_{IR} \propto L_S^{1.16\pm0.09}$, considering a linear fit without the error-bars (using the python class "stats.linregress") and $L_{IR} \propto L_S^{1.27\pm0.09}$ considering the error-bars (using the python class "scipy.odr.ODR"). We have used quiescence and outburst events, and we do not see any discrepancy in results.

For the fit with error bars, the expected slope of an irradiated disk is within the 1σ range, which favors the disk interpretation. Moreover, Fig. 1 considers quiescence/outbursts, and confirmed/candidates indistinctly, which argues in favor of: (i) the same mechanism is possibly responsible for the IR emission in quiescence and outbursts for the majority of objects; (2) candidate emission is possibly correct.

We have also compared the best fit with the IR emission of some few isolated NSs with detected emission in IR: (i) The rotation powered pulsars (RPPs) B0531+21, B0833-45, and B1509-58[12]; (ii) the XDIN RXJ0806.4-4123, and the Central Compact Object (CCO) 1E 161348-5055. We have also included the data from the SGR 1935+2154 in the F140W band. We have not used any of those points in the fit since they are not SGR/AXPs and/or the IR observation is not in the K-band. Even though they were not used in the fit, all but one are in the 90% prediction bound, showing that it is likely that the exact mechanism is responsible for the IR emission in magnetars and other pulsars with IR. This is interesting evidence in favor of a disk: fits using the magnetospheric curvature emission model can reproduce the IR

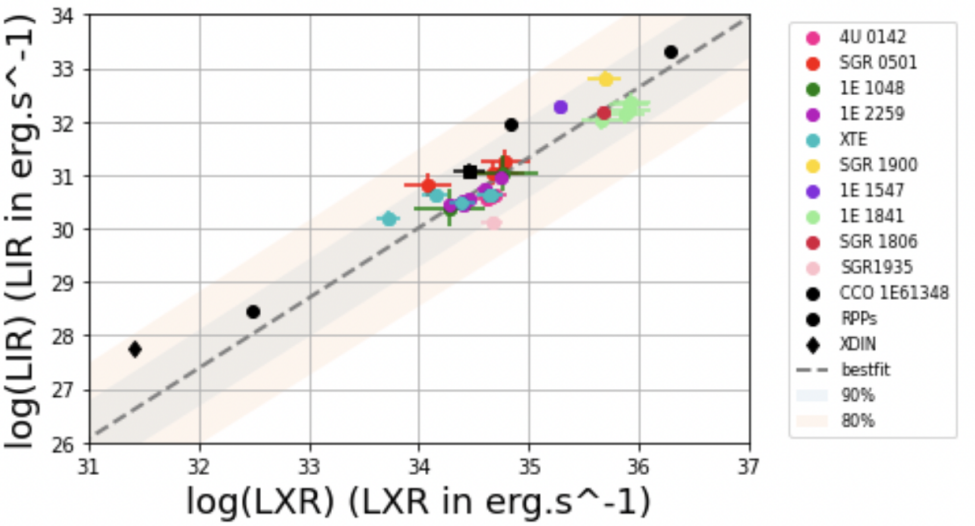

Fig. 1. Best-fit (dotted line) correlation between the luminosity in the Ks band and X-rays. The best-fit was estimated using only magnetars (colored points). The black squares, diamonds, and circles (1E 161348-5055, B0531+21, RXJ0806.4-4123, B0833-45, and B1509-58, respectively) were not used in the best-fit estimate and are only represented for comparison.

luminosity of magnetars using $B \sim 10^{14}$ G.[42] Nonetheless, the highest IR luminosity belongs to Crab Pulsar (B0531+21), a young pulsar with a dipole magnetic field of "only" 7e+12 G.

4. Importance of the disk on magnetars

4.1. *Origin of magnetars*

One of the biggest unanswered questions about magnetars is what are their progenitors. One of the first proposed models relates to massive main-sequence progenitors. A supernova explosion with energy higher than 10^{52} erg/s would enable the formation of such high magnetic fields, since part of the energy would be transferred to the ejecta via the strong magnetic coupling with the proto-neutron star.[35] This high-mass origin is corroborated by the presence of the magnetar CXOU J164710.2 in Westerlund 1, a young star cluster, with 4 Myr, which puts a lower limit in the mass of the progenitor on 40 $M_{\odot}$.[23]

Nonetheless, this massive origin has encountered some challenges. For instance, the explosion of the associated SNR for magnetars is $< 10^{52}$ erg/s, which put a higher limit on the mass of the progenitor in 20 $M_{\odot}$.[43] For those small progenitor masses, the formation of high magnetic fields would have to invoke the amplification of a fossil magnetic field.

For this main-sequence scenario, the presence of the disk can be challenging to explain. 1-D simulations have shown that fallback disk in NSs are formed only

on very fine-tuned SN events.[26] Nonetheless, if this is this case, an IR spectroscopy (with the to-be-launched James Webb Space Telescope) of 4U 0142+61could confirm the SN origin, since the leftover of a supernova event is expected to contain iron, silicon, oxygen, helium, and traces of hydrogen.[17]

Another possible mechanism, that have been long proposed, is the merger scenario. The merger of compact objects can generate isolated NSs with high magnetic fields and WD+WD, WD+NS, and NS+NS mergers have already been proposed as progenitors of magnetars.[16,18,21] This origin mechanism had gained a lot of attention in the last couple of years for being able to explain the occurrence of Gamma-Ray Bursts[22] and Fast Radio Bursts (FRBs) in a magnetar context.[21]

This merger origin would also be detectable in a IR spectroscopy. For instance, for a CO-WD/CO-WD merger, the disk is formed by the remains of the secondary and contains carbon and oxygen, with traces of other elements such as neon, magnesium, silicon, and nickel.[19] Moreover, the AIC event is expected to produce unusual neutron-rich isotopes.[5]

4.2. *Period of 1E 161348-5055*

The CCO 1E 161348-5055 is one of the most singular NSs: with a period of 6.67 hours, this is the slowest isolated NS known.[4] In the last decade, this curious object gained much attention when magnetar-like bursts activities were detected,[3] which raises a canon explanation evoking an ultra-strong magnetic field (in the order of $\sim 10^{15}$ G) and a fallback to explain how this object's large period came to happen.[9,33,41]

This way, proving that the IR emission of this object is consistent with a disk gives an observational evidence for the disk models explaining period of 1E 161348-5055.

4.3. *Periodicity in Fast Radio Bursts*

Since the discovery of FRB-like events in the SGR 1935+2154,[14] models invoking magnetars have been the focal point in understanding FRBs. In this sense, the presence of the disk in magnetars can emerge as an explanation for long periods in FRB events, such as the 16.35 days observed in the FRB 180916.J0158+65.[2]

In an isolated NS, the most plausible reason for such long period is precession. There are some models that were raised in the last years to explain such motion, with some invoking a disk, such as a forced precession caused by fallback disk,[34] or Lense-Thirring precession of the disk. Thus, proving the presence of the disk gives an extra piece of evidence for those models.

5. Conclusion

We searched for a correlation between IR and X-rays for magnetars and the result is consisted with an irradiated disk. We have also found that the results are consistent

the IR emission of some other classes of isolated NSs: RPP, XDINs and CCOs, which suggest a similar IR emission mechanism for all isolated NSs and favors a disk origin for IR. If the presence of such a disk was confirmed, its composition could help determine the origin of magnetars, as well as the long period of 1E 161348-5055 and the two-week-long period of the FRB 180916.J0158+65.

Here we present results from an in-depth search for pulsed emission from both close binary systems AE Aquarii (AE Aqr) and AR Scorpii (AR Sco) in radio and gamma-ray energies. Both systems were observed recently with the MeerKAT telescope, and combined with this, we utilized the combined 10 year Pass 8 Fermi-LAT dataset to search for pulsed gamma-ray emission from both white dwarfs in these systems. Pulsed emission was detected in MeerKAT data from both these close binary systems at a period that is at, or close to, the spin period of the white dwarf. The search for pulsed gamma-ray emission revealed pulsed emission at the spin period of the white dwarf of AE Aqr after selecting data sets with duration of 2 weeks that show excess emission above the 2 σ significance level. Braking these two-week sets up in 10 minute intervals and stacking the power spectra revealed pulsed emission at both the spin ($P* = 33.08$ s) and its associated first harmonic ($P_1 = 16.54$ s). A full 10 year analysis of the AR Sco data revealed pulsed emission at the spin period/beat period of the white dwarf, albeit at a lower significance level. Several control analyses were performed to verify the authenticity of the emission in both radio and gamma-rays, which will be discussed in the main text. The results of this study definitely reveal that both white dwarfs in these systems contain a particle accelerator that accelerates charged particles to high energies resulting in associated non-thermal radio and gamma-ray emission.

Keywords: Cataclysmic variable, white dwarf, pulsar, close binary system, particle acceleration, synchrotron radiation, gamma-rays

1. Introduction

Emission of Very High Energy (VHE) gamma-rays from the novalike variable AE Aqr had been reported in the late 1980's early 1990's by two independent groups (e.g. 1–3). These reports showed that AE Aqr display sporadic aperiodic burst-like gamma-ray emission with associated gamma-ray pulsations at, or close to, the spin period of the white dwarf. On occasions the first harmonic of the spin period ($P_1 = 16.54\,\mathrm{s}$) was also detected.

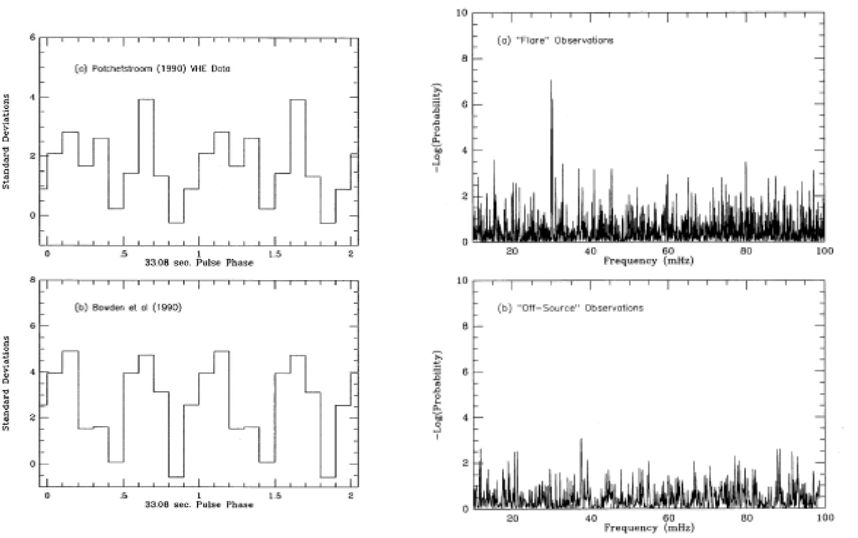

Fig. 1. (a) Pulsed VHE gamma-ray emission detected from AE Aqr at both the 33.08 s and 16.54 s during two contemporaneous burst-like VHE gamma-ray events observed by two independent groups. (b) The top panel represents an incoherently stacked power spectrum of VHE observations made simultaneous with optical flares and show clear indications of pulsed emission at the spin period ($P_* = 33.08\,\mathrm{S}$) of the white dwarf while the control off-source stacked power spectrum of observations made simultaneously with those above displays a white noise profile without any noticeable pulsed signal at or close to the spin period of the white dwarf of AE Aqr.

These reports have never been confirmed by independent follow-up studies (e.g. 4). However, the cadence in these follow-up studies was significantly poorer than the initial studies. The potential of white dwarfs as possible particle accelerators and gamma-ray sources came under the spotlight again with the discovery of the unique close binary AR Sco. The majority of AR Sco's Spectral Energy Distribution (SED) is the result of non-thermal emission since there is no indication of mass transfer and accretion in this system (e.g. 5). A follow-up study (6) revealed high levels of linear polarization in the optical light, a clear indication of a strong synchrotron component. It was shown (see e.g. 7) that the radio to X-ray SED of AR Sco can be explained by two component synchrotron spectrum produced by a pulsar-like process in the magnetosphere of the white dwarf (optical to X-ray), combined with synchrotron emission in the pumped magnetosphere of the secondary

star (radio to infrared). See also (8) for a detailed discussion of the properties of AR Sco.

The evidence of particle acceleration and accompanied non-thermal emission, combined with the availability of the new Fermi-LAT Pass 8 data and the MeerKAT radio telescope array in South Africa, stimulated a new radio and gamma-ray study of these two sources. The paper is constructed as follows: In the following section the results of the radio observations of these two sources will be reported. This will be followed by the results of our Fermi-LAT analysis, after which we will present some conclusions and future prospects.

2. MeerKAT Observations and Results of AE Aqr and AR Sco

Both AE Aqr and AR Sco were observed by the SKA precursor telescope MeerKAT on 25 February 2019 (AE Aqr) and 15-16 June 2020 (AR Sco) respectively. The AE Aqr observation was performed under a ThunderKAT project (e.g.9) while AR Sco was observed under the Director's Discretionary Time (DDT) proposal (DDT-20200615-DB-01).

The L-band (0.9-1.7 GHz) light curves of these observations (see Fig. 2a,b) are presented below. The gaps in the light curves of AE Aqr represent periods when calibration sources were observed. For AR Sco only the last short light curve has been included for illustration purposes since these results are the main focus of another forthcoming publication, i.e Buckley et al. 2021 (in preparation). Both L-band light curves display a significant level of variability from both these sources. Since both these sources are not driven by the direct accretion of mass onto the surface of the white dwarf the variability in the radio band is most probably the result of the interaction between the white dwarf magnetosphere and the propeller ejected matter in the case of AE Aqr, or the secondary star's magnetosphere in the case of AR Sco.

A search for periodicity was conducted for both these sources (see Fig. 3a,b). Here we present the first detection of pulsed emission in the radio band from AE Aqr (see Fig. 3a). Similarly, Fig. 3b shows significant pulsed emission from AR Sco, probably on the beat period between the spin and orbital periods (see 5).

The L-Band spectrum of both these sources reveal a power-law, which may indicate non-thermal synchrotron emission. The exact mechanism driving these pulsations are currently under investigation. The radio flux however displays a non-thermal origin with clear power-law spectral profile in the L-band (see Fig. 4a,b), which may signify a non-thermal synchrotron emission process.

The average L-band flux is also presented on the SED for both AE qr and AR Sco (see Fig. 5a,b).

3. Fermi-LAT gamma-ray emission form AE Aqr and AR Sco

A search was conducted for steady and pulsed gamma-ray emission from both AE Aqr and AR Sco using the upgraded Fermi-LAT Pass 8 dataset. The Pass 8 dataset

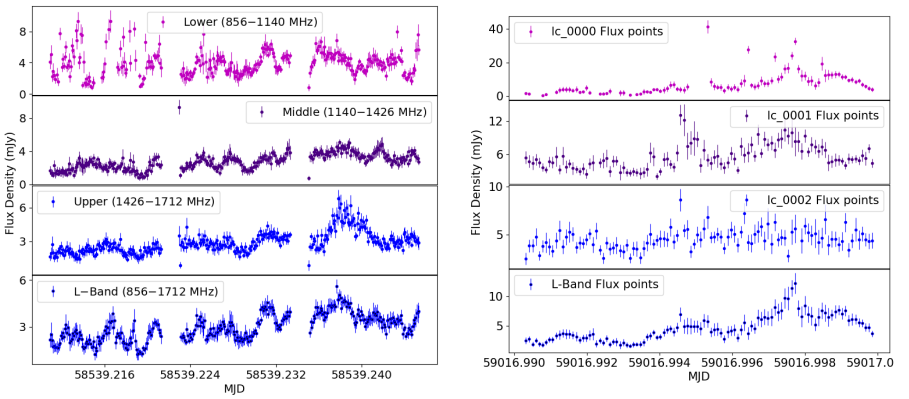

Fig. 2. (a) MeerKAT L-band observation of AE Aqr on 25 February 2019. The light curve was broken up into the lower, middle and upper L-band, with the last light curve representing the total L-Band light curve. The data was binned in 8 second intervals. (b) L-band radio observation of AR Sco performed on 16-17 June 2020. The light curve was broken up in lower, middle and upper L-band, with the last light curve representing the total L-band. The data was binned in 8 second intervals.

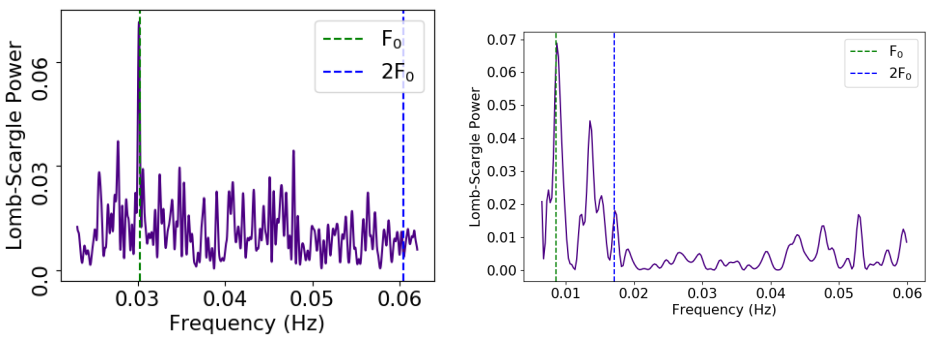

Fig. 3. (a) MeerKAT L-band power spectrum of AE Aqr on 25 February 2019. The power spectrum clearly shows pulsed emission at the spin period of the white dwarf $\nu_\circ = 30.23\,\mathrm{mHz}$. This is the first report of periodic emission from the white dwarf in AE Aqr in radio. (b) MeerKAT total L-band power spectrum of the short AR Sco observation displayed in Fig. 2b. The power spectrum shows strong pulsed emission close to a beat period between the white dwarf spin period and the orbital period.

is an upgraded version of the earlier versions and allowed for better background estimate, gamma-ray source location and energy determination to name a few.

By utilizing the full 10 year Pass 8 dataset with standard Fermi-tools revealed no steady emission from both these sources. However, when a 10 year light curve was determined for AE Aqr there were sections in the light curve that revealed gamma-ray emission above the 2 sigma significance level. Focusing on these data sections, braking it up in 10 minute sections, each section was searched for period-

icity. The periodograms of these sections all had the same frequency resolution and were then added (stacked) incoherently. These stacked power spectra reveal clear indications of pulsations at both 33.08 s and 16.54 s periods (see Fig. 6a for a few examples). To test whether these pulsations are not spurious we selected regions in the sky consecutively further away from AE Aqr's position in the sky $3^\circ - 15^\circ$ and produced the same power spectra for the same periods. The pulsed power distribution of these were determined and the results displayed in Fig. 6b. Clearly visible is that the power at the 33.08 s and 16.54 s periods deviates from the theoretical white noise distribution for the power spectra produced for data corresponding to AE Aqr's position in the sky, while the distribution of power conforms to a white noise distribution for data sections further away from the source. Fermi-LAT data sections that coincide with optical flares observed with the UFS-Boyden 1.5 m telescope (see Fig. 7a) were selected for periodic analysis. Individual power spectra

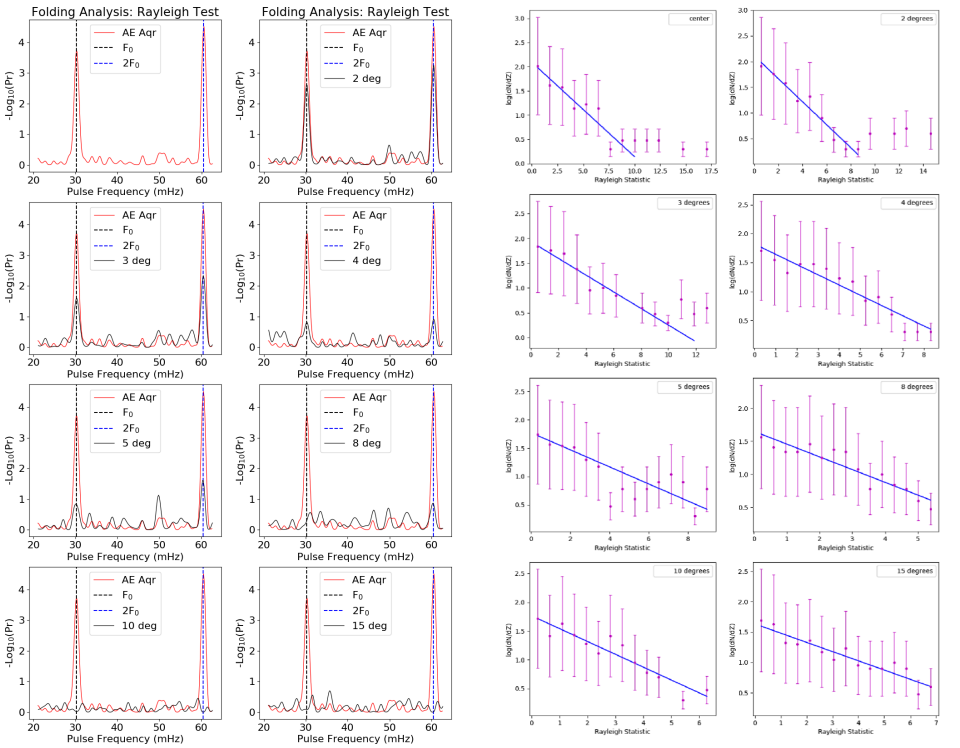

Fig. 6. (a) Example of stacked Fermi power spectra of AE Aqr of epochs showing gamma-ray emission above the 2 sigma significance level. (b) Control analysis showing how the power in the power spectrum return to white noise further away from the source-illustrating that the pulsed power is confined to AE Aqr's position in the sky.

corresponding to flares have been established with the same resolution to enable incoherent stacking (see Fig. 7b). It is clear from Fig. 7b that the gamma-ray periodograms that coincide with enhanced optical activity show clear pulsed emission at a period that corresponds to the spin period of the white dwarf. This result confirms the previously reported pulsed behaviour of VHE emission during optical flares (1, 2).

The unbinned and binned gamma-ray spectra associated with data sections that display a significance above 1σ were produced (see Fig. 8a). Both spectra display a clear power-law profile with photon index $\Gamma \sim 2$. Also shown in Fig. 8a is that the gamma-ray emission seems to be more significant in the lower energy bins. The spectra associated with data sections showing emission above 1 σ and 2 σ respectively reveal power-law spectra that clearly indicate that AE Aqr may be of interest for more sensitive Air Cherenkov detectors like CTA. It is obvious that when the data sections are selected which reveal gamma-ray emission above the 2σ

The gamma-ray data that coincided with optical flares are indicated on the RHS of Fig. 8a. (b) The stacked Fermi-LAT power spectrum of data sections overlapping with optical flares showing clear pulsed emission at or close to the 33.08 s spin period of the white dwarf.

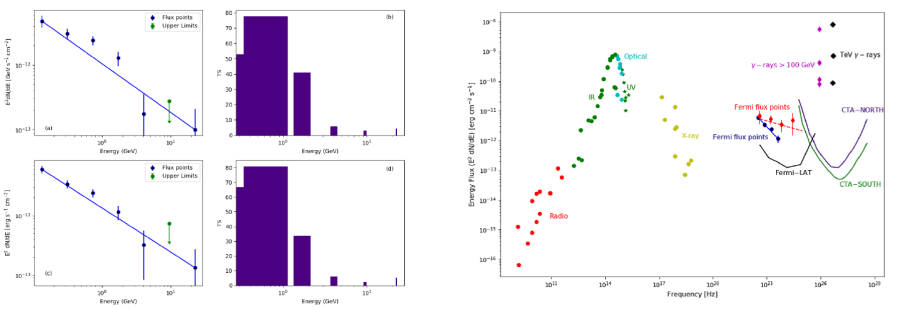

Fig. 8. (a) Gamma-ray spectra for both binned and unbinned analysis, Clearly showing is that the lower energy bins contribute most of the flux. (b) The gamma-ray spectra for quiescence and flare sections of the Fermi-LAT data. It can be seen that the flare sections of the data display spectral hardening which may indicate that AE Aqr may be a source that is of interest for the future Cherenkov Telescope Array (CTA).

level, spectral hardening is observed (see Fig. 8b (red spectrum)), which may result in detectable flux levels during periods of enhanced activity.

The total 10 year Fermi-LAT data of AR Sco was searched for steady gamma-ray emission using the standard Fermi-LAT science tools. No significant steady gamma-ray emission could be distinguished above the 2σ Fermi-LAT threshold (see Fig. 9a). A search for pulsed emission was conducted using the full 10 year Fermi-LAT data. The power spectrum (Fig. 9b) reveals pulsed emission at or close to the spin period of the white dwarf. The period range has been limited to a narrow region around

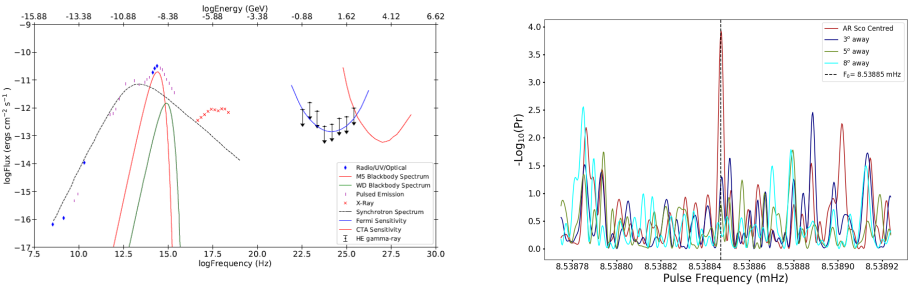

Fig. 9. (a) Gamma-ray spectrum combined with the multi-wavelength SED for AR Sco showing 2 sigma Fermi-LAT upperlimits. Control power spectra at several spatial separations from $3^\circ - 8^\circ$ away from the location of AR Sco does not reveal similar pulsed emission.

the spin period of the white dwarf. To test the validity of these results regions in the sky further away from the position of AR Sco have been selected and the same periodic analysis has been conducted on those sections. These control power spectra correspond to regions in the sky separated from the position of AR Sco between 3° - 8° are also included in Fig. 9b and show no significant pulsed emission at or close to the spin period of the white dwarf. This may support the notion that low-level pulsed gamma-ray activity may in fact be associated with AR Sco.

4. Discussion

The results from the MeerKAT observations and our analyses of the Fermi-LAT data reveal that both AE Aqr and AR Sco contain a particle accelerator of some sort. For example, the MeerKAT data reveal pulsed emission from AE Aqr at the spin period of the white dwarf. This is the first report of pulsed radio emission from AE Aqr and it makes the white dwarf in this system probably one of the fastest white dwarf radio pulsars. Similarly AR Sco is showing pulsed radio emission at the beat period between the spin and orbital period. This may be the result of the white dwarf's magnetosphere pumping the extended magnetosphere of the secondary star, resulting in particle acceleration and non-thermal synchrotron emission. The Fermi-LAT analysis of both these sources reveal pulsed emission. AE Aqr reveals pulsed emission in gamma-rays that resembles reported emission during flare-like events by two independent groups. A period search on data sections displaying flux above the 2 σ level in both binned and unbinned analyses show clear indications of pulsed emission at or close to the white dwarf spin period and its associated first harmonic. A full 10 year periodic power spectrum of AR Sco reveals pulsed power at or close to the spin period of the white dwarf. For both these sources a control analysis has been performed that validates the authenticity of our detection.

Both these sources are not powered by mass accretion and the majority of the emission is in some or other way related to the spin-down power of the white dwarf.

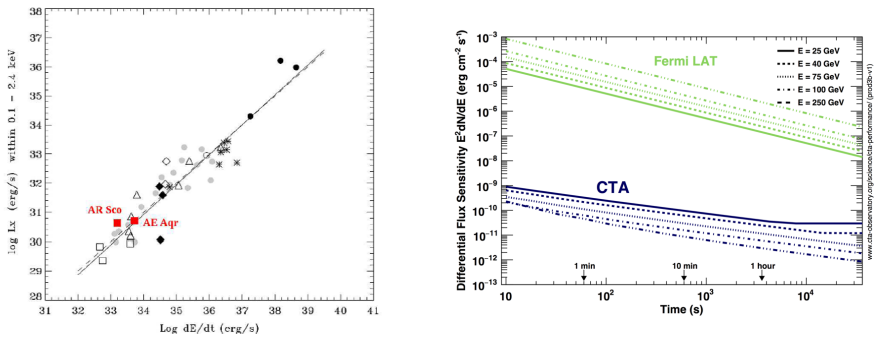

Fig. 10. (a) The X-ray power vs spin-down power of both AE Aqr and AR Sco showing the familiar ratio of X-ray luminosity to spin-down power characteristic of spin-powered neutron stars. Adapted from (12). (b) The most recent 2019 detection threshold comparison between Fermi-LAT and CTA for various observing periods. (**https://www.cta-observatory.org/the-low-end-why-cta-interested-low-energy-gamma-rays**).

Both these sources conform to the well known relation found in rotation powered neutron stars (Fig. 10a), namely that $L_X \sim 10^{-3} L_{s-d}$ (12), meaning that the X-ray emission is not driven by the accretion of mass onto the surface but is driven through a plethora of processes by the spin-down power reservoir. This places both these sources in a unique class. The results that we have presented also show that both these sources provide an opportunity for detection with a new generation of sophisticated ground-based Cherenkov observatories like the Cherenkov Telescope Array (CTA). For example, Fig. 10b shows the latest comparison between the low-energy sensitivity of Fermi-LAT and CTA, which differs slightly form the earlier comparison (13). It is clear that the CTA array will reach the relevant flux levels at energies $\epsilon_\gamma \leq 50\,\mathrm{GeV}$ after observing times of $t_{obs} \sim$ few $\times\, 10^4\,\mathrm{s}$. However, it may be possible to extract a periodic signal after stacking power spectra of shorter observations with similar resolution. The confirmed detection of pulsed gamma-ray emission from both these sources may in fact establish fast rotating highly magnetized white dwarfs in close binaries as a new class of gamma-ray source.

Acknowledgements

The authors thank the organisers of the conference for the invitation to present these results. The authors also acknowledge the Fermi-LAT and MeerKAT collaborations for the gamma-ray and radio data being analysed and presented in this study.

The equilibrium configuration of white dwarfs composed of anisotropic fluid distribution in the presence of a strong magnetic field is investigated in this work. By considering a functional form of the anisotropic stress and magnetic field profile, some physical properties of magnetized white dwarfs, such as mass, radius, density, radial and tangential pressures, are derived; their dependency on the anisotropy and central magnetic field is also explored. We show that the orientations of the magnetic field along the radial direction or orthogonal to the radial direction influence the stellar structure and physical properties of white dwarfs significantly. Importantly, we show that ignoring anisotropy governed by the fluid due to its high density in the presence of a strong magnetic field would destabilize the star. Through this work, we can explain the highly massive progenitor for peculiar over-luminous type Ia supernovae, and low massive progenitor for under-luminous type Ia supernovae, which poses a question of considering 1.4 solar mass white dwarf to be related to the standard candle.

Keywords: Magnetic fields; white dwarfs; super-Chandrasekhar white dwarf; massive stars

1. Introduction

In a recent article, we have shown that the presence of strong magnetic field, orientations of magnetic field and the combined anisotropy due to both the matter and magnetic field exhibit notable influence on the microscopic and thermodynamic properties of compact stars, viz., neutron stars and strange quark stars. We have also very briefly discussed in their study (hereinafter Paper I) that same effects can be observed for magnetized and anisotropic white dwarfs (WDs) which further may leads to possible violation of Chandrasekhar critical mass limit. Importantly Paper I shows that to achieve hydrostatic stable configuration for the highly magnetized compact stars, it is necessary to consider local pressure anisotropy due to matter besides the anisotropy due to magnetic field. Following Paper I, in the present

work we assume two type of magnetic field orientations, such as *radial orientation (RO)* when the magnetic field is directed toward the radial direction and *transverse orientation (TO)* when field is oriented perpendicular to the radial direction (say along θ or ϕ directions). In this work, we investigate in detail the effects of magnetic field strength, their orientations and anisotropy on the highly magnetized WDs and their thermodynamic parameters.

WDs achieve stable stellar configuration via equilibrium of the forces when the inward gravitational pull is counterbalanced by the outward repulsive electron degeneracy pressure. During the accretion of mass from the companion stars when WDs surpass their critical mass limit, immediately a violent explosion triggers, which completely disrupt WDs and releases huge amount of energy of the order $\sim 10^{51}$ erg, known as type Ia supernova (SNIa). The critical mass limit was introduced by Chandrasekhar in his famous works[2,3] where he predicted that the critical mass limit for non-magnetized and non-rotating carbon-oxygen (C-O) WD is 1.4 $M_{\odot}$ which is known as "Chandrasekhar mass limit" (CML) for WDs.

The standard and specific set of relations among colour, intrinsic luminosity and light-curve width[4,5] make SNIa a perfect candidate for "standard candle" which helps astronomers to measure accurately the distance of the host galaxy. Behind the measurement of cosmological parameters, the disproportional relation between distance and luminosity of SNIa is used as a key technique. In fact, SNIa as a "standard candle" had pivotal role to confirm the accelerated expansion of universe.[6,7] However, the idea of "standard candle" faces a major setback with the recent series of observation of several peculiar over-luminous type Ia supernovae (SNeIa) such as *SN 2003cv*,[8] *SN2007fg*,[9] *SN2009if*[10] and *SN 2013dc*,[11] which are best explained through WDs as a progenitor having mass beyond CML. Howell and collaborators[8] predicted that to explain *SN 2003cv* it requires to power by the radioactive decay of $\sim 1.3M_{\odot}$ of ^{56}Ni which further predicts $\sim 2.1M_{\odot}$ WD as a progenitor, known as *super-Chandrasekhar progenitor WD* (SCPWD). Later researchers have predicted further massive SCPWD against the overluminous SN 2009if of mass as high as $\sim 2.8M_{\odot}$.

To explain these unexpected overluminous SNeIa, researchers suggested two possible conjectures such as (i) explosion of rapidly rotating WDs[8,12,13] and (ii) merger of two massive WDs.[14,15] Chen and Li[22] showed that the differentially rotating and accreting WD can not gain mass more than $1.7\,M_{\odot}$. On the other hand, further investigations showed that through the double degenerate scenario, it is not possible to explain such a highly massive 2.8 $M_{\odot}$ SCPWD.[16–21] The results from numerical simulation of massive WD merger suggest that due to off-center carbon burning accreting WD collapses into neutron star.[23,24] Hence, it is evident through the above discussion that the double degenerate scenario conjectures never leads to a SNIa which can explain the massive SCPWDs.

Introducing magnetic model, Mukhopadhyay and collaborators[25,26] are able to explain SCPWDs where they considered Landau levels due to high magnetic field in a plane perpendicular to the magnetic field axis and they[27] are also able

to suitably explain $\sim$ 2.6 $M_{\odot}$ highly massive SCPWD. In another study, Das and Mukhopadhyay[28] showed that the average magnetic field and related magnetic pressure are significantly low compared to the matter pressure when inside magnetized WDs (hereinafter B-WDs) the strong magnetic field is tangled in a length scale larger than quantum length scale, which however leads to the Landau quantization to matter. The mass-radius relation for B-WDs deviates significantly beyond CML when mass accretion continues as the effective pressure counterbalances the inward gravitational pull.[25,29] Das and Mukhopadhyay[30] further predicated that it requires a time scale of 2×10^7 years to turn into a super-Chandrasekhar B-WD (SCBWD) for a 0.2 $M_{\odot}$ accreting WD having surface magnetic field (B_s) 10^9 G. In fact for the last several years, Mukhopadhyay and his group have explored various aspects of SCBWDs through different sophisticated models by considering variation of magnetic field and geometry, Landau quantization, a pure general relativistic effect, differential rotation, deviation from the spherical symmetric stellar configuration and thermal luminosity, etc.[31–38] They also explored the techniques of the possible direct detection of SCBWDs via continuous gravitational wave astronomy by the various upcoming detectors, such as BBO, DECIGO and LISA. The idea of SCBWDs has been further studied and supported by different independent researcher works.[41–47]

Bowers and Liang[48] raised a strong argument against the oversimplified assumption of the isotropic perfect fluid as the constituent matter distribution of compact stars and proposed a modified Tolman-Oppenheimer-Volkoff (TOV) equation,[49,50] which includes another force raised due to pressure anisotropy, besides the hydrodynamic and gravitational force. They also explored notable effect of local anisotropy due to matter on the different physical properties of the stellar objects, such as density, surface redshift, total mass and radius. Letelier[51] and Bayin[52] pointed out that the possible reason behind this local anisotropy is the presence and mixture of two (or more) fluid within stellar interior. On the other hand, the breaking of spatial rotational symmetry $\mathcal{O}(3)$ due to spontaneous creation of magnetic field instigates pressure anisotropy in the stellar interior.[53–55] Interestingly, during the cooling process of WDs at low temperature, they undergoes a first-order phase transition,[56–58] which is another possible reason for the presence of anisotropy inside the dense plasma. Stevenson[59] introduced a phase diagram through which they predicted that carbon and oxygen remains immiscible when WDs begin to freeze. Later, Garcia and collaborators[60] further explored and confirmed this idea. Nag and Chakrabarty[61] also supported the idea of first-order phase transition during the cooling of WDs through the Bose condensation. In fact, they proposed that "*crystalline normal crustal matter*" is present at the massive WDs core, which is also Bose condensed and similar as the ultra-dense structure of the neutron stars. So, based on the above discussion we are convinced to consider local anisotropy of matter inside WDs.

In this context, it is worth mentioning that though there are several articles[32,33,39,40,62–71] which study non-spherical magnetized compact stars in general

relativity based on the perturbative approach to solve the the Einstein-Maxwell field equations or the numerical techniques (such as Lorene and XNS codes) by considering poloidal or toroidal or mixed field geometries, but they did not include the effects of anisotropy. Although, a recent work[72] has explored the effect of anisotropy on WDs in scalar-tensor (ST) theories of gravity but it did not consider magnetic field. The idea of magnetic field orientations viz. RO and TO was originally coined by Chu et al.[73] In the present study, we explore the combined effects of magnetic field strength, its orientations and anisotropy on the WDs to have a more generalized perspective of the WD stellar interior.

This paper is organized as follows: We discuss the basic mathematical formalism in Section 2. Our results and combined effects of the magnetic field, its orientations and anisotropy on the physical properties of WDs are discussed in Section 3. Finally, we summarise our work and present some concluding remarks in Section 4.

2. Basic mathematical formulation

Mukhopadhyay and group[32,33,39] have shown that the magnetized compact stars which are toroidally dominated approximately retains their spherical symmetric stellar structure. Hence in this work we describe B-WDs by the spherically symmetric spacetime metric given by

$$ds^2 = e^{\nu(r)}dt^2 - e^{\lambda(r)}dr^2 - r^2(d\theta^2 + \sin^2\theta d\phi^2), \tag{1}$$

where we assume that the metric potentials ν and λ are functions of radial coordinate r. We choose $c = G = 1$, where G is Newton's gravitational constant and c is the speed of light.

Now neglecting the effect of the electric field by assuming that inside the B-WDs there are no macroscopic charges, the energy-momentum tensor, which describes anisotropic and magnetized matter distribution, reads

$$\begin{aligned} T_m^{\mu\nu} &= (\rho + p_t)u^\mu u^\nu - p_t g^{\mu\nu} + (p_r - p_t)\, v^\mu v^\nu \\ &\quad + \mathcal{M}B\left(g^{\mu\nu} - u^\mu u^\nu + \frac{B^\mu B^\nu}{B^2}\right) + \frac{B^2}{4\pi}\left(u^\mu u^\nu - \frac{1}{2}g^{\mu\nu}\right) - \frac{B^\mu B^\nu}{4\pi}, \end{aligned} \tag{2}$$

where $u^\mu = \delta^\mu_0 e^{-\nu(r)/2}$ is a timelike 4-velocity unit vector of fluid and $v^\mu = \delta^\mu_1 e^{-\lambda(r)/2}$ is a spacelike unit vector acting along the radial direction. It is noteworthy that these orthogonal vectors satisfy $u^\mu u_\mu = -v^\mu v_\mu = 1$ and $u^\mu v_\mu = 0$. Here, ρ, p_r and p_t are the density, radial pressure and tangential pressure of the matter inside B-WDs. $g_{\mu\nu}$ denotes metric tensor and $\mathcal{M}$ represents magnetization per unit volume. B is the magnetic field strength given by $B^\mu B_\mu = -B^2$. On the other hand, we do not consider the associated magnetization effect since magnetic pressure is one order higher in magnitude compared to the magnetization which has already been predicted by a few articles.[53,74] So in this work the presented numerical results do not include effect of magnetization.

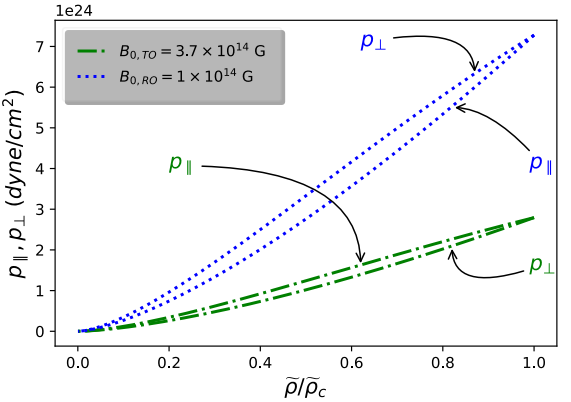

Fig. 1. Variation of parallel pressure ($p_\parallel$) and transverse pressure ($p_\perp$) with the system density ($\widetilde{\rho}$) normalized by the central system density ($\widetilde{\rho}_c$) for a 1.3 $M_\odot$ magnetized WD candidate.

Now using Eqs. (1) and (2) the conservation of energy-momentum tensor, i.e., $\nabla_\mu T^{\mu\nu} = 0$, leads to the essential stellar structure equations which describe static and anisotropic B-WDs as follows:

$$\frac{\mathrm{d}m}{\mathrm{d}r} = 4\pi\widetilde{\rho}r^2, \tag{3}$$

$$\begin{cases} \dfrac{\mathrm{d}p_\parallel}{\mathrm{d}r} = -\left(\widetilde{\rho} + p_\parallel\right)\dfrac{4\pi r^3 p_\parallel + m}{r\left(r-2m\right)} + \dfrac{2}{r}\Delta, & \text{for RO,} \\ \dfrac{\mathrm{d}p_\perp}{\mathrm{d}r} = -\left(\widetilde{\rho} + p_\perp\right)\dfrac{4\pi r^3 p_\perp + m}{r\left(r-2m\right)} + \dfrac{2}{r}\Delta, & \text{for TO.} \end{cases} \tag{4}$$

where $\widetilde{\rho}$ is the system density defined as $\widetilde{\rho} = \rho + \frac{B^2}{8\pi}$, $p_\parallel$ and $p_\perp$ are the system pressures, which take the form based on the magnetic field orientations as follows:

$$p_\parallel = \begin{cases} p_r - \dfrac{B^2}{8\pi}, & \text{for RO,} \\ p_t - \dfrac{B^2}{8\pi}, & \text{for TO.} \end{cases} \tag{5}$$

and (6)

$$p_\perp = \begin{cases} p_t + \dfrac{B^2}{8\pi}, & \text{for RO,} \\ p_r + \dfrac{B^2}{8\pi}, & \text{for TO.} \end{cases} \tag{7}$$

In Eq. (4), Δ denotes effective anisotropy of the stars and based on the choice of magnetic field orientations it takes the forms as $p_t - p_r + \frac{B^2}{4\pi}$ and $p_t - p_r - \frac{B^2}{8\pi}$ due to RO and TO, respectively. One may get the standard form of TOV equations[48, 75] for non-magnetized and anisotropic starts for $B = 0$.

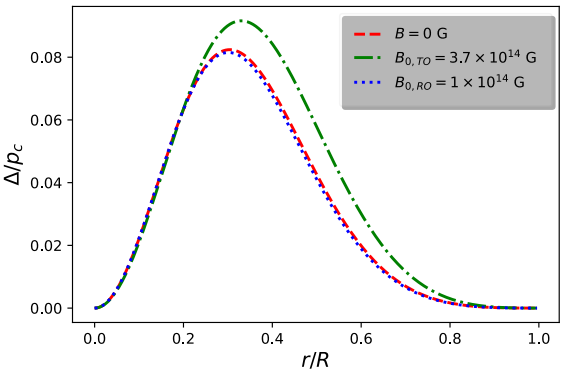

Fig. 2. Variation of anisotropy (Δ) normalized by matter central pressure (p_c) with the radial coordinate r/R for a 1.3 $M_\odot$ magnetized WD candidate.

Bowers and Liang proposed a generalized functional form for the anisotropic stress which has been widely used in different studies. However, since for the present work we require a functional form for anisotropy which includes both the effects of magnetic field strength and magnetic field orientation, we have suitably modified the Bowers-Liang anisotropic form which reads

$$\Delta = \begin{cases} \kappa \dfrac{(\widetilde{\rho} + p_{\parallel})\,(\widetilde{\rho} + 3\,p_{\parallel})}{(r-2m)} r^3, & \text{for RO,} \\ \kappa \dfrac{(\widetilde{\rho} + p_{\perp})\,(\widetilde{\rho} + 3\,p_{\perp})}{(r-2m)} r^3, & \text{for TO,} \end{cases} \tag{8}$$

where κ is a constant parameter that controls the amount of anisotropy within the star and we use κ maintaining its permissible range, given by $\left[-\frac{2}{3}, \frac{2}{3}\right]$.[76] Now, one may notice that if matter anisotropy is not considered, the anisotropic stress become $\sim \mid B^2 \mid$, which has a finite, non-zero value at the stellar center. Since at the center, the hydrodynamic and gravitational forces are zero, non-zero anisotropic force at the center should trigger instability due to nonequilibrium of the forces. We show this issue can easily be overcome considering combined anisotropy due to both the matter and magnetic field.

Further, to describe matter distribution of WDs we consider equation of state (EoS) proposed by Chandrasekhar which reads

$$\begin{aligned} p_r &= \frac{\pi m_e^4 c^5}{3h^3}\left[x\left(2x^2-3\right)\sqrt{x^2+1} + 3\mathrm{sinh}^{-1}x\right], \\ \rho &= \frac{8\pi \mu_e m_H \left(m_e c\right)^3}{3h^3} x^3, \end{aligned} \tag{9}$$

where m_H and m_e denote mass of hydrogen atom and electron, respectively, $\mu_e = 2$ is the mean molecular weight., p_F is the Fermi momentum and $x = p_F/m_e c$. Note that for clarity here we introduce the speed of light c and Planck constant h in their

appropriate places. For the present case of C-O WDs we have $\mu_e = 2$. We consider the exterior spacetime is defined by the well-known Schwarzschild exterior spacetime, given by

$$ds^2 = \left(1 - \frac{2M}{r}\right) dt^2 - \frac{1}{\left(1 - \frac{2M}{r}\right)} dr^2 - r^2(d\theta^2 + \sin^2\theta d\phi^2), \tag{10}$$

where M represents total mass of the star.

Both the fossil field of the progenitor star[31,33,77] and dynamo effect[78] ensure stronger magnetic field at the center (B_c), which decreases gradually to reach its minimum value at the surface (B_s). Hence, in this work we consider a density dependent functional form for the magnetic field,[31,36,79,80] which can suitably mimic the spatial dependence of magnetic field strength, given by

$$B(\rho) = B_s + B_0 \left[1 - \exp\left\{-\eta \left(\frac{\rho}{\rho_0}\right)^{\gamma}\right\}\right], \tag{11}$$

where the η and γ are the dimensionless constants which controls how fast magnetic field strength decays from the center to the surface. In this work we chose $\rho_0 = 10^9\,\mathrm{g/cm^3}$, $\gamma = 0.9$ and $\eta = 0.2$.[36] We also consider $B_s = 10^9$ G which is consistent with the Sloan Digital Sky Survey.[81]

3. Result and discussion

In this study, we explore that besides magnetic field strength, the magnetic field orientations (such as RO and TO) and combined anisotropy due to matter and field significantly influence the mass-radius curve and physical parameters of B-WDs. Note that to present some basic properties of thermodynamics and anisotropy we consider a $1.3\,M_\odot$ B-WD candidate having surface magnetic field 10^9 G in Figs. 1 and 2. Further, our choices of B_0 for RO and TO are different as they exhibit an asymmetric effect on the stellar mass. In the figures, we put RO and TO in the subscript of B_0 to specify the respective magnetic field orientations. It is also noteworthy that our choice of B_0 is also motivated by the highly massive SCPWDs of peculiar over-luminous SNeIa.

In Fig. 1 we feature combined effects of magnetic field strength and its orientations on the system parallel pressure $p_\parallel$ and transverse pressure $p_\perp$. We find that for TO, as B_0 increases, the slope of the system pressures decreases gradually, whereas, for RO with the increasing B_0, the system pressures become gradually stiffened. This phenomenon is because, as B_0 increases in the TO case, the stellar radius increases, which reduces gravitational force and consequently decreases the hydrodynamic force. However, for increasing B_0 in the RO case, the stellar radius of B-WDs decreases, consequently increasing outward hydrodynamic force to support the increased gravitation force. Importantly, note that at the center the effective anisotropy is zero since $p_\parallel = p_\perp$ at $r = 0$, which reflects consistency of TOV equations. In Fig. 2 we show the profile for system anisotropy Δ which also shows zero anisotropy at the center.

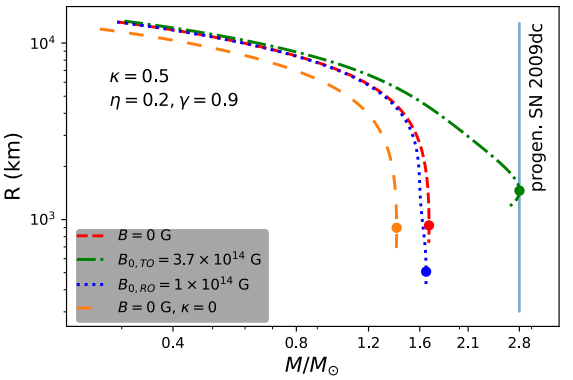

Fig. 3. Variation of the total mass in the units of solar mass ($M/M_\odot$) with the total radius (R) of the stars for varying B_0 and $\kappa = 0.5$. Solid circles represent maximum possible mass for the stars.

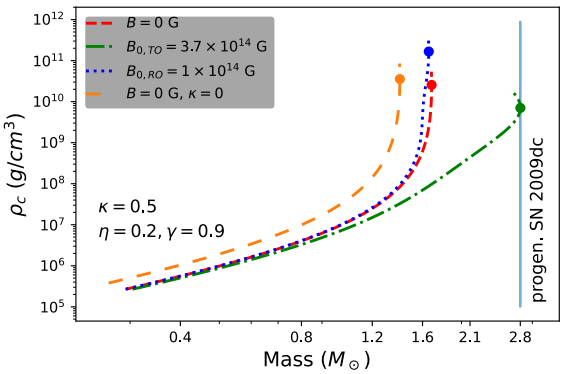

Fig. 4. Variation of $M/M_\odot$ as a function of the matter central density (ρ_c). Solid circles represent maximum possible mass for the stars.

Further, one may note that the maximum magnitude of anisotropy increases with increasing B_0 for the TO case, whereas it decreases for the RO case. We find that for $B_0 = 3.7 \times 10^{14}$ G the maximum magnitude of Δ is $\sim 92\%$ lower compared to the central matter pressure p_c which is insufficient to drive the spherical symmetric stellar structure of B-WDs to non-spherical symmetry.

The total mass and radius (M-R) curve for B-WDs due to different B_0 for both RO and TO is shown in Fig. 3. We find the maximum mass ($M_{\rm max}$) and the corresponding radius ($R_{\rm Mmax}$) in TO due to $B_0 = 3.7 \times 10^{14}$ G are 2.8 $M_\odot$ and 1457.24 km, respectively, whereas in RO due to $B_{0,\rm TO} = 10^{14}$ G they are 1.66 $M_\odot$ and 507.10 km, respectively. In TO due to $B_{0,\rm TO} = 3.7 \times 10^{14}$ G, $M_{\rm max}$ and $R_{\rm Mmax}$ increase compared to their non-magnetized anisotropic case of $\sim$66% and $\sim$57%, respectively, whereas in RO due to $B_{0,\rm RO} = 10^{14}$ G they decrease to $\sim$2% and $\sim$45%, respectively. Only considering local anisotropy due to matter and not

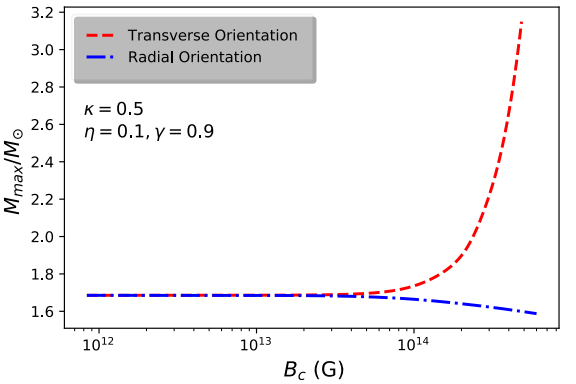

Fig. 5. Variation of $M/M_\odot$ with the central magnetic field (B_c).

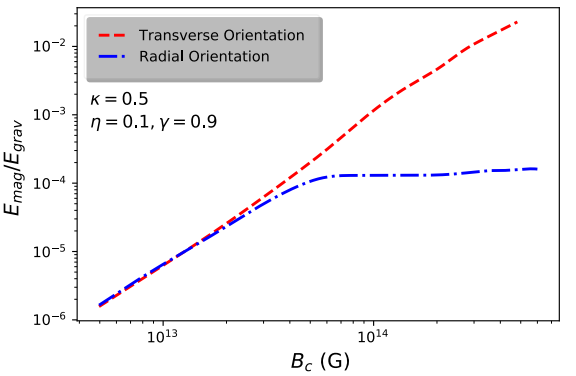

Fig. 6. Variation of the ratio of the magnetic energy ($E_{\rm mag}$) to the gravitational energy ($E_{\rm grav}$) with the central magnetic field (B_c).

considering magnetic field through our model one may have 1.81 $M_\odot$ WD having radius 959.63 km which are ∼29% and ∼7%, respectively, higher compared to their values for WD CML. Harrison et al.[82] predicted that for the stability of a spherically symmetric stellar model the M-R relation should be consistent with $\mathrm{d}M/\mathrm{d}\rho_{\rm c} > 0$ up to $M_{\rm max}$. It has been shown in Fig. 4, which confirms stable B-WDs upto maximum limiting mass.

In Fig. 5 we explore the effects of magnetic field orientations on the mass of B-WDs. The effects of magnetic field strength on $M_{\rm max}$ for the TO and RO cases are asymmetric which motivates us to chose different B_0 for different magnetic field orientations. One may find that for a specific set of constant parameter such as $\eta = 0.1$, $\gamma = 0.9$ and $\kappa = 0.5$ the asymmetry of maximum mass for the TO and RO cases due to $B_c = 4 \times 10^{14}$ G is ∼65% which confirms significant effect of

Table 1. Physical parameters of WDs with $\kappa = 0.5$, $\eta = 0.2$ and $\gamma = 0.9$ for different B_0.

Orientation of magnetic field	B_0 (Gauss)	Maximum mass ($M_\odot$)	Corresponding predicted radius (km)	Central magnetic field B_c (Gauss)	Central density $\tilde{\rho}_c$ (gm/cm^3)	Central pressure $\tilde{p}_c$ ($dyne/cm^2$)	$\frac{E_{\rm mag}}{E_{\rm grav}}$
Transverse Orientation	3.7×10^{14}	2.80	1457.24	2.538×10^{14}	7.040×10^{9}	2.809×10^{28}	1.405×10^{-2}
No magnetic Field	-	1.69	926.91	-	2.560×10^{10}	9.865×10^{28}	-
Radial Orientation	10^{14}	1.66	507.10	10^{14}	1.665×10^{11}	1.152×10^{30}	7.227×10^{-5}

magnetic field orientations on B-WDs. Fig. 5 features that for TO (RO) the increase (decrease) of $M_{\rm max}$ is rapid (slow) with the increase of central magnetic field B_c.

Chandrasekhar and Fermi[83] predicted that for magnetized spherical symmetric stable compact stars it is not sufficient that they are consistent with the inequality $\Gamma > 4/3$ as the strong magnetic field may lead to stellar instability. They further predicted that for the dynamical stability of the magnetized compact stars the necessary condition is $E_{\rm mag}/|E_{\rm grav}| << 1$, where $E_{\rm mag}$ and $|E_{\rm grav}|$ denote the magnetic and gravitational potential energies, respectively. In Fig. 6 we present that for both TO and RO due to different B_0, $|E_{\rm grav}|$ overpowers $E_{\rm mag}$ considerably to achieve dynamical stability of B-WDs.

For the better understanding of the readers, we present the obtained results for the different cases in Table 1. We present the variation of $M_{\rm max}$, R, B_c, system central density ($\tilde{\rho}_c$), system central pressure ($\tilde{p_c}$) and $E_{\rm mag}/\mid E_{\rm grav} \mid$ with different B_0 for both TO and RO and non-magnetized cases in Table 1. Note that the presented results in Table. 1 are based on the chosen set of constants such as $\eta = 0.2$, $\gamma = 0.9$ and $\kappa = 0.5$. Clearly, for TO with the increase of B_0, B-WDs become massive, larger in size and less dense compact object, whereas for RO as B_0 increases B-WDs become gradually less massive, smaller in size and highly dense compact object compared to their non-magnetized case.

4. Conclusion

In the present work we explore the combined effects due to magnetic field strength, orientations of magnetic field and effective anisotropy raised due to matter and field on B-WDs. Although anisotropic WDs were studied by Chowdhury and Sarkar,[72] their study was based on the non-magnetised case. On the other hand, Chu et al.[73] explored the effect of magnetic field and their orientation on total mass of compact stars. However, they ignored important effect of anisotropy and did not show effects of magnetic field orientations on the different physical parameters of compact stars. In this work for the first time we have studied the combined effects of magnetic field strength, their orientations and anisotropy on WDs in the strong magnetic field. In conclusion, the two major results of our study on B-WDs are as follows:

(i) We show that to achieve magneto-hydrostatic stability at the stellar center of B-WDs, the effective anisotropy due to matter and magnetic field should be considered.

(ii) With the choice of appropriate set of constant parameters such as κ and B_0 our model can appropriately explain massive progenitors of peculiar over luminous SNeIa as high as 2.8 $M_\odot$, which further raise question regarding the idea of 1.4 $M_\odot$ WDs as the "standard candle".
